Abstract

In deregulated electricity markets, hydropower portfolio design has become an essential task for producers. The previous research on hydropower portfolio optimisation focused mainly on the maximisation of profits but did not take into account riverine ecosystem protection. Although profit maximisation is the major objective for producers in deregulated markets, protection of riverine ecosystems must be incorporated into the process of hydropower portfolio optimisation, especially against a background of increasing attention to environmental protection and stronger opposition to hydropower generation. This research seeks mainly to remind hydropower producers of the requirement of river protection when they design portfolios and help shift portfolio optimisation from economically oriented to ecologically friendly. We establish a framework to determine the optimal portfolio for a hydropower reservoir, accounting for both economic benefits and ecological needs. In this framework, the degree of natural flow regime alteration is adopted as a constraint on hydropower generation to protect riverine ecosystems, and the maximisation of mean annual revenue is set as the optimisation objective. The electricity volumes assigned in different electricity sub-markets are optimised by the noisy genetic algorithm. The proposed framework is applied to China's Wangkuai Reservoir to test its effectiveness. The results show that the new framework could help to design eco-friendly portfolios that can ensure a planned profit and reduce alteration of the natural flow regime.

1 Introduction

Since the global electricity reform process began in the 1980s (Zelner et al., 2009; Wang and Chen, 2012), and especially after the 1990s, market-oriented reforms in the electric power industry were implemented in many countries to allocate electricity more efficiently through market mechanisms (Williams and Dubash, 2004; Tsai, 2011; Wu, 2012). In the process of reform, vertically integrated electricity utilities were

restructured and unbundled, and competition has been introduced into generation as well as the wholesale and retail segments of the industry (Pollitt, 2009; Holmberg, 2011; Mulder, 2011). In deregulated markets, hydropower producers usually own generation resources and are allowed to participate in any sub-markets such as bilateral contract and spot markets (Karandikar et al., 2010; Ramos et al., 2010). Maximising profits is usually their sole objective for participating in the market (Liu et al., 2009). To maximise profits, hydropower producers need to devise their own strategies for portfolio design, i.e., the allocation of generation proportions for exchanges in each sub-market (Shen and Yang, 2012).

Extensive research has been performed to optimise hydropower portfolios. Bjørgan et al. (1999) integrated the optimisation of future contract and power scheduling based on risk management in a static mean-variance framework, and the efficient frontier was used as a tool to identify a preferred contract portfolio. Using a continuous-time framework, Keppo (2002) proposed a model for optimal long-term electricity trading strategies and the associated production process by maximising production and terminal water reservoir level in the case of multi-reservoir hydropower systems. Fleten et al. (2002) used a four-stage stochastic programming model with 256 scenarios for simultaneous risk management via contracts and hydropower generation planning on a 1.5 yr horizon. Shrestha et al. (2005) presented a portfolio management technique to optimise expected revenue for a hydropower producer, a scenario that utilises tree analysis with corrective recourse actions for probable scenarios. The effect of contract position adjustment is also analysed to minimise revenue variation from the expected values for risk-averse producers. Liu et al. (2009) present a stochastic linear programming framework for hydropower portfolio management with uncertainty in market prices and inflows on medium term, in which the uncertainty was modelled as a scenario tree using the Monte Carlo simulation method, to maximise the expected revenue over the entire scenario tree. These approaches could effectively optimise hydropower portfolios and maximise the total profit of hydropower producers. However, none of the previous research considered the need to protect riverine ecosystems.

Interactive Discussion

The major cause of riverine ecosystem degradation resulting from hydropower generation portfolio management is alteration of the natural flow regime (Babel et al., 2011; Kern et al., 2012; Bhatt and Khanal, 2012). This alteration can have ecological consequences, including: (1) habitat loss from river channels and floodplains; (2) desynchronisation of natural flow variability and life cycle strategies of aquatic species; (3) loss of lateral and longitudinal hydrological connectivity, especially seasonal linkages within the drainage network and channel-floodplain systems; and (4) invasion of exotic and introduced species in river systems (Bunn and Arthington, 2002). The hydropower portfolio could significantly influence the downstream flow regime in deregulated markets, leading to the degradation of riverine ecosystems. Although profit maximisation is the major objective for producers in deregulated markets, the need to reduce flow regime alteration must be incorporated into the process of hydropower portfolio optimisation for riverine ecosystem protection, especially with the background of increasing attention to environmental protection and stronger opposition to hydropower generation (Jager and Smith, 2008; Chen et al., 2013).

Although many new reservoir operating methods have been proposed to better sustain environmental flows (e-flows, the volume of water that should remain in a river and the variation of this provision over time to maintain specific indicators of ecosystem health) in rivers (Richter, 2010; Shiau and Wu, 2010; Brown and King, 2012), these methods are river protection approaches at the hydropower generation stage. Portfolio determination is a task that occurs before hydropower generation, and the designed hydropower portfolio is a key factor influencing reservoir operation parameters (Chen et al., 2012; Yin et al., 2011, 2012). Even if the reservoir operating rules are refined, their ecological protection effects may not be as effective as expected under the conditions of improperly designed portfolios. Research on the optimal portfolios must be performed with the consideration of both economic benefits and ecological needs, which can provide the basis for developing eco-friendly reservoir operating rules.

This research seeks to remind hydropower producers of the requirement of river protection when they design the portfolios and to help the producers design

Interactive Discussion

eco-friendly portfolios. In this work, we extend previous research on hydropower portfolio optimisation and establish a framework to determine the optimal portfolio of a hydropower reservoir, accounting for both economic benefits and ecological needs. This framework may help mitigate the impact of hydropower generation on riverine ecosystems, especially for the situation where the tension between river protection and power generation is very severe.

2 Methods

2.1 Framework for determining optimal hydropower portfolios for both riverine ecosystem and producer needs

2.1.1 Determining the sub-markets for participation

Sub-markets available for hydropower are not the same for each country in the world. Three common markets are bilateral contract (future), day-ahead, and real-time balancing (Alaywan and Wu, 2002; Kranz et al., 2002). Day-ahead and real-time balancing markets are also called spot markets. Participants In the electricity market face the risks of unknown demand and price (Aggarwal et al., 2009; Eichhorn et al., 2009). To avoid revenue risks, hydropower producers and grid companies like to make long-term or mid-term electricity supply contracts, forming the bilateral contract market (Lin and Wu, 2008). In a bilateral contract, the trading power volume and power price are designed. The trading power volume and price will not change in a spot market. In the day-ahead market, participants submit sell/bid offers for electricity for the following day. These offers consist of a quantity of energy to be sold or purchased and a desired price, where sell offers correspond roughly to each producer's marginal cost of energy production. The system operators then rank sell offers from least to most expensive; the last sell offer required to satisfy day-ahead forecast demand clears the market, and the marginal cost of increasing power supply by one additional megawatt determines

Interactive Discussion

the market-clearing energy price. Sellers with offers equal to or below this price then generate revenue equal to their respective bid quantities multiplied by the market-clearing price (Rothwell and Gomez, 2003). In the real-time balancing market, system managers coordinate an hourly real-time energy market, which is used to meet real-time electricity demand when it varies relative to day-ahead forecasts. An hourly real-time market clearing price is determined in a manner similar to that of the day-ahead market (i.e., via the ranking of bid/sell offers), and transactions are consummated as necessary to meet real-time demand (Lambert, 2001).

The hydropower producers choose the submarkets in which they want to participate. The selection depends to some extent on the risk preferences of the producers (Shrestha et al., 2005; Botterud et al., 2010). Risk-taking producers tend to participate in the spot market for possibly higher profit despite higher risk. Risk-averse producers participate in the bilateral contract market that is more reliable, although extensive research supports short-term bidding for potentially higher revenue. Risk-neutral producers tend to participate in both the bilateral contract and spot markets.

2.1.2 Determining the rules for reducing flow regime alteration

Although sustaining the natural flow regime is a basic principle for river protection and e-flow management (Poff et al., 1997, 2010), hydropower generation will inevitably lead to changes. A possible method to reduce flow regime alteration would be to apply a type of e-flow provision strategy (such as sustaining the minimum e-flows and ensuring several high flow pulses, etc.) and optimise the parameters related to the hydropower portfolio to minimise alteration of the natural flow regime or restrict the degree of alteration to a specified threshold. This method has been applied extensively in research (Black et al., 2005; Richter and Thomas, 2007; Jager and Smith, 2008; Yin et al., 2011, 2012).

Reservoir operators can use different e-flow provision strategies depending on their attitude toward riverine ecosystems. Sustaining the minimum e-flow is a commonly used strategy for real-world e-flow provisions. This strategy can provide basic

protection of the riverine ecosystem, avoiding severe degradation. To sustain ecological functions related to high flows, some research proposes occasional high-flow releases for habitat improvement (Ligon et al., 1995; Gore et al., 2001; Renofalt et al., 2009). To better protect riverine ecosystems, hydropower operators can develop and apply more sophisticated e-flow strategies.

2.1.3 Setting the portfolio optimisation objectives and constraints

Maximising the overall profit for a given planning period and reducing the degree of flow regime alteration are two objectives for hydropower portfolio design. However, the two objectives are in conflict and cannot be achieved simultaneously; a typical multi-objective problem. To address this problem, the optimisation objectives need to be set first. An optimisation objective can be set as one of two conflicting objectives, i.e., maximising the overall profit for a given planning period or reducing the degree of alteration of the flow regime. The other objective can be set as one constraint by assigning a threshold accepted by the hydropower producers or river protectors. Alternatively, the two objectives could be integrated into one by some mathematical method such as compromise programming or weighted average.

Constraints for portfolio optimisation include maximum power generation capacity, water release capacity, reservoir maximum storage capacity, etc. If either of the two objectives is chosen as a single optimisation objective, the constraints also need to include the threshold for the other objective, i.e., the minimum acceptable overall profit or the maximum acceptable degree of flow regime alteration. The water mass balance also needs to be considered (Liu et al., 2009).

2.1.4 Choosing the solution method under uncertainty

In a deregulated market, portfolio optimisation is faced with the uncertainty of reservoir inflows and spot electricity prices (Fleten et al., 2002). A series of methods has been developed to obtain optimal solutions under uncertainty, such as stochastic

dynamic programming, stochastic dual dynamic programming, stochastic programming combined with scenario trees, and noisy genetic algorithms (Chang et al., 2005; Chen, 2003; Chen et al., 2007). The optimisation method needs to address these uncertainties.

5 2.2 Methods used in the case study

2.2.1 Range of variability approach

The range of variability approach (RVA) (Richter et al., 1996, 1997, 1998) has been widely used for assessing flow regime alteration and directing hydraulic facility operations (Galat and Lipkin, 2000; Shiau and Wu, 2004, 2006, 2007; Zhang et al., 10 2009). According to the RVA, a range of variation for each hydrological indicator was derived from the natural hydrological time series and was set as the flow management target. A range defined by the 75th and 25th percentile flows has been recommended as the management target (Richter et al., 1998). The degree of alteration, D_m , was used to measure the deviation of the impacted flow regime from the natural one for the 15 m th hydrologic indicator, which was defined by

$$D_m = \left| \frac{N_{o,m} - N_{e,m}}{N_{e,m}} \right| \cdot 100\% \quad (1)$$

where $N_{o,m}$ was the observed number of post-impact years in which the value of the m th hydrologic indicator fell within its RVA target range, and $N_{e,m}$ was the expected number of post-impact years in which the indicator value fell within the RVA target 20 range. The average degree of alteration of these hydrologic indicators was applied to quantify the river's overall impact, which can be expressed as follows:

$$D = \frac{1}{G} \sum_{m=1}^G D_m \quad (2)$$

where D was the overall degree of flow regime alteration, and G was the number of hydrological indicators. The degree of flow regime alteration can be categorised further into three levels: low alterations (values of D between 0 and 0.33), moderate alterations (values of D between 0.33 and 0.67), and high alterations (values of D between 0.67 and 1.0) (Richter et al., 1998).

2.2.2 Tennant method

To illustrate the applicability of the proposed approach, we use the Tennant method (Tennant, 1976), a simple and widely used method, to determine seasonal minimum e-flows. This method was recommended for e-flow assessment by the State Environmental Protection Administration of China (2006). Accordingly, the wet season e-flow was set at 30 % of average daily flow (ADF), and the dry season e-flow was set at 10 % ADF. More sophisticated methods could be used to replace the Tennant method if enough hydrological, biological, and geomorphological data are available.

2.2.3 Optimisation objectives and constraints

In the following case study, the hydropower producer participates in the contract and day-ahead markets according to the hydropower generation planning. The goal for hydropower portfolio optimisation is to maximise the mean annual revenue subject to specified e-flow management requirements. These requirements include the e-flow provision strategy and the specified threshold for the degree of flow regime alteration. The optimisation problem can be expressed by the following equation

$$L = \max \frac{1}{T} \sum_{j=1}^T \sum_{k=1}^{365} (PC_{kj} \cdot CL_{kj} + PD_{kj} \cdot DL_{kj}) \quad (3)$$

Subject to:

$$R_{kj} \leq EF_{kj} \quad (4)$$

$$D \leq D_0 \quad (5)$$

5 where L denotes the overall optimisation objective, PC_{kj} is the designed hydropower price in the hydropower supply contract for day k of year j (constant within one month, RMBkwh⁻¹); CL_{kj} is the designed hydropower volume in the hydropower supply contract for day k of year j (constant within one month, kwh); PD_{kj} is the hydropower price in the day-ahead market for day k of year j (RMBkwh⁻¹); DL_{kj} is the bidding volume for power in the day-ahead market for day k of year j (kwh); R_{kj} is the actual reservoir water release for day k of year j ; EF_{kj} is the designed e-flow for day k of year j ; D is the degree of actual flow regime alteration under a certain portfolio; and D_0 is the specified threshold of degree of flow regime alteration.

15 In the contract market, the producer and electricity grid make an agreement on the contract load for each month and the associated power price. In the day-ahead market, the producers need to determine the bidding volume for power. In this case, we assume that the producers first use inflow and the water in the reservoir to produce electricity to satisfy the contract load, and the producer will buy electricity from the market to satisfy the contract load only when the available electricity is not sufficient. Because the electricity cannot be stored, the bought electricity is set equal to the difference between the contract volume and the available power volume. We use the following equations to determine the bidding volume of power in the day-ahead market.

$$\text{If } AE_{kj} - CL_{kj} > 0, DL_{kj} = \min [k_{kj} (AE_{kj} - CL_{kj}) PD_{kj}, ME - CL_{kj}] \quad (6)$$

$$\text{If } AE_{kj} - CL_{kj} \leq 0, DL_{kj} = AE_{kj} - CL_{kj} \quad (7)$$

25 where AE_{kj} is the available electricity volume that the hydropower plant can generate with the water in the reservoir and inflow for day k of year j (kwh); ME is the maximum

Interactive Discussion

electricity production capacity for one day (kwh); and k_{kj} is the parameter for day k of year j (kwhRMB^{-1}).

In Eq. (6), $k_{kj}(\text{AE}_{kj} - \text{CL}_{kj})\text{PD}_{kj}$ means that the higher the available electricity volume, the higher the day-ahead power price, and the higher the bidding volume for power. There may be some alternative and more sophisticated equations to replace $k_{kj}(\text{AE}_{kj} - \text{CL}_{kj})P_{kj}$, therefore, further research would be valuable. The parameters k_{kj} and CL_{kj} are two variables that need to be optimised. We assume k_{kj} and CL_{kj} do not change over the period of one month and are the same for each year. Thus, k_{kj} and CL_{kj} both have 12 values.

The real electricity produced by a hydropower reservoir is related to many factors such as the turbine release water discharge for power generation, the water head, and the coefficient of hydropower station power generation. The equations for hydropower generation have been presented extensively in the literature (e.g., Cheng et al., 2008; Li et al., 2009; Liu et al., 2011), and thus are not listed in the present paper.

2.2.4 Noisy genetic algorithm

In hydropower portfolio optimisation, the future inflow and spot price are uncertain. The noisy genetic algorithm (NGA) is an effective method to determine the optimal values of parameters under uncertainty (Miller and Goldberg, 1996). The NGA has been applied for stochastic reservoir operation (Yun et al., 2010), ground water remediation (Aly and Peralta, 1999) and groundwater sampling network design (Wu et al., 2005) under uncertainty. In this research, NGA is applied to optimise the hydropower portfolio under uncertainty of flows and spot price.

The term *noise* can be defined as any factor that hinders the accurate evaluation of the fitness of a given trial solution. In this study, noise refers to the stochastic nature of the inflows and the power price in the day-ahead market. Most components in the NGA are the same as in a simple genetic algorithm (GA). The main difference between the NGA and GA is in the fitness function. In the NGA, the fitness value cannot be

evaluated accurately because of the variability of monthly inflows. To overcome this difficulty, the fitness value is substituted by the expected fitness value. The details of the NGA can be found in Miller and Goldberg (1996) and Yun et al. (2010).

3 Study site

The Wangkuai Reservoir is a key hydraulic facility in the Hai River basin of China. The present effective storage capacity of the Wangkuai Reservoir is $6.52 \times 10^8 \text{ m}^3$, and the dead storage capacity is $0.88 \times 10^8 \text{ m}^3$. The catchment area of the reservoir is 3770 km^2 . The installed hydropower generation capacity of the Wangkuai Reservoir is 21.5 MW. In this research, we focus on the hydropower generation function of the Wangkuai Reservoir. The inflow data from 1971 to 1993 and the physical characteristics are used to simulate hydropower generation and optimise the hydropower portfolio. The producer considered in this paper is a price taker. The hydropower price in the day-ahead market is shown in Table 1 (Liu et al., 2009; Liu, 2009). The bilateral contract price between the Wangkuai Reservoir and the grid company is $0.36 \text{ RMB kWh}^{-1}$ (Hebei Province Municipal Price Bureau, HPMPB, 2009).

In this research, we consider two e-flow provision strategies. In the first e-flow strategy, only the minimum e-flows are sustained. This strategy is most commonly used in real-world e-flow provisions. In the second e-flow strategy, in addition to the minimum e-flows, occasional high-flow (flows falling above the 75th percentile of all flows) releases are required to sustain the ecological functions related to high flows. In this research, we also assume for demonstration that after three high-flow events have occurred in a season, no further high flows are released, following the research by Vogel et al. (2007).

4 Results

Matlab 6.5 was used to apply NGA to determine the optimal hydropower portfolio. The generation size and evolution times were set at 600 and 1000, respectively. According to the Tennant method (Tennant, 1976), for the dry season (November–April), the seasonal base flow (10% average daily flow) was $1.8 \text{ m}^3 \text{ s}^{-1}$ and for the wet season (May–October), the seasonal base flow (30% average daily flow) was $5.4 \text{ m}^3 \text{ s}^{-1}$. The threshold for the degree of flow regime alteration is set at 0.67, the upper value for moderate alteration of the flow regime (Richter et al., 1996, 1997, 1998).

The optimised parameters are listed in Tables 2 and 3. These tables show that, during five of the six months in the wet season, the contract load under the second e-flow provision strategy is higher than the contract load under the first strategy because, under the second e-flow strategy, the reservoir is required to maintain several high flow pulses. The releases of greater flows required by the second e-flow strategy make higher contract loads reasonable. In addition, most (9 of 12) of the values for parameter k under the first e-flow strategy are higher than the values of parameter k under the second e-flow strategy, indicating that more water will be released to produce hydropower for the day-ahead market under the first e-flow strategy than under the second strategy.

The optimised mean annual revenues are 8.72×10^6 RMB and 7.55×10^6 RMB under the two e-flow provision strategies. The mean annual revenue under the second strategy is lower than the mean annual revenue under the first strategy, possibly because the extra water releases to maintain the high flows under the second e-flow strategy increase the proportion of electricity assigned in the contract market, reducing the proportion of electricity assigned in the spot market, which sometimes has higher prices than the contract price. Thus, the extra requirement to sustain high flows for river ecosystem protection potentially reduces the profits from hydropower generation.

5 Discussion

5.1 The influence and significance of incorporating environmental policies in portfolio management

In previous research on portfolio optimisation, no specific rules were used for e-flow provision. The e-flows are supplied only by the water released for hydropower generation. This strategy is called non e-flow for short. In the following section, we explore the influence of incorporating environmental policies in portfolio management by comparing revenue and flow regime alteration under the three e-flow strategies (i.e., the non e-flow strategy and the two strategies established in the study site section), possibly helping to test the significance of incorporating environmental policies in portfolio optimisation.

We first determine the maximum mean annual revenue (without the constraint of the threshold for flow regime alteration degree) and corresponding degree of flow regime alteration under the three e-flow strategies. Under the three strategies, the maximum revenue and the corresponding degree of alteration are 12.38×10^6 RMB and 0.82 (non e-flow strategy), 10.27×10^6 RMB and 0.75 (strategy 1), and 9.37×10^6 RMB and 0.68 (strategy 2). In comparison with the maximum annual revenue under the e-flow strategies 1 and 2 (10.27×10^6 and 9.37×10^6 RMB), the non e-flow portfolio optimisation method achieves higher revenue. However, the degree of flow regime alteration corresponding to this high revenue is 0.82, obviously greater than the degree of alteration under the first and second e-flow provision strategies (0.75 and 0.68). Thus, although the non e-flow portfolio optimisation method could yield higher revenue, it would come at the cost of degradation of the river ecosystem. To avoid severe degradation of riverine ecosystems, incorporation of an e-flow provision strategy into the hydropower portfolio optimisation process is necessary, at least with regard to sustaining the minimum e-flows.

The minimum degrees of flow regime alteration are also determined under the three e-flow strategies. The lowest degrees of alteration under the non and the first e-flow

Interactive Discussion

strategies are the same (0.31) because under the non e-flow strategy, the releases are also greater than the minimum e-flows in each month to achieve the minimum degree of flow regime alteration, and the contract load and k are the same under the two e-flow strategies. Thus, if reducing the degree of flow regime alteration is taken as the key objective, it is not necessary to incorporate the minimum e-flow requirement as a constraint. The degree of flow regime alteration (0.21, corresponding to the revenue of 3.59×10^6 RMB) under the second e-flow strategy is obviously lower than the degree of flow regime alteration under the other two strategies, demonstrating the significance of assigning some high flows in the e-flow provision rules.

We further determine the minimum degree of flow regime alteration corresponding to the mean annual revenues of 9.37×10^6 RMB (the maximum mean annual revenue that all the three strategies can achieve), 3.89×10^6 RMB (the minimum mean annual revenue that all three strategies can achieve), and 6.63×10^6 RMB (the median revenue that all the three strategies can achieve) for the three e-flow provision strategies. The results are listed in Table 4. Table 4 shows that the degree of flow regime alteration under the non e-flow strategy is always greater than the degree of flow regime alteration under the other two strategies, and the degree of alteration under the second strategy is always less than the degree of alteration under the other two strategies. Thus, the incorporation of a specific e-flow strategy can result in a lower degree of flow regime alteration with the same annual revenue. It further demonstrates the importance to incorporate e-flow strategy into portfolio optimization process for a specified revenue.

5.2 Determining the optimal e-flow provision strategy

Different e-flow provision strategies will result in different mean annual revenues and different degrees of flow regime alteration. The basic principles for e-flow strategy determination can be stated as follows: if the planned revenue can be achieved by several e-flow strategies, the strategy that results in the lowest flow regime alteration is chosen. If the planned degree of flow regime alteration can be achieved by several e-flow strategies, the strategy that results in the highest revenue should be chosen. On

the basis of these principles, we have drawn the curves for mean annual revenue and minimum degree of alteration under the three e-flow provision strategies. The results are shown in Fig. 1.

On the basis of Fig. 1, the mean annual revenue can be divided into three types of intervals, i.e., exclusive intervals (the intervals that only one e-flow strategy can achieve), shared intervals (the intervals that more than one type of e-flow strategy can achieve), and unachievable intervals (the intervals that no available e-flow strategy can achieve). From the planned revenue, we can easily know which intervals the planned revenue is within. If the planned revenue is within an exclusive interval, the e-flow strategy corresponding to that interval can be applied in the portfolio optimisation process. If the planned revenue is within a shared interval, the e-flow strategy that results in the lowest degree of flow regime alteration should be applied to maintain the riverine ecosystem. For planned revenue within an unachievable interval, if the revenue is above the highest value for all e-flow strategies, no strategy can achieve a low degree of flow regime alteration, and the revenue can possibly be achieved by participating in other electricity markets. If the revenue is below the lowest value for all e-flow strategies, which indicates a very favourable attitude toward river protection, the hydropower producers can apply a more favourable e-flow strategy that could result in a lower degree of flow regime alteration.

On the basis of Fig. 1, the degree of flow regime alteration can also be divided into three categories, i.e., exclusive intervals (an interval that only one e-flow strategy can achieve), shared intervals (intervals that more than one type of e-flow strategy can achieve), and unachievable intervals (intervals that no e-flow strategy can achieve). Like the procedure for the mean annual revenue discussed above, the most suitable e-flow provision strategy for a planned degree of flow regime alteration can be determined. If the planned degree of flow regime alteration is within an exclusive interval, the e-flow strategy corresponding to that interval can be applied in the portfolio optimisation process. If the planned degree of alteration is within a shared interval, the e-flow strategy that results in the highest revenue should be adopted. If the planned

degree of alteration is within an unachievable interval and is below the lowest value for all strategies, the hydropower producers should develop and apply more favourable e-flow strategies.

Choosing an e-flow provision strategy is a process of compromising between hydropower producers and river protectors. The river protectors usually have the authority to ask the hydropower producers to obey some basic rules for riverine ecosystem protection, such as a minimum e-flow release. If the river protectors would like to improve the health of the riverine ecosystem by changing the hydropower generation scheme, a more ecologically favourable e-flow provision strategy should become a legal requirement, or ecological compensation should be given to the hydropower producers. On the basis of Fig. 1, we can make a preliminary assessment of the compensation criteria. For example, if the present legally required e-flow rules are to sustain the minimum e-flows and the river protectors want hydropower producers to use the second e-flow strategy, the compensation criteria should be approximately 0.9×10^6 RMB, i.e., the difference between the maximum possible mean annual revenue under the first (10.27×10^6 RMB) and second e-flow strategies (9.37×10^6 RMB).

6 Conclusions

Previous research on hydropower portfolio optimisation focused mainly on the maximisation of profits but neglected the requirement of riverine ecosystem protection. This research seeks mainly to remind hydropower producers of the requirement for river protection when they design portfolios and help make a shift of portfolio optimisation from economically oriented to ecologically friendly. In this study, a new framework has been developed to determine optimal hydropower portfolios considering both economic benefits and ecological needs. Within this framework, the degree of flow regime alteration is adopted as a constraint for e-flow provision and riverine ecosystem protection, and the maximisation of mean annual revenue is set as the optimisation objective. The following objectives are achieved.

- For the same planned mean annual revenue, the alteration in flow regime is lower for portfolios with e-flow provision strategies than for the portfolio without an e-flow strategy. A lower degree of alteration indicates a lower degree of river degradation. If a planned mean annual revenue can be achieved under either an e-flow strategy or a non-e-flow strategy, incorporating the e-flow strategy into the portfolio optimisation process is both economically and ecologically beneficial.
- The proper e-flow provision strategy depends on the planned revenue and the planned degree of flow regime alteration. If the planned revenue can be achieved by several e-flow strategies, the strategy that results in the lowest flow regime alteration should be chosen. If the planned degree of flow regime alteration can be achieved by several e-flow strategies, the strategy that results in the highest revenue should be chosen.

In the case study of Wangkuai Reservoir, the contract and day-ahead markets are participated in according to the planned needs of the reservoir. In future research on portfolio optimisation in other cases that account for both riverine ecosystem and producer needs, the real-time balancing market may also be participated in according to the planning needs of these specific cases and the risk preferences of the hydropower producers. In these cases, the proposed framework for portfolio optimisation can also be used. The difficulties are the precise prediction of hydropower price in the real-time balancing market and the assessment of hydrological alteration at hourly time steps, which require further research.

Table 4. Minimum degree of flow regime alteration under different planned revenues and different e-flow provision strategies.

Revenue	9.37×10^6 RMB	6.63×10^6 RMB	3.89×10^6 RMB
Non e-flow strategy	0.78	0.69	0.36
E-flow strategy 1	0.72	0.61	0.31
E-flow strategy 2	0.68	0.57	0.28

Portfolio optimisation for hydropower producers

X. A. Yin et al.

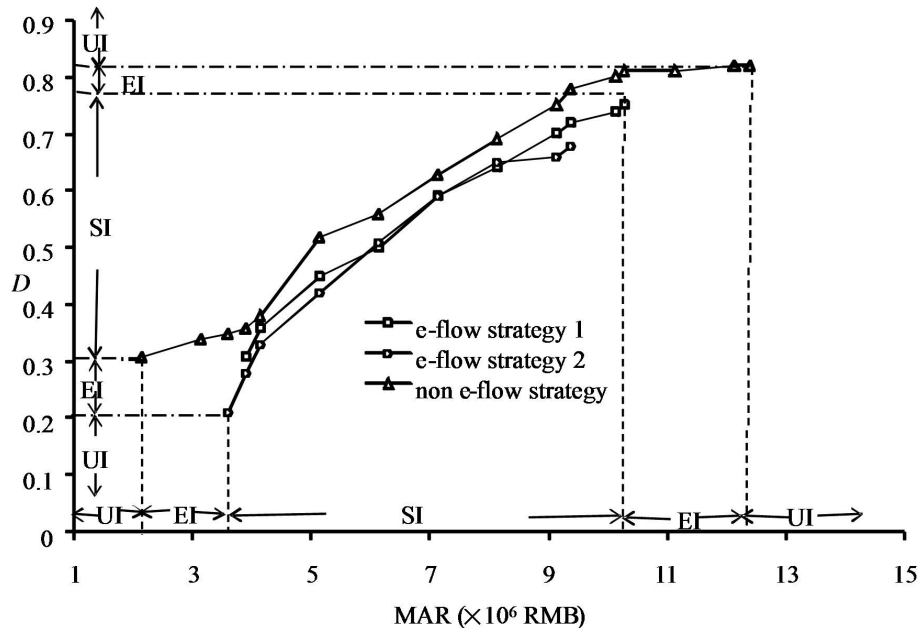

Fig. 1. Minimum degree of flow regime alteration for different planned mean revenues under three e-flow provision strategies. D is the degree of flow regime alteration; MAR is the mean annual revenue; UI is the unachievable interval; EI is the exclusive interval; SI is the shared interval.
