## Abstract

Precipitation is the key factor controlling the high-frequency hydrological response in catchments, and streamflow simulation is thus dependent on the way rainfall is represented in the hydrological model. A characteristic that distinguishes distributed from lumped models is the ability to explicitly represent the spatial variability of precipitation. Although the literature on this topic is abundant, the results are contrasted and sometimes contradictory. This paper investigates the impact of spatial rainfall on runoff generation to better understand the conditions where higher-resolution rainfall information improves streamflow simulations. In this study, we used the rainfall reanalysis developed by Météo-France over the whole French territory at 1 km and 1 h resolution over a 10 yr period. A hydrological model was applied in the lumped mode (a single spatial unit) and in the semi-distributed mode using three unit sizes of sub-catchments. The model was evaluated against observed streamflow data using split-sample tests on a large set of 181 French catchments representing a variety of size and climate conditions. The results were analyzed by catchment classes and types of rainfall events based on the spatial variability of precipitation. The evaluation clearly showed different behaviors. The lumped model performed as well as the semi-distributed model in western France where catchments are under oceanic climate conditions with quite spatially uniform precipitation fields. In contrast, higher resolution in precipitation inputs significantly improved the simulated streamflow dynamics and accuracy in southern France (Cévennes and Mediterranean regions) for catchments in which precipitation fields were identified to be highly variable in space. In all regions, natural variability allows for contradictory examples to be found, showing that analyzing a large number of events over varied catchments is warranted.

# 1 Introduction

A review of the hydrologic literature shows that there is no consensus on the impact of spatial resolution on the performance of hydrological models (e.g., Reed et al., 2004; Smith et al., 2012). There are several reasons for that. First, most previous studies have been limited to a single or a few catchments (Ajami et al., 2004; Bell and Moore, 2000; Das et al., 2008; Finnerty et al., 1997; Lindström et al., 1997; Reed et al., 2004; Smith et al., 2004, 2012; Winchell et al., 1998; Zhang et al., 2004), which makes conclusions highly dependent on the characteristics of the catchments studied. Interestingly, their contradictory conclusions show that the impact of the rainfall spatial distribution on runoff depends on catchment and event characteristics (Segond et al., 2007; Singh, 1997; Tetzlaff and Uhlenbrook, 2005; Viglione et al., 2010; Woods and Sivapalan, 1999; Zoccatelli et al., 2011). Second, many studies are virtual experiments based on synthetic flows, in which model simulations are compared to other simulations chosen as reference. This makes it difficult to reach conclusions transposable to actual case studies (Andréassian et al., 2004; Das et al., 2008). Last, the parameterization strategies used may introduce a bias in the evaluation of modeling approaches with different resolutions if parameters are not recalibrated or rescaled at each spatial resolution investigated (Kampf and Burges, 2007; Koren et al., 1999; Kumar et al., 2013; Morin et al., 2001; Samaniego et al., 2010).

That being said, the sensitivity of hydrological simulations to the spatial variability of precipitation inputs has been an active research area over the last three decades. There are at least two origins for this sensitivity: (i) the density of the precipitation measurement network, which more or less finely samples the actual precipitation field, and (ii) the inadequacy of the rainfall-runoff models' structure and spatial discretization. This review will not examine the first point, which has already been widely studied. All authors agree that spatial rainfall measurement is important at all scales and that its importance increases as catchment size decreases (Beven and Hornberger, 1982; Ogden and Julien, 1993; Michaud and Sorooshian, 1994; Obled et al., 1994; Faures

et al., 1995; Shah et al., 1996; Winchell et al., 1998; Sun et al., 2000; Carpenter et al., 2001; Andréassian et al., 2001; Berne et al., 2004; Arnaud et al., 2011; Vaze et al., 2011; Emmanuel et al., 2012).

Let us here focus on the relationship between spatial rainfall representation and runoff response. Results presented in the literature are contrasted and sometimes contradictory. Several studies concluded that including more detailed information on rainfall spatial distribution improves discharge simulation, whereas other studies have, surprisingly, shown the lack of significant improvement in simulations. A variety of studies have shown little (or no) impact of explicitly accounting for rainfall variability and several authors have suggested that a correct assessment of the rainfall input volume is more important than the rainfall spatial pattern itself (even in a highly spatially variable pattern) for simulating streamflow hydrographs (Andréassian et al., 2001; Beven and Hornberger, 1982; Naden, 1992; Obled et al., 1994; Woods and Sivapalan, 1999). Other studies have tested different modeling configurations, from lumped to (semi-) distributed, to investigate the impact of spatial precipitation inputs on streamflow simulations. Many of them reported that increased resolution in space had little effect on the model's performance and that distributed modeling approaches may not always provide improved outlet simulations compared to lumped approaches (Ajami et al., 2004; Apip et al., 2012; Bell and Moore, 2000; Das et al., 2008; Lindström et al., 1997; Liu et al., 2012; Naden, 1992; Nicòtina et al., 2008; Obled et al., 1994; Reed et al., 2004; Refsgaard and Knudsen, 1996; Smith et al., 2004; Zhang et al., 2004).

However, other studies have found that runoff prediction errors were considerably higher when spatially averaged rainfall was used and that including explicit information on rainfall spatial distribution improves the quality of predicted streamflow (Bonnifait et al., 2009; Carpenter and Georgakakos, 2006; Cole and Moore, 2008; Dodov and Fofoula-Georgiou, 2005; Krajewski et al., 1991; Ogden and Julien, 1994; Saulnier and Le Lay, 2009; Singh, 1997; Trambly et al., 2011; Winchell et al., 1998; Yu et al., 2012). Among these studies, some have underlined that the improvements in streamflow modeling were not systematic (Arnaud et al., 2011; Koren et al., 2004; Nicòtina

Interactive Discussion

et al., 2008; Segond et al., 2007; Tetzlaff and Uhlenbrook, 2005; Viglione et al., 2010; Winchell et al., 1998). They argued that improvements were only significant in catchments with significant spatial rainfall variability (Arnaud et al., 2002, 2011; Koren et al., 2004) and for large catchments due to the greater need for distributed consideration of spatial rainfall gradients (Nicòtina et al., 2008; Vaze et al., 2011). Others have attempted to explain the differences by different runoff-generating processes, strongly dependent on soil characteristics and soil moisture, which interacts with rainfall characteristics (Merz and Blöschl, 2009; Merz et al., 2006; Nicòtina et al., 2008; Norbiato et al., 2009; Penna et al., 2011; Viglione et al., 2010). These points of view suggest that rainfall-runoff processes are strongly variable between catchments and rainfall events.

It is our opinion that the previous studies have investigated too few catchments and too few flood events to draw any definitive conclusions. To reach general conclusions on the link between rainfall spatial variability and hydrological model performance, this paper presents tests made on a large set of events showing various spatial patterns of precipitation fields in different types of hydroclimatic conditions: this study uses a large set of 3620 flood events observed on 181 catchments in France representing a variety of conditions. A common model set-up, calibration and testing framework was applied for the various modeling options tested.

The catchment set and hydrological model are presented in Sect. 2. Section 3 details model implementation and the methods used to evaluate the streamflow simulations. Then the results are discussed in Sect. 4, starting from the analysis of the entire data set and then distinguishing different behaviors. The conclusions are summarized in Sect. 6.

## 2 Data and study area

### 2.1 A high-resolution precipitation data set

Weather radar provides rainfall estimates with high temporal and spatial resolution, but unfortunately, despite the major progress that has been made over the past decades on understanding and correcting radar errors, radar quantitative precipitation estimation products may still occasionally suffer from biases that may significantly affect rainfall-runoff simulations. Consequently, the benefit that could be gained from the improved spatial resolution of rainfall estimates has often been limited in hydrological applications (Biggs and Atkinson, 2011; Borga, 2002; Delrieu et al., 2009; Emmanuel et al., 2011; Krajewski et al., 2010).

Météo-France, the French national weather service, has recently produced a 10 yr (1997–2006) quantitative precipitation reanalysis at the hourly time step and 1 km<sup>2</sup> spatial resolution (Tabary et al., 2012). This reference data set combines all the information available in the operational archives (manual and automatic rain gauges as well as weather radars) in order to obtain the best precipitation estimation over France (550 000 km<sup>2</sup>). Figure 1 presents the location of available weather radar and rain gauge data in operation between 1997 and 2006. The French operational network was based on 13 radars in 1997 and 10 additional radars have been deployed over the 1997–2006 period, increasing the total number of operational radars to 23 in 2006. The ground measurement network consists of 1400 automatic and 2500 manual rain gauges (from which hourly and daily time series, respectively, can be derived).

We give a short description of the procedure followed by Météo-France to establish the reanalysis, but further detail can be found in Tabary et al. (2012). These data treatments are based on the operational experience of radar data processing at Météo-France. The precipitation data from the rain gauge network are routinely checked and corrected by expert systems. The radar network provides reflectivity images every 5 min, which are pre-processed before being merged with rain gauge data. The reflectivity images are corrected for residual ground-clutter, clear air echoes (insects,

dusts, . . .), partial beam blocking and undersampling effects before being converted into rainfall rates using the Marshall Palmer  $Z-R$  relationship. Daily calibration factors are computed for every  $1 \text{ km}^2$  pixel by comparing 24 h accumulated radar rainfall rates and daily rain gauge estimates computed from hourly and daily gauge measurements

5 by kriging with external drift. Hourly radar rainfall accumulations are then corrected using the daily calibration factors. Finally, hourly precipitation accumulation fields are computed from the available hourly (calibrated) radar and rain gauge data using kriging with external drift. For the time steps when no radar data are available or in case no calibration factor can be computed, the composite map is filled by ordinary kriging of

10 hourly rain gauge data.

The final composite  $1 \text{ km}^2$  hourly rainfall estimates have been successfully validated against independent hourly rain gauge data (not used for the whole reanalysis process) over 1 yr in southeastern France (Tabary et al., 2012). Hence, the reanalysis can be considered to provide reliable hourly precipitation estimations with high spatial res-

15 olution suitable to investigate the impact of rainfall spatial variability on the catchment response.

## 2.2 Catchment data set

A large set of 181 French catchments (see Fig. 2) was selected to run semi-distributed rainfall-runoff simulations. Hourly discharge data at the basin outlets were obtained

20 from the HYDRO national archive ([www.hydro.eaufrance.fr](http://www.hydro.eaufrance.fr)) for the 10 yr period of the rainfall reanalysis (1997–2006). Since weather radar measurements are considered accurate within a 100 km radius, the catchments were selected within this distance.

The catchment data set represents a wide variety of physiographical and hydroclimatic conditions (Fig. 2), ranging from oceanic to Mediterranean. This catchment set

25 consists of small to medium-size catchments, with 32 catchments smaller than  $100 \text{ km}^2$  and 27 catchments larger than  $1000 \text{ km}^2$ . The largest catchment is the Moselle at Custines ( $6834 \text{ km}^2$ ) in northeastern France. The characteristics of rainfall events on these catchments also vary, with both stratiform and convective events with a wide

range of intensities. Higher values of the rainfall intensity coefficient (calculated as the ratio between the 99th percentile and the mean hourly precipitation) and lower values of the streamflow 6 h autocorrelation coefficient (Table 1) are found in basins located in southeastern France in the Cévennes region and Mediterranean area where strong convective storms and flash floods are frequent (Berne et al., 2009; Delrieu et al., 2005; Javelle et al., 2010; Saulnier and Le Lay, 2009). Note that mountainous catchments were intentionally not selected here due to large uncertainties in radar measurements. Hence, there is no significant snow influence in the catchments studied.

### 3 Methodology

#### 3.1 Semi-distributed rainfall-runoff model

We used a semi-distributed model derived from the work of Lerat (2009). It is based on the GR5H hourly lumped rainfall-runoff model proposed by Le Moine (2008) (Fig. 3). The GR5H model only has five free parameters (see Fig. 3 and Table 2).

In the semi-distributed model, the catchment is divided into hydrologic units (i.e. sub-catchments) following the drainage network. A digital elevation model was used to build the sub-catchments (O’Callaghan and Mark, 1984). We chose to use sub-catchments of roughly the same size (Fig. 4). Mean rainfall is calculated for each sub-catchment (Fig. 5) and used as input to the GR5H model applied in lumped mode to simulate the outflow of each hydrological unit. Then a channel-routing method is used to route the sub-catchment flows to the downstream catchment outlet through the river network. Given the steep mean slope (greater than 0.01) for all the catchments (Table 1), the kinematic wave approximation can be considered valid to route natural flow in the river network (Henderson, 1966; Morris and Woolhiser, 1980). In this study, the linear lag propagation model (Bentura and Michel, 1997) was found to provide a satisfactory level of efficiency compared to more sophisticated channel routing methods. This is

in agreement with the results of Lerat et al. (2012). This function has a single free parameter: average river flow celerity  $C$  ( $\text{m s}^{-1}$ ).

The sensitivity of streamflow simulations to the spatial resolution of rainfall estimates was investigated by testing the semi-distributed rainfall-runoff model for three sizes of sub-catchments:  $64 \text{ km}^2$  (SD64),  $16 \text{ km}^2$  (SD16) and  $4 \text{ km}^2$  (SD04) (Fig. 4). The number of sub-catchments per catchment ranges between 2 and 108 for SD64, 2 and 432 for SD16, 4 and 1733 for SD04. In each case, the sub-catchment rainfall-runoff models were fed with rainfall inputs averaged over the sub-catchment, as illustrated in Fig. 5. The lumped configuration was also tested to serve as a reference, using precipitation averaged over the whole catchment as input.

### 3.2 Model parameterization and calibration

The calibration of a distributed or semi-distributed model is a complex task (Carpenter and Georgakakos, 2006; Lerat et al., 2012; Pechlivanidis et al., 2010; Pokhrel and Gupta, 2011) since the number of unknown parameters is magnified, with higher risks of overparameterization, equifinality and non-identifiability issues (Beven, 1993, 1996, 2001; Göttinger and Bárdossy, 2007; Kirchner, 2006). Pokhrel and Gupta (2011) even argued that calibration of spatially distributed parameter fields is impossible, since errors in model structure and data remain larger than the effect of spatial variability.

Here, we deliberately chose to let only the precipitation input vary spatially, while keeping model parameters uniform, in order to focus on the sole impact of spatial variability of precipitation on catchment response. This option is supported by the results of previous studies that reported more improvements in model performance related to the spatial distribution of the rainfall input than the distribution of model parameters (Ajami et al., 2004; Andréassian et al., 2004; Boyle et al., 2001). Thus the parameters of the semi-distributed model were constrained to be the same on all sub-catchments. Therefore, only six parameters have to be estimated: the five parameters of the GR5H model and the celerity parameter of the channel-routing method (Table 2). They are calibrated against flow measurements at the outlet of the catchment (no internal information is

Interactive Discussion

used). Calibration is renewed for each spatial resolution (lumped, SD64, SD16 and SD04) to overcome the scale-sensitivity of model parameters (Bárdossy and Das, 2008; Finnerty et al., 1997; Kumar et al., 2013; Samaniego et al., 2010). Investigating the impact of flow simulation at internal points within the catchment was not within the scope of this study and the reader may refer to Lerat et al. (2012) for a detailed discussion on this issue.

Given the small number of model parameters, the steepest descent local-search procedure used by Editjano et al. (1999) was deemed sufficiently robust to optimize the parameters. It was applied with the Kling–Gupta efficiency (KGE) objective function (Gupta et al., 2009). The initial parameter set to start optimization is determined by a gross pre-sampling of the parameter space using the discrete sampling method proposed by Perrin et al. (2008). This further limits the risk of the procedure being trapped in local optima.

### 3.3 Method and criteria for the evaluation of streamflow simulations

We performed split-sample calibration-validation tests (Klemeš, 1986). The 10 yr study period (1997–2006) was divided into two independent 5 yr sub-periods (1997–2001 and 2002–2006). Model parameters were calibrated on the first sub-period and model performance was validated on the second one, and vice-versa.

Although the model was continuously run on the periods tested, model performance was evaluated by comparing simulated and observed flow at the outlet of the catchment only for flood events, to focus on the periods when rainfall variability has the greatest influence. For each catchment, the 20 largest floods were selected, leading to a complete set of 3620 events (181 catchments × 20 events) representing a wide variety of floods. The flood events were automatically selected using the following procedure: (i) the maximum discharge is found, (ii) the beginning (respectively the end) of the event is defined when the previous (respectively the next) discharge is lower than a threshold discharge and (iii) if the precipitation is not null at the beginning of the event previously defined, then the beginning of the event is the first of the preceding time steps at which

Interactive Discussion

the precipitation is null. The threshold discharge  $Q_0$  is defined for each event, rising limb and declining limb of the hydrograph by Eq. (1):

$$Q_0 = \max_{\substack{t_p-240 < t < t_p \\ t_p < t < t_p+240}} (Q_p/4; Q_m + 0.05 \cdot (Q_p - Q_m)). \quad (1)$$

where  $Q_p$  is the peak flow (i.e., the maximum discharge found),  $t_p$  is the time step at which the peak flow is observed,  $Q_m$  is the minimum discharge observed over the 10 day period before (respectively after) the peak flow to calculate the threshold discharge needed to define the beginning (respectively the end) of the event.

Table 3 presents the four event-based performance criteria used for the evaluation. KGE (Gupta et al., 2009) measures the overall fit between simulated and observed flows. The peak flow, time to peak and volume errors evaluate the quality of the model simulation on the peak discharge value, timing of the peak discharge and total flow volume of the event, respectively. Note that the peak flow was defined as the maximum discharge, so there was only one peak flow for each event and if several peak flows occurred on the same event only the highest peak flow was considered for the evaluation.

The relative performance index  $R_m[b|a]$  formulated by Lerat et al. (2012) is used to compare the performance of modeling option  $b$  to modeling option  $a$ :

$$R_m[b|a] = \frac{m[Q^{\text{obs}}, Q^a] - m[Q^{\text{obs}}, Q^b]}{m[Q^{\text{obs}}, Q^a] + m[Q^{\text{obs}}, Q^b]}. \quad (2)$$

where  $m$  is a metric measuring the discrepancies between the simulated and observed streamflows which ranges between 0 and infinity (with  $m = 0$  when the error is null),  $Q^a$  and  $Q^b$  are, respectively, the discharge computed by the model (or the spatial resolution input)  $a$  and  $b$ . The  $R_m[b|a]$  criterion is bounded between  $-1$  and  $1$  ( $m = 0$  when the error is null), which limits the comparison problems on large sets of catchments arising from the use of non-bounded criteria, as discussed by Mathevet et al. (2006), Schaefli and Gupta (2007) and Seibert (2001). Table 4 details the interpretation of  $R_m$ .

### 3.4 Criteria for the evaluation of rainfall spatial variability

We used two indexes to quantify and compare the spatial variability of precipitation fields: the index of spatial rainfall variability,  $I_\sigma$ , and the location index,  $I_L$ , proposed by Smith et al. (2004) and shown in Eqs. (3) and (4) respectively.

$$I_\sigma = \frac{\sum_{t=1}^T \sigma_t \cdot P_t}{\sum_{t=1}^T P_t}, \quad (3)$$

$$I_L = \frac{\sum_{t=1}^T I_{pcp}(t) \cdot P_t}{\sum_{t=1}^T P_t}, \quad (4)$$

In addition to Eqs. (3) and (4), we also have:

$$\sigma_t = \sqrt{\frac{\sum_{i=1}^N [P_i(t)]^2}{N} - \frac{[\sum_{i=1}^N P_i(t)]^2}{N^2}}, \quad (5)$$

$$I_{pcp}(t) = \frac{C_{pcp}(t)}{C_{bsn}}, \quad (6)$$

$$C_{pcp}(t) = \frac{\sum_{i=1}^N P_i(t) \cdot A_i \cdot L_i}{\sum_{i=1}^N P_i(t) \cdot A_i}, \quad (7)$$

$$C_{\text{bsn}} = \frac{\sum_{i=1}^N A_i \cdot L_i}{\sum_{i=1}^N A_i}. \quad (8)$$

Where  $\sigma_t$  is the standard deviation of the hourly precipitation field covering the basin,  $P_i(t)$  is the hourly rainfall data for the pixel  $i$  at the time step  $t$ ,  $N$  is the total number of rainfall pixels within the watershed,  $C_{\text{bsn}}$  is the basin's center of mass,  $C_{\text{pcp}}(t)$  is the center of rainfall mass for each time step  $t$ ,  $I_{\text{pcp}}(t)$  is the rainfall centroid ratio for each time step  $t$ ,  $A_i$  is the pixel area ( $A_i = 1 \text{ km}^2$  in the present case) and  $L_i$  is the hydraulic distance between the pixel  $i$  and the catchment outlet calculated through the river network.

The spatial rainfall variability and location indexes are computed over the hourly gridded ( $1 \text{ km} \times 1 \text{ km}$ ) rainfall database for each entire flood event. The spatial rainfall variability index  $I_\sigma$  ranges from 0 to infinity: small values indicate that the spatial variability of the observed rainfall field is low (typical for stratiform events), while high values indicate high spatial variability (convective event). Values of the location index ( $I_L$ ) less than 1 indicate that the largest rainfall amount measured over the event was generally located at the region closest to the outlet, whereas the values greater than 1 indicate that the center of rainfall is far from the outlet.  $I_L$  values close to 1 indicate that the rainfall and basin centroids coincide.

## 4 Results and discussion

### 4.1 Typology of the 3620 observed flood events

The distribution of characteristics of the 3620 observed flood events are presented in Fig. 6. The spatial representations shown in Fig. 7 use values averaged over the

20 events selected for each catchment. About 5% of events are longer than 490 h (20 days): they are observed in catchments with dominant groundwater contributions, mainly located in northern France (Fig. 7). The mean rainfall amounts at the event scale vary between 1 and 500 mm over the 181 catchments with a mean value equal to 72 mm (Fig. 6). The rainfall amounts greater than 300 mm are observed for 32 events with generally short duration (less than 138 h), which are typical of late summer Mediterranean conditions (Fig. 7). The highest peak flow value is observed in the Massane at Argelès-sur-Mer ( $16 \text{ km}^2$ ,  $\max(Q_p) = 36.7 \text{ mm h}^{-1}$ ), which is the smallest catchment in the catchment set. Peak flows greater than  $4 \text{ mm h}^{-1}$  are observed for 111 flood events (3% of events), which all occurred in the Cévennes and Mediterranean regions: in the Ardèche at Meyras ( $99 \text{ km}^2$ ,  $\max(Q_p) = 11.3 \text{ mm h}^{-1}$ ), the Gardon at Mialet ( $244 \text{ km}^2$ ,  $\max(Q_p) = 10.7 \text{ mm h}^{-1}$ ), ..., and the Hérault at Gignac ( $1430 \text{ km}^2$ ,  $\max(Q_p) = 4.3 \text{ mm h}^{-1}$ ).

The median value of the location index is almost equal to 1, which indicates that events are equally distributed between events closer to or farther from the outlet than the catchment centroid. The spatial rainfall variability index is quite low (the third quartile is less than 1), which means that the precipitation fields in the 3620 observed events are generally stratiform or spatially uniform (Fig. 6). Nevertheless, the spatial rainfall variability index is greater than 1.11 for 20% of the events, which means that the data set has a significant number of high-variability events (Fig. 6).

The localization index is correlated to the spatial rainfall variability index: values far from 1 are usually observed in the regions where high values of the spatial rainfall variability index are also observed (Fig. 7). Indeed, precipitation fields localized close to (or far from) the outlet are most likely to be observed in regions where precipitation fields are spatially variable. In addition, extreme values of the localization index are also observed in northeastern France where the largest catchments of the set are located: these large catchments are more exposed to high localization indices (i.e. with precipitation fields centered on the upstream part of the catchment) because of the orographic effect.

Interactive Discussion

The precipitation fields with a strong spatial variability have short durations (Fig. 8) and they are typically observed between May and October (Fig. 8) in the Mediterranean area (Fig. 7). The largest peak flow coefficients are also observed in the Mediterranean area where the catchments are exposed to summer convective storms with high spatial variability of precipitation fields (Fig. 7). The highest values are obtained in the Ardèche catchment ( $I_{\sigma} = 4.39$ ) at Vogüé (625 km<sup>2</sup>), the Hérault catchments and the Gardon catchments ( $I_{\sigma} > 3.5$ ), which are all located in the Mediterranean area (Fig. 7).

## 4.2 Impact of spatial rainfall resolution on streamflow simulation efficiency

The impact of spatial rainfall resolution inputs on flow simulation was investigated by comparing model simulations for the four spatial resolutions: (i) lumped, (ii) 64 km<sup>2</sup> (SD64), (iii) 16 km<sup>2</sup> (SD16) and (iv) 4 km<sup>2</sup> (SD04). The results were analyzed by catchment classes based on the catchments' characteristics, shown in Table 1. The catchment area and the rainfall intensity coefficient were found to be the most relevant to explain the impact of spatial rainfall resolution on model performance.

Figure 9 presents model performance by catchment classes based on catchment area: the catchment set is divided into three sub-samples of 60 catchments (one sub-sample having 61 catchments). The size ranges from 16 to 155 km<sup>2</sup> for the G01 group of the smallest catchments and from 497 to 6834 km<sup>2</sup> for the G03 group of the largest catchments (Fig. 9). Note that for G01, only the smaller sub-catchment size (4 km<sup>2</sup>) could be tested for all catchments. Therefore, the results for the two other resolutions are not shown.

Some obvious hydrological truths can be observed in Fig. 9:

(i) Model performance is higher for the largest catchments (see, e.g., Merz et al., 2009). Significant differences were found in model efficiency between the smallest-catchment group (G01;  $\Delta Q_p = 37\%$ ,  $\Delta V = 26\%$ ,  $\Delta t_p = 0.14$ , KGE = 0.44) and the largest-catchment group (G04;  $\Delta Q_p = 21\%$ ,  $\Delta V = 16\%$ ,  $\Delta t_p = 0.11$ , KGE = 0.60).

(ii) The KGE criteria followed identical trends as the three event-based criteria  $\Delta Q_p$ ,  $\Delta t_p$  and  $\Delta V$ . This may be due to the fact that KGE is perfectly balanced between the

Interactive Discussion

bias (e.g., volume of flow), the relative variability in the simulated and observed values (i.e., the spread of flow) and the coefficient of correlation (i.e., the timing and shape of the hydrograph) (Gupta et al., 2009).

(iii) For all catchment subsets, the lumped model performs almost as well as the semi-distributed model, regardless of the spatial resolution of precipitation input. Only slight improvements were noted with higher spatial resolution in precipitation inputs and they were larger for the largest-catchment sub-sample (group G03). Similar conclusions were made by Arnaud et al. (2011), for example. In the present study, the KGE averaged over 1200 flood events (for the 60 largest catchments) rose from 0.594 for the lumped model to 0.624 for the semi-distributed model with the finest resolution, and the averaged absolute volume, peak and time to peak errors decreased from 22.4 % to 21.4 %, from 16.4 % to 15.7 % and from 0.112 to 0.108, respectively (Fig. 9).

In Fig. 10, model performance is analyzed by catchment classes based on catchment area and the rainfall intensity coefficient. Each catchment sub-sample (based on catchment area) is divided into three sub-classes based on the rainfall intensity coefficient (Table 1). Each sub-class has the same number of catchments (20 catchments) except one having 21 catchments (G01 and low rainfall intensity coefficient). The low rainfall intensity coefficients range from 17.3 to 19.4 for G01, from 16.8 to 19.0 for G02 and from 14.3 to 18.0 for G03. The high rainfall intensity coefficients range from 21.6 to 27.7 for G01, from 20.9 to 28.3 for G02 and from 19.3 to 25.4 for G03. Note that the rainfall intensity coefficient (Table 1) was calculated over the whole period of records (1997–2006) and was not limited to the selected events (we consider this coefficient as a catchment descriptor).

Model performance was better for catchments with a low rainfall intensity coefficient for all catchment area groups (Fig. 10). Significant differences were found in model efficiency, which decreased when the rainfall intensity coefficient rose: on average, between the low and high rainfall intensity coefficient, the KGE criteria ranged from 0.49 to 0.35 for the smallest-catchment group and from 0.68 to 0.48 for the largest-catchment group (Fig. 10).

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[I ◀](#)[▶ I](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

The lumped model performed as well as the semi-distributed model regardless of the spatial resolution of precipitation input for catchments with a low rainfall intensity coefficient. Interestingly, improvements were noted with higher spatial resolution in precipitation inputs for catchments with a high rainfall intensity coefficient ( $P_{99}/P_m > 20$ ) and for all ranges of catchment area (Fig. 10). Although model performance improvements were slight for the G01 (16–156 km<sup>2</sup>) and G02 (156–513 km<sup>2</sup>) catchment groups, significant improvements were obtained for the largest-catchment group (G03: 513–6834 km<sup>2</sup>): the KGE averaged over 20 flood events (for the 20 largest catchments with a high rainfall intensity coefficient) rose from 0.483 for the lumped model to 0.564 for the semi-distributed model with the finest resolution.

Regardless of the catchment area and rainfall intensity coefficient, the semi-distributed model performed equally well at the different spatial resolutions investigated (SD64, SD16 and SD04). Indeed, the improvements in streamflow simulation at the catchment outlet between the lumped model and the semi-distributed model at the finest spatial resolution (SD04) were nearly equivalent at coarser spatial resolutions (SD16 and SD64) (Fig. 10).

These results allow generalizing with confidence the conclusions drawn by previous studies (but only obtained over a few catchments) that reported a lack of significant differences between lumped and semi-distributed flow simulations at the catchment outlet (Ajami et al., 2004; Apip et al., 2012; Bell and Moore, 2000; Lindström et al., 1997; Naden, 1992; Nicôtina et al., 2008; Obled et al., 1994; Refsgaard and Knudsen, 1996). However, we found that the impact of higher resolution in precipitation inputs were catchment-dependent since the quality of streamflow simulations was significantly improved at the outlet of catchments exposed to high rainfall intensity, and these improvements rose with catchment area.

### 4.3 Do criteria describing rainfall spatial variability explain the observed differences?

The previous results were averaged over the 20 flood events for each catchment, which may hide some of the model behavior variability between events, depending on the characteristics of the precipitation fields. This aspect has now been further investigated. Given the very limited differences between the three sizes of sub-catchments, hereafter we will only consider the lumped and semi-distributed (SD04, finest resolution) simulations. Figure 11 shows the links between the relative performance index (see Eq. 5) applied using the KGE criterion (here noted  $R_{1-KGE}$ ) and the indexes of rainfall variability (location index  $I_L$  and spatial rainfall variability index  $I_\sigma$ ). A positive  $R_{1-KGE}$  criterion indicates that the semi-distributed approach is better than the lumped one, and the reverse is true for negative values.

First of all, it is worth noting that flood events with strong spatial variability of precipitation rarely occur compared to stratiform storms with uniform precipitation fields: most of the  $I_L$  values are close to 1 and  $I_\sigma$  values are generally low (Fig. 11). Interestingly, the median  $I_L$  value rises with catchment area from 0.97 for the smallest-catchment group (G01) to 0.99 for the mid-size catchment group (G02) and up to 1.01 for the largest-catchment group (G03). Similarly, the median  $I_\sigma$  value rises with catchment area from 0.52 to 0.66 and 0.69 for the G01, G02 and G03 catchment groups, respectively. Thus, the precipitation centroid is generally located at the upstream part of the basin for large catchments and the probability of obtaining uniform spatial rainfall fields is lower in large catchments.

For the small-catchment sub-samples (groups G01 and G02: from 16 to 513 km<sup>2</sup>), the semi-distributed model (with high spatial resolution of precipitation inputs) and the lumped model (with spatially uniform precipitation inputs) performed equally well (Fig. 11). For the largest catchments (group G03: from 513 to 6834 km<sup>2</sup>), the results were mixed for low spatial rainfall variability and location indexes close to and greater than 1 (Fig. 11).

Interactive Discussion

Nevertheless, for the largest catchments (group G03: from 513 to 6834 km<sup>2</sup>), the semi-distributed model with high spatial resolution yields better streamflow simulations for the few flood events in which the greatest spatial variability in precipitation fields are observed (high  $I_{\sigma}$  values or  $I_L < 1$ ) (Fig. 11). Interestingly, the semi-distributed model performed better than the lumped model (for large catchments) for the events where the precipitation fields were located close to the outlet ( $I_L < 1$ ), while the lumped model was able to cope with rainfall fields located far from the outlet ( $I_L > 1$ ). This may be due to the fact that larger precipitation amounts are more often concentrated at the upstream part of the catchment due to an orographic effect and a strong altitudinal gradient in large catchments (Fig. 7). Thus, through calibration the lumped model acquires the ability to accurately reproduce the catchment response for such more common rainfall field patterns, but not for the other “extra-ordinary” (from a precipitation spatial variability point of view) events.

These results – based on a large set of 181 catchments and a wide variety of flood events – clearly show that the impact of spatial variability of precipitation is scale-dependent and event-characteristic-dependent, as suggested by several authors (Ajami et al., 2004; Bell and Moore, 2000; Koren et al., 2004; Segond et al., 2007; Smith et al., 2004; Tetzlaff and Uhlenbrook, 2005; Winchell et al., 1998). This may explain why contradictory results can be found in the literature on the impacts of spatial rainfall variability on the catchment response: this study shows that some flood events are improved using higher spatial rainfall information and others are not (Fig. 11).

#### 4.4 Which catchments should be modeled in a semi-distributed way?

Here we investigate the possibility of identifying catchments where a spatially distributed representation would bring a definite advantage. Figure 12 shows the comparison between lumped and semi-distributed simulations evaluated by the relative performance index on KGE for the whole set of 181 catchments (left, overall distribution on the 3620 flood events) and by catchment (right, 181 distributions on 20 flood

events each). The analysis based on the 3620 observed flood events shows that the results are contrasted (Fig. 12): 44 % of flood events are better simulated with the lumped model (fed with spatially uniform precipitation inputs). Using higher spatial resolution of precipitation inputs only improves model performance for a small majority (56 %). It is difficult to draw conclusions given the low median value of the relative performance index, equal to 0.006 (Fig. 12).

However, when the large set of flood events is analyzed by catchment (Fig. 12, right), these contrasted results appear to be catchment-dependent: spatial precipitation inputs greatly improve the streamflow simulations at the outlets of some catchments, whereas the impact of spatial forcing is insignificant or semi-distributed modeling is worse than lumped modeling for other catchments (Fig. 12). These findings highlight the need to test model hypotheses on large and diversified catchment sets (Andréassian et al., 2009).

#### 4.5 Can specific catchment behaviors be explained?

To identify the catchments that benefit (or not) from higher-resolution rainfall information, the relative performance indexes calculated over 20 flood events (Fig. 12) were averaged by catchment. The cumulative distribution of the mean relative performance index and the geographic localization for the 181 catchments are shown in Fig. 13. The performance of the lumped model was better than the semi-distributed model for 39 % of catchments. Hence the semi-distributed approach appears beneficial for 61 % of the catchment set (Fig. 13).

The analysis applied independently for each catchment pointed out regional tendencies concerning the impact of spatial rainfall resolution on streamflow simulation (Fig. 13). In western France, streamflow simulation at the outlets of the catchments located close to the Atlantic coast were not improved when using higher spatial rainfall information. In this region, catchments are exposed to an oceanic climate with precipitation fields that are spatially quite uniform (Fig. 7), which may explain the fact that the lumped model performed as well as the semi-distributed model (Fig. 13). Two

Interactive Discussion

catchments, the Petite Leyre and the Eyre catchments (Fig. 13 and Table 5), exhibited strong model performance decreases when used in spatial distribution mode. Detailed analysis showed that the semi-distributed model was affected by absurdly high values in spatial precipitation data inputs coming from radar measurements (despite the treatments applied to correct them and the numerous quality checks). These inaccurate precipitation values were smoothed by averaging the spatial precipitation data over the catchment in the lumped model. As a result, the lumped model successfully computed the flow at the catchment's outlets, contrary to the semi-distributed model.

In northern France, the results were contrasted. In this region, many catchments are influenced by significant groundwater contribution. Model performance remained low on these catchments whatever the spatial distribution (Fig. 13): for example, for the Es-sonne catchment, the KGE value increased from 0.322 with the lumped model to only 0.397 with the semi-distributed model (Table 5). Increasing spatial information in precipitation inputs did not necessarily yield better flow simulations and strong decreases in model performance could be observed between the lumped and the semi-distributed model (Fig. 13 and Table 5). Our interpretation is that (i) spatial rainfall variability is already quite low in this region (Fig. 7), while (ii) the impact of spatially variable precipitation is dampened by the high infiltrability in this catchment dominated by subsurface flow (Nicòtina et al., 2008).

The catchments that benefit most from higher spatial resolution of precipitation inputs (Fig. 13) are the catchments in which precipitation fields are identified to be significantly variable in space (Fig. 7). We identified two regions strongly exposed to spatial rainfall variability: the Cévennes and Mediterranean regions in southern France with high spatial rainfall indexes (Fig. 7) and northeastern France with extreme location index values (Fig. 7). As examples, we present three flood events with high spatial rainfall variability that occurred on the large Hérault catchment (1430 km<sup>2</sup>) and the medium-size Allier (323 km<sup>2</sup>) and Alagnon catchments (322 km<sup>2</sup>). The observed precipitation fields were highly variable in space, as indicated by the high values of the spatial rainfall variability index:  $I_{\sigma} = 6.73$  (September 2000),  $I_{\sigma} = 1.66$  (November 1997) and  $I_{\sigma} = 0.94$

(October 2003). As a consequence, the simulated peak flow was well depicted with the semi-distributed model due to spatially distributed precipitation inputs, whereas it was missed with spatially uniform precipitation input in lumped modeling (Fig. 14). Similar conclusions were reached for two catchments in northeastern France and one Cévennes catchment where extreme location index values were identified: the quality of streamflow simulations was improved due to higher spatial rainfall information within the semi-distributed model (Fig. 15).

## 5 Conclusions

### 5.1 Summary

The impact of higher-resolution rainfall information on streamflow simulation was investigated over a large set of 3620 flood events selected on 181 French catchments. Semi-distributed streamflow simulations were run at different spatial resolutions and evaluated against observed flow data at catchment outlets. The results were analyzed (i) by catchment classes based on catchment area and (ii) by flood events based on the spatial variability of observed precipitation fields.

This study first confirms that on average, the differences in model performance between lumped and semi-distributed options are not significant. However, the analysis applied by catchment and by flood event clearly showed that the impact of spatial rainfall information on flow simulation is scale-dependent, catchment-dependent and event characteristic-dependent. This result underlines that catchment response to spatial heterogeneity of precipitation fields is highly variable between catchments.

The catchments' size and the rainfall intensity coefficient were shown to be effective indicators to identify catchments on which detailed spatial rainfall information is useful to improve simulations. In addition, the indexes proposed by Smith et al. (2004) to evaluate spatial rainfall variability showed that the greatest improvements on streamflow

simulation were obtained at the outlet of large catchments and for events with significant spatial variability in precipitation fields.

By investigating catchment responses independently for each catchment and for a variety of flood events, regional tendencies were pointed out concerning the potential benefit of high spatial rainfall resolution for runoff modeling in France. While a better spatial representation of precipitation inputs did not yield better streamflow simulations at the outlet of catchments exposed to oceanic climate conditions, significant improvements were obtained in regions frequently exposed to rainstorms with high spatial variability, such as the Cévennes and the Mediterranean regions.

These results highlight the need to work on large and varied sets of catchments (Gupta et al., 2013). Catchment dependency on rainfall spatial variability is confirmed. By carefully analyzing the changes in simulated hydrographs at different spatial resolutions, the significant influence on particular sub-catchments can be detected. In this way, the methodology applied in this study provides insights to investigate the catchment properties that may influence the catchment response.

## 5.2 Limits and perspectives

In spite of our effort to obtain general results, we do see some limits to our conclusions. First of all, we must mention that the results may still be somewhat dependent on the model or testing methodology used, which may not be adapted to certain particular basin behaviors (Pokhrel et al., 2012; Smith et al., 2012). Here, we have applied a single model structure to all catchments, where others would have preferred catchment-specific structures (Fencia et al., 2011). The spatial heterogeneities in catchment characteristics may interact with the spatial heterogeneity in precipitation fields, with the risk of masking the impact of spatial rainfall variability. Working on optimizing the model structure on a catchment-by-catchment basis could help resolve a few surprising results, with a few catchments in the Mediterranean region (where the spatial rainfall variability was high) that were not improved with semi-distributed modeling (Fig. 13). In addition, substantial improvements due to semi-distributed modeling were obtained on

a few catchments in central France (Fig. 13 and Table 5), although these catchments were not exposed to strong spatial rainfall variability (Fig. 7), but they are long catchments with a particular morphology where streamflow simulations may benefit from the channel-routing function of the semi-distributed model. These particular catchments need complementary analysis to validate these hypotheses, which is beyond the scope of this paper.

At this point, we see a natural continuation of this work in further investigations with models whose parameters will be allowed to be distributed spatially, in order to explore the impact of catchment heterogeneities on catchment response. In our opinion, however, this complementary work should not fundamentally modify the conclusions of this paper.

## An evaluation on 3620 flood events

F. Lobligeois et al.

**Table 1.** Summary of physiographical and hydrometeorological characteristics of the catchment set. The rainfall intensity coefficient is the ratio between the 99th percentile  $P_{99}$  and the mean hourly precipitation  $P_m$ .

Basin characteristics	Min	Median	Max
Drainage area (km <sup>2</sup> )	16	264	6834
Mean elevation (m)	41	250	1276
Mean slope (–)	0.01	0.06	0.37
Annual runoff, $Q$ (mm)	57	307	1228
Annual precipitation, $P$ (mm)	489	913	1841
Annual potential evapotranspiration, PE (mm)	556	696	892
Runoff coefficient, $Q/P$ (–)	0.10	0.33	0.80
Aridity index, $P/PE$ (–)	0.55	1.33	2.85
Rainfall intensity coefficient, $P_{99}/P_m$ (–)	14	19	28
Streamflow 6 h autocorrelation (–)	0.52	0.97	1.00

Model parameter	Description
$X_1$	Production (soil moisture accounting) store capacity (mm)
$X_2$	Groundwater exchange coefficient (–)
$X_3$	Time base of the unit hydrograph (h)
$X_4$	Routing store capacity (mm)
$X_5$	Threshold for groundwater exchange (–)
$C$	Average celerity in the river network ( $\text{m s}^{-1}$ )

## An evaluation on 3620 flood events

F. Lobligois et al.

**Table 4.** Interpretation of the relative performance index  $R_m[b a]$  comparing the performance of model  $b$  to the reference model  $a$  using a metric  $m$  (Lerat et al., 2012).

$R_m[b a]$	$m[Q^{\text{obs}}, Q^a]/m[Q^{\text{obs}}, Q^b]$	Interpretation
1	0	Model $a$ is perfect according to the metric $m$ with $m[Q^{\text{obs}}, Q^a] = 0$
0.5	1/3	$m[Q^{\text{obs}}, Q^a]$ is three times smaller (better) than $m[Q^{\text{obs}}, Q^b]$
0	1	Models $a$ and $b$ are equal to $m[Q^{\text{obs}}, Q^a] = m[Q^{\text{obs}}, Q^b]$
-0.5	3	$m[Q^{\text{obs}}, Q^a]$ is three times larger (worse) than $m[Q^{\text{obs}}, Q^b]$
-1	$+\infty$	Model $b$ is perfect according to the metric $m$ with $m[Q^{\text{obs}}, Q^b] = 0$

## An evaluation on 3620 flood events

F. Lobligeois et al.

**Fig. 9.** Distributions of model performance in validation mode using the four efficiency criteria (top to bottom) for three catchment groups (G01, G02 and G03, left to right) sorted by increasing catchment area. Model performance was computed for 3620 flood events and for different spatial resolutions of precipitation forcing (LUMPED, SD64, SD16 and SD04). The boxplots show the 0.05, 0.25, 0.50, 0.75, 0.95 percentiles, and the mean value is given and shown by a dot.

## An evaluation on 3620 flood events

F. Lobligois et al.

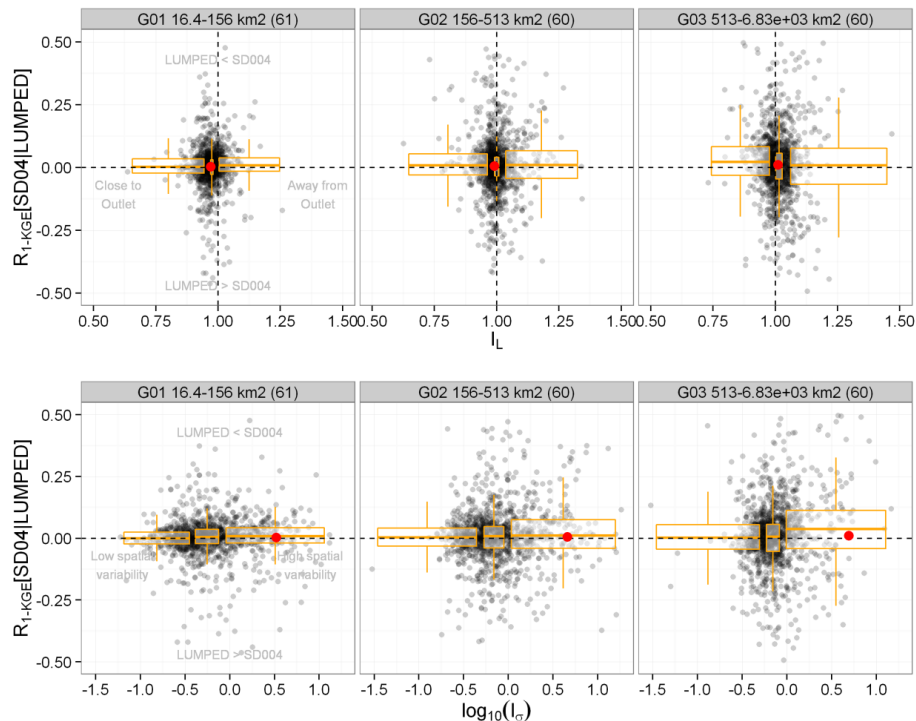

**Fig. 10.** Distributions of model performance in validation mode for three catchment groups sorted by increasing catchment area (G01, G02 and G03, left to right) and by increasing rainfall intensity coefficient (low, intermediate and high  $P_{99}/P_m$ , top to bottom). The model performance was computed for 3620 flood events and for different spatial resolutions of precipitation forcing (LUMPED, SD64, SD16 and SD04). The boxplots show the 0.05, 0.25, 0.50, 0.75, 0.95 percentiles, and the mean value is given and shown by a dot.

An evaluation on  
3620 flood events

F. Lobligois et al.

**Fig. 11.** Relative KGE performance index in validation mode between the lumped and the semi-distributed (SD04) simulations. The relative performance indexes are computed for 3620 flood events ordered by location index (top) and spatial rainfall variability index (bottom), for three groups of 60 catchments classed by area (G01, G02 and G03). The red points show the median values. The boxplots show the distribution of the relative KGE performance index for three groups of events with the same number of events per boxplot.

An evaluation on  
3620 flood events

F. Lobligeois et al.

**Fig. 12.** Distribution of relative performance index values in validation mode between the lumped model and the SD04 semi-distributed model. The distribution is drawn for the whole set of 3620 flood events (left) and for the 20 events of each catchment (right). The red points show the median values of the relative performance index for each catchment.

An evaluation on  
3620 flood events

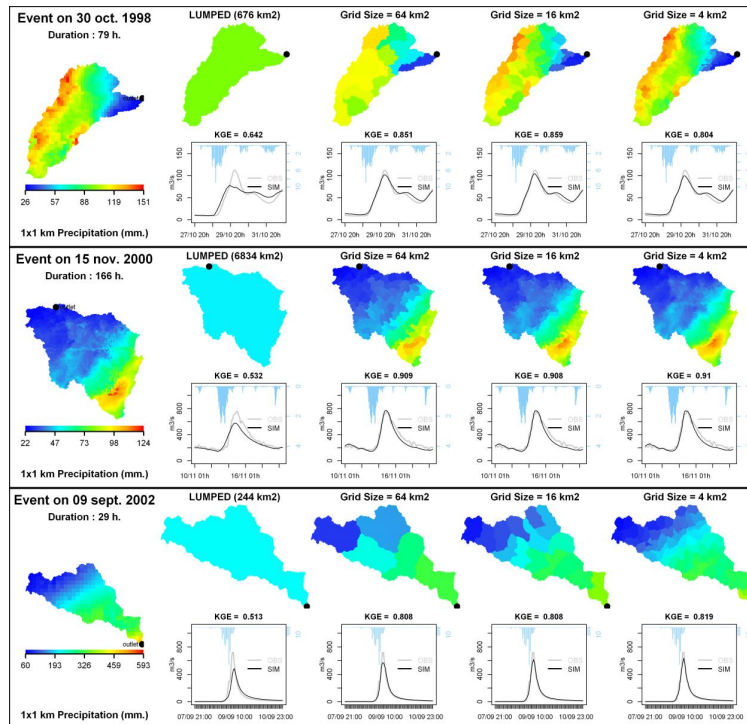

F. Lobligeois et al.

**Fig. 14.** Cumulated precipitation fields observed in the Cévennes and Mediterranean regions for three flood events with simulated and observed streamflow at different spatial resolutions: (top) November 1997 flood event ( $I_L = 1.08$  and  $I_\sigma = 1.66$ ) on the Allier catchment at Langogne (323 km<sup>2</sup>); (middle) September 2000 flood event ( $I_L = 1.02$  and  $I_\sigma = 6.73$ ) on the Hérault catchment at Gignac (1429 km<sup>2</sup>); (bottom) October 2003 flood event ( $I_L = 1.05$  and  $I_\sigma = 0.94$ ) on the Allagnon catchment at Joursac (322 km<sup>2</sup>).

An evaluation on  
3620 flood events

F. Lobligeois et al.

**Fig. 15.** Cumulated precipitation fields (with extreme location index values) observed for three flood events with simulated and observed streamflow at different spatial resolutions: (top) October 1998 flood event ( $I_L = 1.07$  and  $I_\sigma = 2.00$ ) on the Bruche catchment at Holtzheim (676 km<sup>2</sup>); (middle) November 2000 flood event ( $I_L = 1.12$  and  $I_\sigma = 1.17$ ) on the Moselle catchment at Custines (6834 km<sup>2</sup>); (bottom) September 2002 flood event ( $I_L = 0.85$  and  $I_\sigma = 13.47$ ) on the Gardon catchment at Mialet (244 km<sup>2</sup>).
