## Abstract

This paper describes a new bio-indicator method for assessing wetland ecosystem health; as such, the study is particularly relevant to current legislation such as the EU Water Framework Directive, which provides a baseline of the current status of surface waters. Seven wetland sites were monitored across northern Britain, with model construction data for predicting eco-hydrological relationships collected from five sites during 1999. Two new sites and one repeat site were monitored during 2000 to provide model test data. The main growing season for the vegetation, and hence the sampling period, was May–August during both years. Seasonal mean concentrations of nitrate ($NO_3^-$) in surface and soil water samples during 1999 ranged from 0.01 to 14.07 mg N $l^{-1}$, with a mean value of 1.01 mg N $l^{-1}$. During 2000, concentrations ranged from trace level (<0.01 mg N $l^{-1}$) to 9.43 mg N $l^{-1}$, with a mean of 2.73 mg N $l^{-1}$. Surface and soil-water nitrate concentrations did not influence plant species composition significantly across representative tall herb fen and mire communities. Predictive relationships were found between nitrate concentrations and structural characteristics of the wetland vegetation, and a model was developed which predicted nitrate concentrations from measures of plant diversity, canopy structure and density of reproductive structures. Two further models, which predicted stem density and density of reproductive structures respectively, utilised nitrate concentration as one of the independent predictor variables. Where appropriate, the models were tested using data collected during 2000. This approach is complementary to species-based monitoring, representing a useful and simple tool to assess ecological status in target wetland systems and has potential for bio-indication purposes.

**Keywords**: bio-indicators, surface water, water quality, wetland vegetation

## Introduction

Nutrient enrichment from point sources such as sewage treatment works and from diffuse agricultural inputs may lead to problems of increased plant biomass production in rivers and lakes, and exacerbate the problems associated with resultant reduced dissolved oxygen concentrations within these systems (Neal and Whitehead, 2002). Standing waters are also under threat worldwide from various land-use pressures, including agriculture (Lemly, 1994), drainage (Sheil and Wells, 1983; Gerakis and Kiriaki, 1998), and flood control management (Washitani *et al.,* 1997). Even oligotrophic lakes in Western Europe, located in upland areas not normally subject to such pressures, are under threat of acidification and also eutrophication, primarily from atmospheric nitrogen deposition (Murphy, 2002).

Many wetlands are now recognised as important ecosystem resources and have varying levels of protection.

For example, via the Ramsar Convention (RAMSAR Convention Bureau, 1990), via inclusion in the Natura 2000 network of the European Union (Directive on the Conservation of Wild Birds: 79/409/EEC) or, more locally (in a UK context), as Special Areas of Conservation (SACs), Sites of Special Scientific Interest (SSSIs) and local nature reserves. However, wetlands are still amongst those habitats most vulnerable to disruption by human interference, both intentional and accidental (Etherington, 1983).

Studies of various wetland systems have provided evidence that the underlying hydrology is often both complex and difficult to quantify (Grieve *et al.*, 1995; Gilvear *et al.*, 1997). Within individual sites, variations in hydrological and hydrochemical regimes are major factors driving wetland vegetation composition and structure, (Sjors, 1950; Gorham, 1953; Ingram, 1967; Damman and Dowhan, 1980; Malmer, 1986; Mountford and Chapman,

1993; Kennedy, 2001), and may control the distribution of individual species (Brown and Scott, 1997; Kennedy and Murphy, 2003; Kennedy *et al.* 2003). Certain studies have also begun to elucidate the role of riparian wetlands in such systems as potential nutrient stores (e.g. Prior and Johnes, 2002) and it is recognised that in modelling sequential routing through agricultural hillslopes and riparian wetlands is required to better understand in-stream nutrient loading.

Legislative drivers in many parts of the world now require the assessment of biological, morphological, water quality and hydrological quality elements to define baseline reference conditions for freshwaters, including wetlands. Within this framework, there is often a strong emphasis on the use of ecological assessments (see Murphy *et al.*, 2002). Within the EU, the Water Framework Directive (WFD, *Establishing a framework for community action in the field of water policy:* 2000/60/EC) fills this role and requires baseline assessments for river catchments and for standing waters. Whilst no specific reference is made to freshwater wetland systems within the WFD, they are covered under transitional waters, and as parts of surface water bodies and protected areas, etc. under the *Common Implementation Strategy for the Water Framework Directive* (2000/60/EC). They are also integral to the principal of integrated monitoring of freshwaters at the catchment scale (Kennedy, 2001; Murphy *et al.*, 2002). Furthermore, *The EC Nitrate Directive* (91/676/EEC) is concerned with the control of nitrate inputs into the environment, including wetlands. As such, the need for ecological assessments that are relatively simple to implement is clear.

Assessments using plant functional types in community descriptions and biogeography have great potential, and should be seen as complementary to traditional taxonomic methodologies (Duckworth *et al.*, 2000). Within wetlands, there has been success in recent years in applying trait-based assessments to the understanding of vegetation–hydrology interactions (Murphy *et al.*, 1994; Hills *et al.*, 1994; Ali *et al.*, 1999; Willby *et al.*, 2000; Kennedy and Murphy 2003; Kennedy *et al.*, 2003). However, with limited exceptions (e.g. Vretare *et al.*, 2001), linkages remain to be made between phenotypic responses and specific functions such as nutrient uptake capacity of wetland vegetation. Nonetheless, recent complementary work has begun to characterise wetland community types in relation to differences within their underlying hydrological and hydrochemical regimes, and in terms of representative vegetation attributes (Kennedy, 2001).

This paper describes the results of a study undertaken at sites across northern Britain involving the monitoring of structural features (species richness, stem density and reproductive structure density, and nearest-neighbour

distance) within a range of tall herb fen and mire systems. Models are described which predict interactions between nitrate, other hydrochemical and hydrological variables, and the structure of wetland vegetation. The study therefore forms the basis for a tool which uses non species-specific vegetation variables as a bio-indicator to assess ecological status of typical freshwater wetland vegetation. As such, the tool has potential global applicability.

## Study sites

Fifty-five stations along eleven transects at seven wetland sites were monitored during 1999 and 2000 (see Table 1; Fig. 1). The main growing season for the vegetation (and hence the sampling period) was May–August. Sampling was conducted 18th May–17th August during 1999, and 22nd May–3rd August during 2000. At each station, the water level and bulked soil and surface water chemistry were measured and the vegetation characterised. Fixed stations

Fig. 1. *Field site locations in Scotland and Northern England sampled during 1999 and 2000.*

*Table 1.* Sites sampled during 1999 and 2000, showing number of sample stations per transect, UK locations, and grid references.

| Site name | UK region | Transect number | No. of sample stations | UK NGR (for start and finish stations) | Year sampled |
|---|---|---|---|---|---|
| Glen Moss | Central Scotland | 1 | 3 | NS367696 – 368698 | 1999 |
| | | 2 | 3 | NS366697 – 366699 | 1999 |
| Insh Marshes | Northern Scotland | 1 (Insh Fen) | 9 | NH775001 – 774005 | 1999; 2000 |
| | | 2 (Invertromie Fen) | 7 | NH812023 – 805029 | 1999 |
| | | 3 (Balavil Fen) | 4 | NH793022 – 796019 | 1999 |
| Lochwinnoch | Central Scotland | 1 (Aird Meadow) | 3 | NS364585 – 365587 | 1999 |
| | | 2 (Aird Meadow) | 3 | NS361585 – 362585 | 1999 |
| Nether Whitlaw Moss | South East Scotland | 1 | 6 | NT506294 – 511295 | 1999 |
| Tarn Moss | Northern England | 1 | 5 | NY398274 – 402276 | 1999 |
| Endrick Marshes | Central Scotland | 1 | 6 | NS438873 – 438877 | 2000 |
| Wood of Cree | South West Scotland | 1 | 6 | NX375719 – 376717 | 2000 |

were established at intervals of 30–50 metres along each transect and were visited monthly during the plant growth season (May–August) of 1999. This was repeated during 2000 at Insh Fen and at two new sites: Endrick Marshes and Wood of Cree. The wetland vegetation surveyed represented a range of UK National Vegetation Classification (NVC) community types (Rodwell *et seq.,* 1991; see Table 2), comprising various tall herb fen, swamp, mire and rush pasture communities (Kennedy, 2001). These also fall within wider CORINE biotopes (EU Coordination of Information on the Environment; Devillers *et al.*, 1991) comprising bottle sedge beds, and *Epilobio-Juncetum effusiia* and *Sphagno-Caricetum rostratae* vegetation types.

## Methods

ENVIRONMENTAL DATA

At each station, water level range gauges (see Bragg *et al*., 1994) were installed to a maximum depth of 75 cm in the wetland soils, following removal of a soil core with a hand-held auger. These were used to measure minimum (MIN: cm) and maximum (MAX: cm) water levels relative to ground surface during periods between sampling. Overall levels of fluctuation (FLU: cm) between sampling periods were derived from these two readings. Water levels (WAT: cm) were measured using fully perforated dipwells installed to a depth of 75cm alongside the gauges. The pH and electrical conductivity (CON: $\mu$S cm s$^{-1}$) were measured in each dipwell using Hanna meters. This followed a purging and refilling of each dipwell using a 50 ml syringe connected to a length of PVC tubing. Soil redox potential (RED: mV) was measured at a soil depth of 2–3 cm using a Hanna meter

*Table 2.* Site representation within relative TWINSPAN groups for average 1999 vegetation data, showing indicator species; G = Glen moss; I = Insh marshes; L = Lochwinnoch; N = Nether Whitlaw moss; T = Tarn moss. See Kennedy (2001) for full details.

with a self-referencing platinum electrode probe. Following evacuation and re-filling, water samples were taken from each dipwell (therefore representing either a soil water sample, or a mixed soil/ surface water sample at stations

**665**

where standing water was present) using a 50 ml syringe and were placed into acid-washed PVC bottles in an insulated cool-box. On return to the lab, the samples were filtered through 0.5 μm Whatman GF/C glass fibre filters and Cl, F, $NO_3^-$, and $SO_4^{2-}$ were determined from sub-samples using a DIONEX ion chromatograph (QIC Model). Samples were eluted with sodium hydroxide ($Na_2CO_3$/ $NaHCO_3$) solution and conductivity was reduced with dilute sulphuric acid ($H_2SO_4$) to suppress interference. The detection limit for these elements was 0.02 mg l hr$^{-1}$. K and Na were determined using flame photometry. Ca, Mg and Mn were determined using flame atomic absorption spectrometry (AAS); samples were dosed with strontium nitrate solution (0.4%) to suppress interference for Ca and Mg. Fe was determined by graphite furnace AAS. Samples were diluted where appropriate and the detection limit was 0.01 mg l$^{-1}$ (see Grieve et al., 1995 for full details).

VEGETATION DATA

At each sample station, species assemblage and richness (S, per m$^2$) was recorded within a 1m × 1m quadrat; nomenclature followed Stace (1997). Stem density (STDE) and density of reproductive structures (REPR) was estimated from three random counts conducted within a 10cm × 10cm quadrat (Kennedy, 2001). Nearest-neighbour distance (NENE) was measured between three random pairs of stems and scored on a 1–5 scale (1 = 0 to <2 cm; 2 = 2 to <4 cm; 3 = 4 to <6 cm; 4 = 6 to <8 cm; 5 = >8 cm: Kennedy, 2001). Shade was estimated where 0 = no shade and 5 = heavy shade.

DATA ANALYSIS

Site data for 1999 were classified into groups, based upon relative species abundances, using TWINSPAN (Two-Way Indicator Species Analysis (Hill, 1979): see Kennedy (2001) for full details).

A constrained ordination analysis, with species data constrained upon environmental data, was conducted using Canonical Correspondence Analysis (CCA) within the 'Canoco for Windows' package (ter Braak and Šmilauer, 1998). Environmental variables which were auto-correlated (minimum and average water level, and sodium (Na) concentration: indicated by a Variance Inflation Factor > 20) were omitted. Monte-Carlo permutation tests were conducted to determine which remaining variables significantly influenced the ordination ($p \leq 0.05$).

Three models were constructed from the 1999 dataset. In the first model the independent variable was nitrate concentration and the predictor variables were species richness, nearest neighbour distance and density of reproductive structures. In the second model the independent variable was stem density and the predictor variables were average water level, average minimum water level, degree of water table fluctuation, pH and nitrate concentration. In the third model, the independent variable was density of reproductive structures and the predictor variables were pH and nitrate concentration. The response curve of each variable (i.e. linear, cubic, quadratic) was assessed in relation to independent variables using SPSS 9.0. Stepwise regressions were then carried out, starting with full models. Variables were removed if they explained little or no variance in the dependent variable (an increase in the $R^2$ of at least 0.03). Predicted scores were compared with observed values by calculation of the product-moment correlation coefficient and residuals were checked for normality by the construction of normal probability plots. Models were tested, where appropriate, using data collected in 2000 from independent sites and repeat sites.

## Results

TWINSPAN groups for 1999 contained sample stations from each of the various sites (Table 2), indicating the suitability of the data for the construction of generally applicable models.

During both 1999 and 2000 a range of soil and surface water conditions was observed over the sites, with saturated and unsaturated soils and comparable ranges in pH, conductivity and nutrient status observed in both years (Table 3). Slightly drier surface conditions were observed at transect 1 within the Insh Marshes during 2000, although the largest levels of water table fluctuation were also recorded here. However, nitrate concentrations were somewhat lower overall in 2000. Mean water levels were slightly lower at the two independent test sites (Endrick Marshes and Wood of Cree) in 2000 than those measured during 1999 at the sites used to construct models (Glen Moss, Insh Marshes, Lochwinnoch, Nether Whitlaw Moss and Wood of Cree). However, inundation during the sampling periods was experienced during both years, as were variations in the overall level of water table fluctuation: levels of fluctuation were within comparable limits across the two years.

Mean nitrate concentrations in the water samples from all of the sites monitored during 1999 ranged from 0.01 to 14.07 mg $NO_3$-N l$^{-1}$, with a mean concentration of 1.01 mg l$^{-1}$ (s.e. = 0.24). During 2000 (model test data) concentrations ranged from trace level (< 0.01) to 9.43 mg $NO_3$-N l$^{-1}$, with a mean of 2.73 mg l$^{-1}$ (s.e. = 1.73).

Of the environmental variables monitored, five influenced significantly the ordination of the species and site data (Table

Table 3. Ranges of mean site and environmental variable values per transect for (a) 1999 and (b) 2000; *trace* = undetectable at <0.01mg l⁻¹

Fig. 2. *CCA ordination of site and species data constrained upon environmental variables, 1999. Groups (G) and NVC classifications are shown (see Table 2 for group details):* □ = G1 (S27a); O = G2 (M23b); × = G3 (M9b); ● = G4 (S27a); = G5 (S9b); △ = G6 (M2). *Cumulative variance of species-environment relation = 25.2% for axis 1; 47.2% for axis 2; 80.1% for all four axes combined. All variables shown are significant (*p < 0.05*) under Monte-Carlo permutation.*

4). These primary environmental gradients also allowed a differentiation between defined National Vegetation Classification (NVC) community types (Fig. 2). Generally, M2 *Sphagnum cuspidatum/recurvum* bog pool community samples were associated with relatively acidic soil conditions, and low levels of water table fluctuation. Examples representative of the M23b *Juncus effusus/ acutiflorus-Galium palustre* rush pasture, however, were

characterised in most cases by higher levels of water table fluctuation and less reducing soils.

Whilst nitrate concentration within the systems studied did not influence vegetation community structure significantly (Table 4), it was useful in the prediction of structural and reproductive components of the wetland vegetation. Conversely, aspects of the vegetation structure were found to be useful predictors of nitrate concentrations within the surface and soil water component of the systems: nitrate concentration within the mixed water samples was successfully predicted from three basic features of the vegetation sampled (Eqn. 1: see Methods section for explanation of codes). An increase in nitrate concentration is characterised by a linear increase in species richness (S per $m^2$) and, similarly, by a linear increase in the density of reproductive structures per $m^2$. There is a slightly more complex relationship with nearest-neighbour distance, with a decrease in values (i.e. less spaces between neighbouring stems), followed by a subsequent increase in values (i.e. an increase in the spacing of stems), characterising increasing nitrate concentrations.

$$\ln\mathbf{NO_3} = -0.308 + 0.041\mathbf{S} - 0.780\mathbf{NENE} + 0.045\mathbf{NENE^3} + 0.245\ln\mathbf{REPR} \qquad (1)$$

(F = 4.077; d.f. = 4; $R^2$ = 0.31; $p$ = 0.008; n = 43)

A regression model for stem density (Eqn. 2) utilised average and minimum water level, overall degree of water level fluctuation, pH and nitrate concentration as predictor variables. The nitrate concentration of the water ($\ln NO_3$) has a cubic function within the equation. This suggests that in relation to an increasing stem density, nitrate concentration characteristically increases, then decreases, and finally increases again within the confines of the model. Mean water level relative to the wetland soil surface has a quadratic response expressed relative to increasing stem density, with an initial decrease followed by an increase (i.e. greatest stem density in wetter sites). Minimum water level (i.e. depth of water table below ground surface) takes the same form within the equation, with an increase in stem density characterised initially by wetter soils, but with the highest stem densities characterised by drier soils (i.e. greatest depths of water table below ground surface). The degree of water table fluctuation characterises increasing stem density by an initial increase; however, the sites with the greatest levels of fluctuation had lower stem density. The relationship between pH and stem density is linear, with an increased stem density as water samples became less acidic and approached circumneutral conditions.

$$\ln\mathbf{STDE} = 4.054 - 0.046\mathbf{WAT} - 0.037\mathbf{MIN} + 0.997\ln\mathbf{FLU} + 0.363\mathbf{PH} - 0.001\mathbf{WAT^2} + 0.001\mathbf{MIN^2} - 0.241\ln\mathbf{FLU^2} + 0.639\ln\mathbf{NO_3} - 0.405\ln\mathbf{NO_3}^2 + 0.080\ln\mathbf{NO_3}^3 \qquad (2)$$

(F = 6.14; d.f. = 10; $R^2$ = 0.67; $p$ = <0.001n = 43)

A third model (and the second involving nitrate as a predictor variable: Eqn. 3) illustrates a simplified but weaker relationship, with an increasing density of reproductive structures within the wetland vegetation being characterised by a linear increase in both the pH of the wetland hydrosoil, and in the nitrate concentration of the water samples.

$$\ln\mathbf{REPR} = 3.094 + 0.392\mathbf{PH} + 0.260\ln\mathbf{NO_3} \qquad (3)$$

(F = 3.280; d.f. = 2; $R^2$ = 0.15; $p$ = 0.049; n = 43)

Due to the relatively low predictive capacity of the models predicting nitrate concentration (Eqn. 1) and density of reproductive structures (Eqn. 3), they were not validated using independent test data. However, they are included because they suggest a strong potential for further development at targeted wetland vegetation types. The use of test data from 2000 to test the model predicting stem density (Eqn. 2) showed that predicted values were relatively noisy (Fig. 3). However, 11 of the 20 predicted values were within approximately one unit (on a logarithmic scale) of their corresponding observed values. The scores were positively correlated, but only marginally significant ($r$ = 0.41; $0.05 < p < 0.1$).

## Discussion

Several of the sites studied (Kennedy, 2001) are likely to have varying nutrient inputs from agriculture and other land use practices, such as forestry, from adjacent areas within the their catchments (e.g. Endrick Marshes, Nether Whitlaw Moss, Glen Moss and Tarn Moss). Others (e.g. Lochwinnch and Wood of Cree) might be inundated periodically by enriched or acidified waters from within the wider catchment or, alternatively, are located in areas with potentially minor anthropogenic impacts (e.g. Insh Marsh). However, at just over 1 mg N l$^{-1}$, mean nitrate concentrations were not excessively high within the ranges observed for wetlands in the U.K. context (for example, concentrations of between 2.0 and 4.0 mg N l$^{-1}$ were observed within the Boxford Marsh riparian wetland on the River Lambourn in southern England: Prior and Johnes, 2002).

Within the range of wetlands sampled, relative nitrate concentration does not appear to be a factor with a highly
Fig. 3. *Rank scores of observed stem density values (m⁻²) plotted against values predicted from model (Equation 1);* R *=0.41; e = Endrick Marshes; i = Insh Marshes; w = Wood of Cree.*

significant role to play in differentiating vegetation community composition (e.g. Kennedy, 2001). However, nitrate may well have predictable relationships with structural aspects of the vegetation. Similarly, Wheeler and Proctor (2000) reported significant differences in biomass values relative to trophic status within samples which were otherwise classified as identical community types within the NVC (e.g. S27 *Carex rostrata-Potentilla palustris* Tall-herb fen: Rodwell, 1995).

The results suggest that even within the relatively short growing periods characteristic of northern European wetlands, nitrate has the potential to act as a predictor of species richness, the abundance of reproductive structures within wetland vegetation, and of nearest-neighbour distance (as a measure of how crowded the vegetation is within the basal parts of the vegetation canopy). In addition, characterisation of stem density was aided by reference to a range of environmental variables, including nitrate concentrations within the wetland soil and surface waters sampled, as was the density of reproductive structures within the vegetation. An apparent contradiction in the findings may also be explained: both wetter and drier sites are characterised by high stem density, while sites with intermediate levels of inundation aided the prediction of lower values for stem density (e.g. Kennedy and Murphy, 2003). This could be explained by the observation that wetter sites represent relatively dense *Carex rostrata* beds, for example, whilst the driest sites may be characterised by wetland grass communities, which are also more likely to have high stem density values (e.g. Kennedy *et al*., 2003). An increase in stem density appears to be linked to initially increasing, then decreasing, levels of water table fluctuation. This might be explained by the same mechanism of changing

vegetation type but, additionally, mineralisation might be increased within surface soils where they experience interspersed periods of wetting-up and drying out (Patrick and Malhapatra, 1968; Davidsson and Leonardson, 1998), increasing the availability of nitrate for plant uptake. However, where fluctuations become more extreme, or soils generally wetter, denitrification may lead to a net loss of nitrogen from the soil sink, limiting stem density (Patrick and Malhapatra, 1968).

Soil-water nitrate concentration has also been predicted by reference to vegetation bio-indicator variables, with an increase in species richness and associated reproductive structures predicting increasing nitrate concentration in the surface waters. Where diffuse or point source inputs into a freshwater system are minimal, then nitrate may well be a limiting factor to plant growth (Neal and Whitehead, 2002). In several of the stations sampled (Kennedy, 2001), bryophytes dominated in areas associated with low surface water nitrate concentrations (and therefore often had low vascular plant presence). The potential relationship outlined above between increasing levels of fluctuation, denitrification and subsequent nitrate loss, might also help to explain a decrease in nearest-neighbour distance (i.e. less well spaced stems), followed by an increase in stem spacing in relation to increasing nitrate concentrations (moving from drier through to wetter systems). It is evident from the nitrate model that the predictive relationships between nitrate concentration and the vegetation structural elements used as independent variables are difficult to separate. However, there is potential to develop this approach, and make predictions more robust, by targeting it at wetland types, such as riparian wetlands, where nitrate is likely to be less limiting within the surface water system (e.g. Prior and

Johnes, 2002) and might reach concentrations which begin to threaten the ecological functioning of freshwater systems (Neal and Whitehead, 2002). The prediction of values might be improved by targeting certain wetland types (e.g. riparian wetlands or reed beds). Also, sampling specifically from soil waters (rather than using mixed soil and surface water samples) might benefit the predictive capacity of the models. The residence time of standing waters on wetlands such as Insh Marshes, which are large and hydrologically complex (Grieve *et al.*, 1995), may be too short to allow uptake of nitrate by vegetation. A sensible development of this approach, therefore, may be to investigate potential differences in nitrate concentrations between soil and surface water components.

The need to incorporate wetland ecosystems into a unified framework which considers water quality, biological and hydrological processes for the prediction of the flow of nitrate (and other target parameters) through catchments is well recognised (Neal and Whitehead, 2002). However, the specific role which wetlands play as nutrient sequestration zones in riparian locations is still not clear (Prior and Johnes, 2002). Given that climate change may also play a role in the relative ability of wetland systems to undertake processes such as mineralisation and denitrification (Davidsson and Leonardson, 1998), this is an area in need of further research. Indeed, all these issues are important in relation to managing wetlands, which are an important component of aquatic ecosystems, not only in the UK, but globally.

## Conclusions

The use of relatively simple 'traits' in predicting aspects of eco-hydrological functioning within wetlands goes some way to answering the call for generally applicable tools in ecological assessment (e.g. Keddy, 1992a, b; Wheeler and Shaw, 1995) and can be highly complementary to purely taxonomic approaches in this respect (Duckworth *et al.*, 2000). In addition, this study indicates a potential ability to predict nitrate concentrations within wetland systems from observations of the representative vegetation. In the context of biomonitoring and wetland management, such observations might give early indications of the occurrence of nitrate enrichment; this would be especially useful where water quality is not monitored routinely. Conversely, observed soil-water nitrate concentrations could be used as an indicator of the vegetation present. Such knowledge may have applications in the remediation of degraded wetlands. The equations presented here, therefore, have the potential for application to target wetland types (e.g. tall herb fens and other typical riparian wetland vegetation), as bio-indicators of wetland ecosystem functioning.
