Abstract

- One of the main challenges in the application of coupled or integrated hydrologic models, is
- specifying a catchment's initial conditions in terms of soil moisture and depth to water table
- 20 (DTWT) distributions. One approach to reduce uncertainty in model initialization is to run the
- 21 model recursively using either a single or multiple years of forcing data until the system
- 22 equilibrates with respect to state and diagnostic variables. However, such "spin-up"
- approaches often require many years of simulations, making them computationally intensive.
- In this study, a new hybrid approach was developed to reduce the computational burden of the
- 25 spin-up procedure by using a combination of model simulations and an empirical DTWT
- 26 function. The methodology is examined across two distinct catchments located in a temperate
- 27 region of Denmark and a semi-arid region of Australia. Our results illustrate that the hybrid
- 28 approach reduced the spin-up period required for an integrated groundwater-surface water-
- 29 land surface model (ParFlow.CLM) by up to 50%. To generalize results to different climate

and catchment conditions, we outline a methodology that is applicable to other coupled or

integrated modelling frameworks when initialization from an equilibrium state is required.

2

1 Introduction

- 5 The issue of model initialization is important for hydrologic simulation and prediction, as the
- 6 initial state has a major impact on a catchment's modelled response (Berthet et al., 2009). In
- 7 coupled or integrated surface-subsurface models, uncertainty in a catchment antecedent
- 8 condition is of particular importance as both the soil moisture distribution and depth to water
- 9 table (DTWT) need to be specified at the start of a simulation (Ivanov et al., 2004; Noto et al.,
- 10 2008).

11

- 12 Since information on the spatial pattern of water table and soil moisture distributions is
- generally unavailable, various approaches have been developed to determine the initial
- 14 DTWT variation. Sivapalan et al. (1987) used a topography-soil index to map the spatial
- distribution of initial DTWT. In another approach, Troch et al. (1993) used recession flow
- analysis to estimate the effective water table height of a catchment. Regardless of the choice
- of initial DTWT, the uncertainty involved is such that a period of spin-up is always required
- 18 (Cloke et al., 2003), as the applied atmospheric forcing is often inconsistent with the
- 19 hydrodynamic initialization of the catchment inferred from limited observations (Ajami et al.,
- 20 2014).

- 22 The two most common initialization approaches in coupled or integrated distributed
- 23 hydrologic models are: (1) initial depth to water table is specified at a certain uniform depth
- below the land surface (Kollet and Maxwell, 2008) and the impact of initialization is reduced
- 25 through recursive simulations over either a single or multiple years of forcing data, until
- equilibrium conditions are reached, which are usually related to spin-up criteria based on
- changes in groundwater heads (Refsgaard, 1997) or changes in water and energy balances
- 28 (Kollet and Maxwell, 2008); or (2) the model is initialized from a fully saturated condition
- and simulations are continued until modelled baseflow matches the observations (Jones et al.,
- 30 2008). Equilibrium based initializations have been utilized previously for exploring land
- 31 surface-groundwater coupling (Kollet and Maxwell, 2008) and assessing the impact of

1 climate change on groundwater-land surface interactions using an integrated hydrologic

model (Ferguson and Maxwell, 2010).

Results of a ParFlow.CLM spin-up study for a catchment in Denmark showed that at least 20 years of recursive simulations were required to reach equilibrium in subsurface storages, defined as occurring when percent changes in monthly unsaturated and saturated zone storages were less than 0.1% and 0.01% respectively (Ajami et al., 2014). For reference, 20 years of spin-up simulations required 20,000 service units (a service unit is equivalent to 1 hour of time used by one processor) on a high performance parallel computing cluster: equivalent to over 26 days of computation using 32 processors. The challenge lies in designing methodologies to reduce spin-up period in computationally intensive integrated hydrologic models such as ParFlow.CLM (Ashby and Falgout, 1996; Jones and Woodward, 2001; Kollet and Maxwell, 2006) when initialization from equilibrium states is required for transient simulations. In integrated hydrologic models like ParFlow, numerical solution of the Richards equation in 3D increases computational time (Kim et al., 1997; Maxwell et al., 2014) in comparison to approaches that use a 1D Richards equation for the vadoze zone and a 2D groundwater flow formulation for simulating subsurface flow.

The objective of the current study is to develop a *hybrid* spin-up approach that significantly reduces the number of years of spin-up required for model state equilibrium. The equilibrium based initialization represents a correct initial state for catchments in which the land use does not change over time and the inter-annual variability of atmospheric forcing is very small: assumptions that are common to most simulation frameworks. This technical note provides a method for improving the efficiency of this commonly used initialization technique. The performance of the proposed approach in reducing the spin-up period for a catchment scale application of the ParFlow.CLM model is evaluated against the standard continuous recursive simulation approach that is commonly applied for land surface model spin-up, and referred to here as the baseline spin-up approach.

2 Data and methodology

- 2 The hybrid approach consists of three main stages: a two-stage model simulation step and an
- 3 intermediate state-updating step using the DTWT function. Figure 1 illustrates this hybrid
- 4 spin-up approach. The utility of the proposed scheme is compared against the equilibrated
- 5 initial condition for a sub-catchment of the Skjern River basin in Denmark, using the
- 6 ParFlow.CLM model as developed by Ajami et al. (2014) that employed a traditional baseline
- 7 spin-up approach. An additional assessment of the hybrid approach in reducing the spin-up
- 8 period is undertaken by developing ParFlow.CLM for a semi-arid catchment in Australia.

9

10

1

2.1 Overview of the ParFlow.CLM model

- ParFlow is a 3D variably saturated groundwater flow model that solves the mixed form of the
- 12 three-dimensional Richards equation for the subsurface (Ashby and Falgout, 1996; Jones and
- Woodward, 2001; Maxwell et al., 2014). ParFlow has a fully integrated overland flow
- simulator (Kollet and Maxwell, 2006) and performs routing of the ponded water on the land
- surface via the kinematic wave equation. The Common Land Model (CLM 3.0) (Dai et al.,
- 16 2003) is integrated into ParFlow to simulate water and energy fluxes at the land surface
- 17 (Maxwell and Miller, 2005; Kollet and Maxwell, 2008). ParFlow.CLM versions 605 and 653
- were used for the Skjern River and Baldry simulations respectively, which are described
- below. The terrain following grid of Maxwell (2013) is not implemented in these modelling
- set-ups.

21

22

2.1.1 Sub-catchment of the Skjern River Basin, Denmark

- 23 The sub-catchment of the Skjern River basin in western Denmark has an area of 208 km²
- 24 (Fig. 2) and is characterized by mild topography and a temperate climate (Jensen and
- 25 Illangasekare, 2011). Agricultural land is the dominant cover type (78%), with the remainder
- of the catchment area covered by evergreen needle leaf forest.

- 28 To reduce the impact of boundary conditions on catchment scale fluxes, the computational
- domain is extended beyond the delineated catchment boundary. As such, the ParFlow.CLM

- 1 model domain covered a 28 km by 20 km area that encompasses the Skjern River sub-
- 2 catchment (Fig. 2). The modelling grid had a horizontal resolution of 500 m and a vertical
- 3 discretization of 0.5 m. Catchment topography was determined via a 500 m digital elevation
- 4 model (DEM) and the bottom elevation of the domain was a uniform -75 m, resulting in a 56
- $5 \times 40 \times 406$ dimension grid.

- 7 At the land surface, the ParFlow free-surface overland flow boundary condition was assigned.
- 8 A no-flow boundary condition was specified for the sides and bottom boundary. Spatially
- 9 uniform hourly atmospheric forcing (air temperature, wind speed, specific humidity, air
- 10 pressure, precipitation, incoming shortwave and downward longwave radiation) for the year
- 11 2003 was used for spin-up. In 2003, annual precipitation was 801.6 mm and minimum and
- maximum daily air temperature were 261.2 K and 295.2 K respectively. Initial DTWT was
- assigned uniformly at 3m below the land surface. Ground surface temperature was set to the
- mean annual air temperature (281 K) at the start of a simulation. Prescribed subsurface
- hydraulic parameters include the saturated hydraulic conductivity (0.3 m h⁻¹), porosity (0.39),
- van Genuchten parameters (α =1.5 m⁻¹ and n =2), and relative residual saturation (0.1).

17

18

2.1.2 Baldry sub-catchment, Australia

- 19 The Baldry sub-catchment, located in central west New South Wales of Australia, has an area
- of 1.9 km² with an elevation range from 443 m to 500 m inside the catchment boundary (Fig.
- 21 2). For the spin-up experiment, the catchment land cover was assumed to be evergreen
- broadleaf forest representing eucalyptus plantation.

- 24 The ParFlow.CLM model of the site was set up over a 2.9 by 2.9 km area encompassing the
- 25 Baldry sub-catchment (Fig. 2) in order to reduce the impact of boundary conditions on
- 26 catchment scale fluxes. Catchment topography was represented using a 60 m pre-processed
- 27 DEM. The bottom elevation of the modelling grid was a uniform 400 m resulting in a
- subsurface thickness of 43 to 101 m across the computational domain. The modelling grid had
- a 60 m resolution in the x and y directions and a vertical discretization of 0.5 m, resulting in a
- $48 \times 48 \times 203$ dimension grid.

As for the Skjern River implementation, the ParFlow free-surface overland flow boundary condition was assigned at the land surface. A no-flow boundary condition was specified for the lateral and bottom boundaries of the computational domain (gray domain in Fig. 2). Hourly forcing data for the year 2004 were obtained from a weather station at the site. For the hourly downward longwave radiation, the Modern Era Retrospective Analysis for Research and Applications (MERRA) reanalyses data interpolated to $0.25^{\circ} \times 0.25^{\circ}$ resolution were used (Decker et al., 2012). In 2004, annual precipitation was 674.8 mm, and minimum and maximum daily air temperature were 277 K and 305.5 K respectively. Prescribed subsurface hydraulic parameters include the saturated hydraulic conductivity (0.18 m h⁻¹), porosity (0.25), van Genuchten parameters (α =1.5 m⁻¹ and n =2), and relative residual saturation (0.1). The model was initialized with a uniform DTWT of 2m below the land surface. Ground surface temperature was set to mean annual air temperature 288.1 [K].

2.2 Development of empirical DTWT functions for model re-initialization

Analysis of ParFlow.CLM spin-up behavior using the baseline spin-up approach for the sub-catchment of the Skjern River identified that percentage changes in subsurface storages and DTWT had the form of an exponential decay for a model initialized from a uniform 3 m DTWT (Ajami et al., 2014). Due to spatial adjustment of the water table during the spin-up, groundwater levels declined near the catchment divide and reached the land surface along the channel network causing an overall decline in mean annual DTWT relative to the initial condition. Using the functional relationships between the number of simulation years and the percentage change of a variable, Ajami et al. (2014) produced a series of spin-up functions based on 16 years of initial ParFlow.CLM simulations. These spin-up functions were used to predict the number of years required until the model equilibrated, based on a predefined threshold i.e. 0.1% or 0.01% change for a given variable. Sensitivity of spin-up functions across multiple criteria and variables showed that the estimated spin-up period based on mean annual DTWT were more stable when compared to other spin-up criteria, such as changes in the mean DTWT for the last day of recursive simulations (Ajami et al., 2014).

The inverse of a spin-up function for DTWT predicts percent changes in DTWT as a function of simulation years, which hereinafter is referred to as the empirical DTWT function. In this

study, we examined the capabilities of empirical DTWT functions as a means for updating DTWT and hence groundwater storage after just a few initial ParFlow.CLM spin-up simulations. The expectation is that this state updating should reduce the total number of spin-up years of simulation, substantially reducing the computational burden. To do this, a series of spin-up simulations were performed based on an arbitrary initial state (DTWT of 3 m below the land surface for the Skjern River sub-catchment as in Ajami et al. (2014)), in order to identify the minimum number of data points required to develop an empirical DTWT function (stage 1 of model simulation).

Due to the anticipated large changes in mean annual DTWT values between the first and second year of the spin-up simulation, the first year of data is removed from the analysis. As a minimum of four data points (i.e. 6 cycles of ParFlow.CLM simulations) are required to fit a double exponential function, six years of spin-up simulations are performed using a single year of forcing data. To assess the sensitivity of DTWT functions to the number of ParFlow.CLM cycles, various exponential functions with single (Eq. 1) or double exponential (Eq. 2) terms are fit to the ParFlow.CLM cycles 2 to 6:

$$17 y = a \exp(bx) (1)$$

$$18 y = a \exp(bx) + c \exp(dx) (2)$$

where *y* is the percentage change in DTWT, *x* is the number of simulation years, and *a*, *b*, *c*, *d* are the fitting parameters. Coefficient of determination and root mean square error are used as goodness of fit measures. Further, the performances of global versus local scales DTWT functions are evaluated. In this analysis, a domain based global DTWT function is based on percent changes in mean annual DTWT values from all the grid cells inside the computational domain, while a catchment based DTWT function is based on the grid cells inside the catchment boundary. Local DTWT functions are developed for every grid cell based on percent changes in mean annual DTWT values at that grid cell.

The empirical DTWT functions calculated above estimate percentage changes in mean annual DTWT as a function of simulation year. To predict spatially distributed mean annual DTWT from a global DTWT function, the mean annual DTWT from the final cycle of the ParFlow.CLM spin-up simulation for every grid cell is used as the initial value to successively estimate DTWT distributions as a function of simulation year. These DTWT

distributions are based on the predicted percent change values from the global DTWT

2 function. Sensitivity of DTWT functions to the number of ParFlow.CLM cycles was also

3 examined by developing a number of DTWT functions using data from 2 to 6 cycles of

4 ParFlow.CLM. To assess the performance of these DTWT functions, estimated mean annual

5 DTWT from the DTWT functions were compared against mean annual DTWT from the

6 ParFlow.CLM model of Ajami et al. (2014) that had been spun-up for 20 years. Root mean

7 square difference (RMSD), mean absolute error (MAE) and bias were computed to find the

8 best performing DTWT function. These objective functions are calculated as follows:

9

10
$$RMSD = \sqrt{\frac{1}{N} \sum_{i=1}^{N} (B_i - M_i)^2}$$
 (3)

11
$$MAE = \frac{1}{N} \sum_{i=1}^{N} |B_i - M_i|$$
 (4)

12
$$\%bias = \frac{\sum_{i=1}^{N} (B_i - M_i)}{\sum_{i=1}^{N} (B_i)} \times 100$$
 (5)

where N is the number of grid cells in the domain, B is the mean annual DTWT from the

baseline simulation of Ajami et al. (2014) for every grid cell, and M is the estimated mean

annual DTWT at a grid cell obtained from a DTWT function.

16

14

17 In the state updating stage, the best performing empirical DTWT function (a double

18 exponential DTWT function as discussed in section 3.1) was used to estimate percentage

19 changes in DTWT as a function of simulation years, until percentage changes reached the

20 0.01% threshold. Using the percent change values and mean annual DTWT distribution from

the sixth cycle of the ParFlow.CLM spin-up simulation, spatially distributed DTWT was

predicted for the entire computational domain.

23

25

26

27

22

21

24 In the second stage of model simulations, the ParFlow.CLM was re-initialized using newly

estimated DTWT values from a double exponential DTWT function, and spin-up simulations

were continued until equilibration based on subsurface storage spin-up criteria. The second

stage of spin-up simulations was necessary to ensure equilibrium after re-initialization,

28 especially for the unsaturated zone storage.

One issue with the re-initialization of DTWT using the DTWT function is that the distribution of soil moisture above the water table cannot be estimated. Here, we considered two approaches to define pressure head distribution above the water table: (1) implementing the commonly used hydrostatic equilibrium assumption, where pressure head at the water table was linearly decreased as a function of elevation head towards the land surface; and (2) adjusting the pressure head distribution of the unsaturated zone from the last day of the sixth cycle of ParFlow.CLM spin-up simulations based on new DTWT values from the DTWT function. In the adjusted pressure head approach, the hydrostatic equilibrium assumption is used in regions between the new DTWT and the initial DTWT. The ParFlow.CLM pressure head distribution is adjusted to begin at the new pressure head from the initial WT such that the vertical profile is maintained (Fig. 3). This adjustment may represent a lack of consistency in the proposed approach as the DTWT function estimates mean annual DTWT, while pressure head adjustments in the unsaturated zone are taken from the last day of the sixth cycle of ParFlow.CLM. While it is possible to use DTWT values from the last day of simulations to develop a DTWT function, estimated DTWT values from such a function exhibit larger variability and result in a larger bias. For the Skjern River sub-catchment, percent bias between the estimated DTWT values from the DTWT functions and the baseline simulation of Ajami et al. (2014) were -4% and -1.6% for the DTWT functions based on the last day and mean annual DTWT values respectively.

2.3. Evaluating the hybrid spin-up approach

The performance of the hybrid spin-up approach in reducing the spin-up period is evaluated by developing a ParFlow.CLM model for the Baldry sub-catchment. The baseline spin-up simulations were performed using spatially uniform, hourly forcing data for the year 2004 and an arbitrary initial state (DTWT of 2 m below the land surface). The equilibrium condition was achieved when percent changes in catchment averaged monthly groundwater storages were below 0.1% threshold level. Similar to the Skjern River sub-catchment, sensitivity of empirical DTWT functions to the number of ParFlow.CLM cycles (i.e. cycles 2 to 6) are explored and assessed against the baseline spin-up simulations of Baldry sub-catchment. In the next step, the hybrid spin-up approach outlined in section 2.2 was implemented to reinitialize the ParFlow.CLM using a domain based double exponential DTWT function to estimate spatially distributed DTWT and the adjusted pressure head distribution approach

above the water table. Recursive simulations after re-initialization continued until equilibrium

2 condition was achieved.

3 Results

3.1 Performance of empirical DTWT functions in predicting DTWT-Skjern River sub-catchment

Optimum parameter values for single and double exponential DTWT functions were obtained using nonlinear least squares method. Performance of the single and double exponential DTWT functions in predicting 14 years of DTWT were compared against ParFlow.CLM baseline spin-up simulations (years 7 through 20) of Ajami et al. (2014) to find the optimum empirical DTWT function for the Skjern River sub-catchment. Post-simulation analysis indicates that global DTWT functions based on domain or catchment averaged percentage change values are better predictors of DTWT response compared to local DTWT functions developed for every grid cell. Instability of local DTWT functions occurs in grid cells where percent changes in DTWT oscillate between positive and negative values through initial spin-up simulations. Spatial distribution of these grid cells are shown in Fig S1.

Calculated RMSD and percent bias relative to the baseline spin-up simulations indicate that global double exponential functions using ParFlow.CLM spin-up simulations 2 to 6 provide a better fit compared to various single exponential functions obtained from different spin-up simulation years (e.g. 2 to 3, 2 to 4, etc.). Because the first six cycles of ParFlow.CLM simulations were the same between the baseline spin-up simulations and DTWT distributions from DTWT functions presented in Fig 4, comparisons were made with simulations 7 to 20 of the baseline spin-up approach of Ajami et al. (2014).

As can be seen from Fig. 4a, the mean annual DTWT over the domain derived from the single exponential functions (fitted to percentage change data from simulations 2 to 6) under-predict the baseline spin-up simulations, due to their consistent small underestimates in comparison to double exponential functions fitted to the same data points. Only for the mean absolute error (MAE) calculated at each pixel do single exponential functions based on simulations 2 to 6 perform slightly better and produce smaller errors on average than the double exponential

functions (Fig. 4b). It should be noted that the percent bias in mean annual DTWT for simulation cycle 20 is -1.6% for the domain based double exponential function and -6.2% for the single exponential function, with both functions derived from simulation cycles 2 to 6. Therefore, single exponential functions are not further examined in re-initializations of the DTWT. In terms of mean DTWT across the domain (Fig. 4a), the catchment delineated double exponential DTWT function provides a better prediction and the smallest mean bias when compared to the function based on the entire model domain. However, Figure 4b indicates that the mean absolute error values are slightly smaller for the domain based double exponential function. The higher MAE of the catchment based double exponential function is a result of slightly more regions with over and underestimated DTWT values that contribute to a good overall mean DTWT (Fig. 4a), but contain more errors spatially compared to the domain based double exponential function.

To investigate this result further, three empirical semi-variograms were generated. As the impact of an east-west spatial trend in the mean annual DTWT values was evident in the semi-variograms, the trend should first be removed from the mean annual DTWT values. To remove the trend, a plane was fitted to the observed mean annual DTWT values, with an equation of the form:

$$19 z = ax + by + c (6)$$

where *a*, *b* and *c* are fitted coefficients, x and y are the coordinates of every grid cell, and z is the mean annual DTWT. Residuals are computed by subtracting the estimated mean annual DTWT from Equation 6 from the observed mean annual DTWT values. Finally, the semi-variogram of the residuals as a function of distance is calculated. The semi-variance is a measure of spatial variance and presents average (dis-)similarity between data pairs at a given distance. Investigating the empirical semi-variograms of mean annual DTWT values (Fig. 4c) indicates that the domain based double DTWT function is a better predictor of mean annual DTWT, because the spatial structure of DTWT is sufficiently reproduced by the domain based function, and the catchment based function has a higher variance compared to the baseline simulations. Therefore, it is recommended to use the domain based DTWT function, as it contains data from high elevation regions on the eastern side of the domain that contribute to topographically driven flow and equilibrates slower than in other regions (Ajami et al., 2014). In summary, double exponential functions are chosen as they have less bias

- compared to single exponential functions and there is very little difference in terms of MAE
- 2 amongst predictions. The choice is further supported by the RMSD and semi-variograms.

3.2 Impact of unsaturated zone re-initialization on ParFlow.CLM spin-up

Impacts of re-initializing the unsaturated zone using the hydrostatic equilibrium versus adjusted vertical pressure distribution on the spin-up period were also explored using the ParFlow.CLM simulations of the Skjern River sub-catchment. As can be seen from Fig. 3, the difference between the two initialization methods is more pronounced in areas of deep water table, where hydrostatic pressure head distribution results in a drier unsaturated zone compared to adjusted pressure head distribution. Results indicate that after re-initialization, the system equilibrated after 6 additional years of spin-up simulation when using the hydrostatic equilibrium option. With the adjusted pressure head distribution option, only 4 additional years of spin-up simulation were required. Therefore, depending on the pressure head distribution above the water table, either 10 or 12 years of ParFlow.CLM simulations were sufficient to ensure subsurface storage equilibrium, reducing the spin-up time by 40% or

50%, compared to the baseline spin-up approach.

The improved performance of the adjusted pressure distribution is related to the fact that information about soil moisture distribution from stage 1 of spin-up simulations is preserved in this approach. In both initialization approaches, the groundwater storage was equilibrated at the 0.01% threshold level, based on changes in mean monthly values. In comparison to the baseline spin-up approach, both groundwater and unsaturated zone storages of the equilibrium year are closely reproduced by the adjusted pressure head distribution option (Fig. 5). While in both re-initializations, DTWT and subsequently groundwater storage volume were the same at the start of the simulations, unsaturated zone storage of the hydrostatic equilibrium option was drier than the adjusted pressure head option. Additional ParFlow.CLM simulations after re-initialization ensured equilibrium of groundwater storage. As can be seen from Fig. 6a, hydrostatic re-initialization results in a deeper WT at equilibrium (simulation 12) relative to the baseline equilibrium year (simulation 20). Higher DTWT values of the hydrostatic option at equilibrium correspond to smaller groundwater storage and subsequently larger unsaturated zone storage compared to the baseline spin-up (Fig. 5). It should be noted that in

ParFlow.CLM, groundwater and unsaturated zone storages are not explicitly determined by fixed size compartments and the extent of an unsaturated zone is determined by the location of the water table. Percent changes in mean annual unsaturated zone storage between the last two years of recursive simulations were 0.1% for the hydrostatic equilibrium and 0.3% for the adjusted pressure head re-initializations, indicating unsaturated zone equilibrium at different threshold levels.

Changes in annual water balance after re-initialization were also compared against the baseline spin-up approach of Ajami et al. (2014). While changes in annual evapotranspiration were approximately 1 mm between the two spin-up approaches (annual baseline evapotranspiration of 447.3 mm), percent bias in annual discharge against observations decreased by about 2% compared to the baseline approach (Table 1). In the hybrid approach, changes in groundwater storage were positive, because after re-initialization, DTWT decreased as simulations proceed and the system reached equilibrium (Fig. 5). At equilibrium, differences in simulated DTWT from the last day of the ParFlow.CLM simulations after re-initializations (hydrostatic equilibrium and adjusted pressure head distribution) and the baseline spin-up approach varied by up to 2 m inside the catchment boundary (Fig. 6), although most areas were within 0.5m. Differences were more pronounced in areas of higher elevation in the catchment. Figure 6 shows that the hydrostatic equilibrium pressure head adjustment leads to a clear bias with consistent over estimation of the DTWT, while the adjusted vertical pressure distribution produces a distribution of pressure head errors centred on the expected value.

3.3 Evaluation of the hybrid spin-up approach over the Baldry sub-catchment

Similar to the Skjern River sub-catchment, percent changes in monthly groundwater storages were used to assess the equilibrium condition. However, for the Baldry sub-catchment, a threshold level of 0.1% was chosen as the convergence criterion. Results indicated that 28 years of recursive simulations were required until the model equilibrated based on monthly groundwater storage changes. For reference, 28 years of baseline spin-up simulations for Baldry required 37,000 service units, which is equivalent to 24 days of computation using 64 processors of a high performance computing cluster.

To obtain optimum parameter values for single and double exponential DTWT functions nonlinear least squares method is used. Similar to the Skjern River sub-catchment, a double exponential DTWT function using simulations 2 to 6 resulted in WT distributions with the smallest RMSD and percent bias, relative to the baseline spin-up simulations. For Baldry, a domain based double exponential function had the closest mean over the domain (Fig. S2a) and the smallest mean absolute error relative to the baseline simulation (Fig. S2b). However, DTWT semi-variograms showed higher variances in the domain based double exponential function relative to the catchment based function (Fig. S2c). Despite the slight differences in the predictive power of DTWT functions between the two catchments, a double exponential function seems to perform best based on most of the criteria.

To re-initialize the ParFlow.CLM model of the Baldry sub-catchment, the new DTWT distribution obtained from the domain based double exponential function was used. After reinitialization with the adjusted pressure head distribution, only 8 additional simulation years were required until percent changes in monthly groundwater storages reached below the 0.1% level. This result indicates a 50% reduction in the spin-up period of a semi-arid catchment when the hybrid spin-up approach is used.

Comparison of WT distributions from the last day of equilibrium simulations (baseline simulation and the hybrid approach) illustrated differences of up to 1 m (Fig. 7). However, for the majority of cells inside the catchment, differences were less than 0.5 m. Similar to the Skjern River sub-catchment, the largest differences in WT distribution were observed in higher elevation areas in the southern part of the catchment. Lower WT levels in the hybrid spin-up approach resulted in larger unsaturated zone storage compared to the baseline spin-up (Fig. S3). In this semi-arid catchment, no stream flow was generated at the catchment outlet for the equilibrium year. The difference in annual evapotranspiration was only 0.2 mm between the two equilibrium simulations (Table 2).

4 Summary

We present a hybrid approach for reducing the period of spin-up required to reach equilibrium with the integrated hydrological model ParFlow.CLM. In the case of the Skjern River and the

1 Baldry sub-catchments, the simulation period decreased by 50% compared to the baseline

2 spin-up approach when an adjusted pressure head distribution was specified above the water

3 table. Although ParFlow.CLM was used as a modelling platform, the developed methodology

is applicable to other coupled or integrated hydrologic models.

5

4

- 6 A general approach to spin-up should include the following steps: (1) perform six years of
- 7 hydrologic model simulations with DTWT initialized via expert knowledge/informed guess
- 8 (here 2m and 3m below the land surface for the Baldry and Skjern River sub-catchments
- 9 respectively); (2) calculate a global double exponential DTWT function using domain wide
- data and estimate the new DTWT for the desired equilibration level; (3) implement the
- adjusted pressure head approach for the unsaturated zone initialization; and (4) continue spin-
- 12 up simulations until desired equilibration level is reached. Previous efforts in calibrating
- coupled or integrated hydrologic models required a spin-up process after every parameter
- update (Stisen et al., 2011; Weill et al., 2013). Development of a computationally efficient
- spin-up approach will enable this type of systematic calibration of integrated or coupled
- 16 hydrologic models.

17

- 18 Additional experiments across multiple catchments with different climate and subsurface
- 19 heterogeneity and DTWT initializations are required to assess the efficiency of the proposed
- 20 approach in reducing the simulation period to equilibration in a variety of settings. In
- addition, the role of topography and spatially distributed forcing should be further examined.
- 22 Reducing the required spin-up years of coupled or integrated hydrologic models will expand
- 23 their application for hydrological investigations and facilitate the use of these models to
- investigate both real world and theoretical system behavior.

1 Table 1. Skjern River sub-catchment annual water balance for the equilibrium year after the

2 baseline spin-up approach and the hybrid approach using the hydrostatic equilibrium and

adjusted pressure head distribution options above the water table. Annual precipitation is

4 801.6 mm.

Simulation Name	Number of simulations	%bias¹ Q	ET [mm/y]	dS^2 GW^3 [mm]	dS UZ ⁴
ParFlow baseline simulation	20	20.3	447.3	-3.3	-0.2
ParFlow+DTWT function (Hydrostatic equilibrium)	12	18.1	446.8	3.3	-0.7
ParFlow+DTWT function (Adjusted Pressure)	10	18.5	446.3	3	-1.6

^{5 &}lt;sup>1</sup>Percent bias is based on observed discharge at the gauge shown in Fig. 2; ²changes in

⁶ storage; ³groundwater storage; ⁴unsaturated zone storage

- 1 Table 2. Baldry sub-catchment annual water balance for the equilibrium year after the
- 2 baseline spin-up approach and the hybrid approach with the adjusted pressure head
- 3 distribution option above the water table. Annual precipitation is 674.8 mm.

Simulation Name	Number of Simulations	ET [mm/y]	dS ¹ GW ² [mm]	dS UZ ³ [mm]
ParFlow baseline simulation	28	519.2	-12	4.4
ParFlow+DTWT function (Adjusted Pressure)	14	519	-0.2	1.0

^{4 &}lt;sup>1</sup>changes in storage; ²groundwater storage; ³unsaturated zone storage

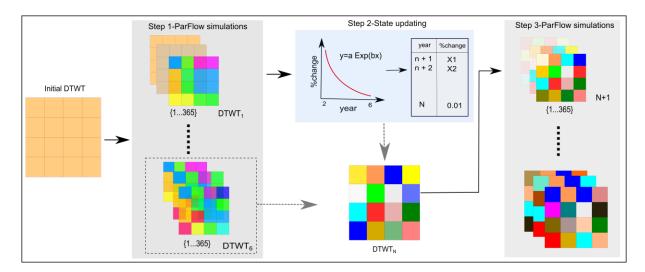

Figure 1. The hybrid spin-up approach consists of three main steps: (1) initial ParFlow.CLM spin-up simulations based an arbitrary DTWT distribution, (2) state updating step by developing a DTWT function based on percent changes in mean annual DTWT in initial spin-up simulations, and (3) stage 2 of ParFlow.CLM spin-up simulations until desired equilibration level is reached.

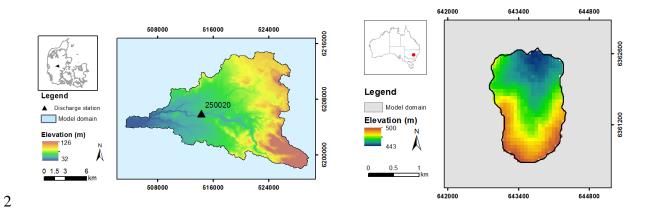

Figure 2. Sub-catchment of the Skjern river basin located in western Denmark (reproduced from Ajami et al. 2014) (left), and Baldry sub-catchment in Australia (right). Modelling domains are extended beyond the catchment boundary to remove the impact of boundary conditions on catchment fluxes.

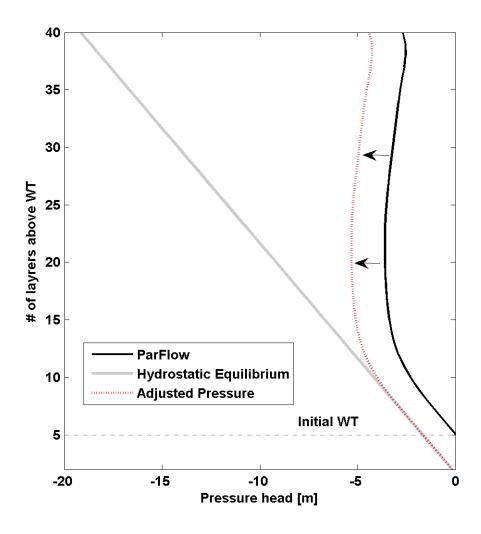

Figure 3. Adjusted pressure head distribution above the estimated DTWT from the DTWT function. Pressure head distribution of the last day of ParFlow.CLM spin-up simulation 6 was adjusted at every grid cell based on the position of DTWT estimated from the DTWT function. In this approach, the hydrostatic equilibrium assumption is used in regions between the new DTWT and the initial DTWT. The ParFlow.CLM pressure head distribution is adjusted to begin at the new pressure head from the initial WT such that the vertical profile is maintained. Hydrostatic pressure distribution is shown as a reference for the new DTWT, which is lower than the WT in simulation 6.

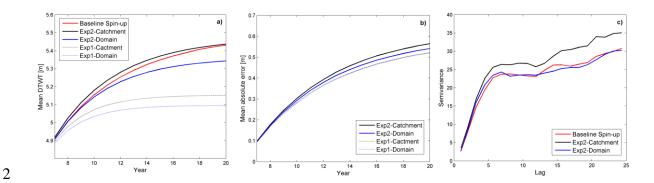

Figure 4. a) Comparison between the simulated mean annual DTWT obtained from the baseline spin-up approach of ParFlow.CLM of the Skjern River sub-catchment and empirical DTWT functions. The single exponential model was formulated using the domain and catchment averaged data from spin-up simulations 2 to 6; b) estimated mean absolute error based on simulated DTWT from the baseline spin-up together with both catchment and domain averaged single and double exponential functions; and c) experimental semi-variograms of mean annual DTWT from ParFlow.CLM equilibrium year (after 20 years of simulations) and DTWT from catchment and domain averaged double exponential functions, showing that catchment based semi-variances are higher than the baseline simulation. Exp1 and Exp2 refer to single and double exponential functions respectively.

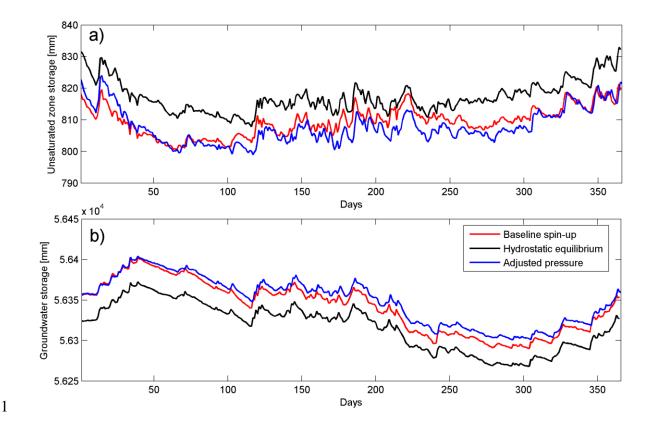

Figure 5. Comparison of a) unsaturated and b) groundwater storages of ParFlow.CLM equilibrium year using the hybrid and baseline spin-up approaches (Ajami et al., 2014). The equilibrium year corresponds to simulation cycles of 10, 12 and 20 for the adjusted pressure head, hydrostatic equilibrium, and baseline simulations, respectively. The dynamics of groundwater and unsaturated zone storages are closely reproduced by the adjusted pressure head distribution approach relative to the baseline spin-up approach for the Skjern River subcatchment.

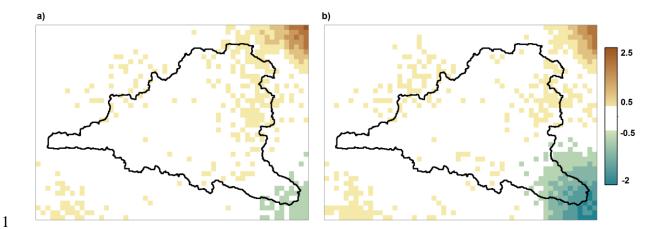

Figure 6. Differences in equilibrium DTWT between ParFlow.CLM simulations after reinitializations and ParFlow.CLM after 20 years of baseline spin-up simulations in (m), where a) is based on hydrostatic pressure distribution above the water table for the initial condition, while b) is based on adjusted pressure head distribution above the water table for the Skjern River sub-catchment. White regions correspond to grid cells where the differences in equilibrium DTWT are less than 0.5.

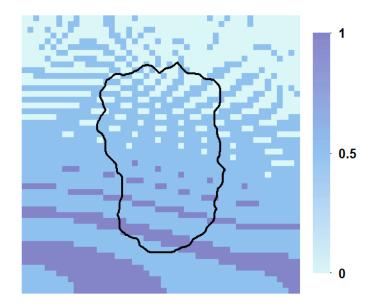

Figure 7. Differences in equilibrium DTWT of Baldry ParFlow.CLM simulations after reinitialization with the adjusted pressure head distribution above the water table and ParFlow.CLM after 28 years of baseline spin-up simulations in (m). The contours of DTWT overestimation are along the direction of flow lines from high elevation areas toward the catchment outlet.
