## 9 **Abstract**

10 Lake eutrophication is a serious global environmental issue. Phytoremediation is a promising,  
11 cost-effective, and environmentally friendly technology for water quality restoration.  
12 However, besides nutrient removal, macrophytes also deeply affect the hydrologic cycle of  
13 lake system through evapotranspiration. Changes in hydrologic cycle caused by macrophytes  
14 have a great influence on lake water quality restoration. As a result of the two opposite effects  
15 of macrophytes on water quality restoration (i.e., an increase in macrophytes can increase  
16 nutrient removal and improve water quality while also increasing evapotranspiration,  
17 reducing water volume and consequently decreasing water quality), rational macrophyte  
18 control through planting and harvest is very important. In this study, a new approach is  
19 proposed to optimise the initial planting area and monthly harvest scheme of macrophytes for  
20 water quality restoration. The month-by-month effects of macrophyte management on lake  
21 water quality are considered. Baiyangdian Lake serves as a case study, using the common  
22 reed. It was found that water quality was closest to Grade III on the Chinese water quality  
23 scale when the reed planting area was 123 km<sup>2</sup> (40% of the lake surface area) and most reeds  
24 would be harvested at the end of June. The optimisation approach proposed in this study will  
25 be a useful reference for lake restoration.

26

## 27 **1 Introduction**

28 As a global environmental issue, lake eutrophication has become an enormous challenge in  
29 the water resources protection and water safety management field (Anderson and Garrison,

1 1997; Smith, 2003). As a result of over discharge of nutrients from agricultural runoff and  
2 untreated industrial and urban sewage, many lakes are experiencing eutrophication (Smith et  
3 al., 1999; Jin, 2003). Degradation of water quality can lead to a series of side effects and  
4 result in loss of ecological functions and degradation of aquatic ecosystems (National  
5 Research Council, 2000). Eutrophication has a severe effect on many sectors of the economy,  
6 with high social, ecological, and policy response costs (Pretty et al., 2003). Frequent algal  
7 blooms caused by eutrophication are inedible or even toxic to consumer species, resulting in  
8 foodweb alterations and potentially detrimental effects on biodiversity and fisheries (Paerl et  
9 al., 2001; Qin, 2009). An eco-friendly and effective measure for water quality restoration is  
10 needed urgently in eutrophic shallow lakes.

11 Reducing the discharge of nutrients from point and non-point sources is the primary measure  
12 to control eutrophication. Measures to remove nutrients from lakes are also necessary for  
13 severely eutrophic lakes (Klapper, 1991; Wade et al., 2007; Hamilton and Landman, 2011).  
14 Phytoremediation is a promising, cost-effective, and environmentally friendly technology for  
15 water quality restoration (Salt et al., 1995). Phytoremediation is defined as the use of green  
16 plants to remove pollutants from the environment or to render them harmless (Salt et al.,  
17 1998). Nutrient pollutants are one of the major targets of phytoremediation, and can be  
18 removed from lakes through plant uptake and rhizosphere denitrification. Plant uptake  
19 happens when macrophytes convert nutrients into organic compounds, as building blocks for  
20 cells and tissues (Vymazal, 1995). Denitrification is the biological mechanism through which  
21 bacteria break down inorganic nitrogen such as nitrate and nitrite into innocuous fundamental  
22 nitrogen gas in low-oxygen environments (Lee et al., 2009). Various kinds of macrophytes  
23 have been successfully used for lake water quality control, such as the common reed  
24 (*Phragmites australis*), cattail (*Typha spp.*), and bulrush (*Scirpus spp.*). Research into nutrient  
25 removal by these macrophytes has been carried out in recent years and has proven that they  
26 are effective for water quality restoration (Wu et al., 2011; Borin and Salvato, 2012).

27 Phytoremediation can remove nutrients, while the macrophyte community also leads to high  
28 evapotranspiration. The huge evapotranspiration results in significant loss of water in lakes  
29 (Sun and Song, 2008; Borin et al., 2011). It was reported that the evapotranspiration of reed-  
30 dominated shallow lakes was one to seven times as high as the evaporation of those without  
31 vegetation cover (Baird and Wilby, 1999; Zhou and Zhou, 2009). Shallow lakes are very  
32 sensitive to evapotranspiration due to their large area and low water depth. The loss of water

1 leads to higher nutrient concentrations, which will aggravate the deterioration of water quality.  
2 As a result of the two opposite effects of macrophytes on water quality restoration—i.e.,  
3 increased macrophytes can increase nutrient removal and improve water quality while also  
4 increasing evapotranspiration, reducing water volume in a lake and consequently decreasing  
5 water quality—the management of macrophyte populations is very significant for shallow  
6 lakes.

7 Zhao et al. (2012) determined optimal reed density through a field simulation experiment  
8 considering the two effects of macrophytes on water quality. The average reed density in the  
9 current reed growth zone of Baiyangdian Lake is 120 plants  $m^{-2}$ . Their results indicated that  
10 water quality was the best when reed density was reduced to 72 plants  $m^{-2}$ . Thus they  
11 proposed that the reed density should be adjusted to 72 plants  $m^{-2}$  in the reed growth zone of  
12 Baiyangdian Lake. However, optimising plant density is not enough for lake restoration. Plant  
13 area also affects the total amount of macrophytes, and thus water quality restoration. Both  
14 planting density and area are key parameters for managing macrophytes in a lake although no  
15 research has proposed an optimisation approach for macrophyte planting area.

16 Zhao et al. (2012) suggested that the aboveground biomass of reeds should be harvested in  
17 September because the highest aboveground nutrient storage occurred in this month. The  
18 underlying rationale for this suggestion is that this harvest scheme could remove most of the  
19 nutrients from the lake and consequently make the water quality better in the following  
20 months. However, this harvest scheme may not be best for water quality in the following  
21 months, because in addition to nutrient removal reeds also undergo evapotranspiration. Water  
22 quantity and nutrient amounts remaining in the lake have a deep influence on water quality in  
23 next months. If reeds are harvested earlier than September, fewer nutrients would be removed,  
24 although the evapotranspiration also would be less. Both nutrient removal and  
25 evapotranspiration would decrease, which may lead to better water quality in the following  
26 months. Thus harvest in September may be not the best harvest scheme for water quality in  
27 the following months. For the months before September, harvest in September may also be  
28 not the best scheme for the water quality. For example, if the evapotranspiration of reeds in  
29 August and September was significant, while the amount of nutrients absorbed by reeds in  
30 these two months was small, harvesting reeds at the end of July may be better for water  
31 quality in August and September than harvesting at the end of September. We do not know in

1 which months reed growth is advantageous for water quality given the two opposite effects of  
2 reeds. Thus all the months of the growing season are potentially the best time to harvest reeds.  
3 In this study, a method will be proposed to optimise macrophyte management for water  
4 quality restoration, including the initial planting area and monthly harvest scheme. The  
5 month-by-month effects of macrophyte management on lake water quality are considered.  
6 The goal of the optimisation method is to meet the water quality demand according to the  
7 national water quality standards. If the demand cannot be achieved through macrophyte  
8 management, the water quality is optimised to approach the demand as close as possible.  
9 Adaptive Genetic Algorithm (AGA) will be applied to solve the optimisation model. Monthly  
10 nutrient balance and water quantity balance will be investigated in this study. Baiyangdian  
11 Lake, the largest shallow lake in North China, is chosen as a case study using the common  
12 reed.

13

## 14 **2 Materials and methods**

### 15 **2.1 Description of the study site**

16 Baiyangdian Lake (38°43'N to 39°02'N, 115°45'E to 116°07'E), the largest shallow  
17 freshwater lake in northern China, is a famous natural wetland due to its significant ecological  
18 functions and high tourist value. It is very important for controlling floods, regulating regional  
19 climate, and providing habitat for various animals and plants. Its largest water surface area is  
20 308 km<sup>2</sup> when the water level reaches 8.8 m. The drought level is 6 m, which occurs when the  
21 lake's surface area decreases below 50 km<sup>2</sup>. Its climatic and geographical conditions provide  
22 a favourable growing environment for macrophytes. The common reed is the dominant  
23 wetland species in the region, covering an area of about 80 km<sup>2</sup>. Because of its vitality, high  
24 biomass production, and capacity for nutrient accumulation, the common reed has been  
25 widely planted as a potential remediation macrophyte in lake ecosystems (García et al., 2004;  
26 Huett et al., 2005). The reed yield of Baiyangdian Lake removes significant amounts of  
27 nutrients from the lake and produces economic benefits. In recent years, Baiyangdian Lake  
28 has suffered serious eutrophication because of increasing nutrient inputs from sewage  
29 discharge, aquaculture, and industrial waste. The monthly average nutrient inputs for total  
30 nitrogen (TN) and total phosphorus (TP) are 21.83 t and 0.56 t, respectively (Zhao et al.,  
31 2010). The average TN and TP concentrations of water sample in the lake are respectively

1 5.15 mg L<sup>-1</sup> and 0.54 mg L<sup>-1</sup> (Zhao et al., 2012), which are much worse than the desired level  
 2 for Grade III on the Chinese water quality scale (State Environmental Protection  
 3 Administration of China, 2002).

## 4 **2.2 Nutrient balance calculation**

5 Large amounts of nutrients put pressure on lake ecosystems, although natural lakes have  
 6 strong decontamination functions to remove a considerable part of them. The removal of  
 7 phosphorus from a water body is mostly due to plant uptake and exchange with sediments,  
 8 while the removal of nitrogen is more complex (García-Linares et al., 2003). Generally,  
 9 nitrogen can be removed from a water body mainly through ammonia volatilisation, chemo-  
 10 denitrification, and the contribution of plants and sediments. The plant contribution includes  
 11 uptake and rhizosphere denitrification. Nutrient release due to rhizome decay also needs to be  
 12 considered. The sediment contribution includes biological denitrification at the sediments and  
 13 exchange between water and sediments. Ammonia volatilisation describes the escape of  
 14 nitrogen from the lake as ammonia gas, which is not significant when pH ranges between 7.5  
 15 and 9.3 (Reddy et al., 1984). Chemodenitrification is a chemical process of nitrite  
 16 decomposition to gaseous N compounds (Chalk and Smith, 1983), that usually takes place at  
 17 low pH values (Van Cleemput and Baert, 1984). The pH value in Baiyangdian Lake is about  
 18 8.0, with small yearly fluctuation (Zhao et al., 2010), so the ammonia volatilisation and  
 19 chemodenitrification processes are not significant and N removal by these methods can be  
 20 neglected. To sum up, the removal of nitrogen from this water body is mostly due to the  
 21 contributions of plants and sediments.

22 The mass balance equations in the water body can be shown as follows.

$$23 \quad \mathbf{TN}_i = \mathbf{TN}_{i-1} + \mathbf{TN}_{\text{input},i} - \mathbf{TN}_{\text{plant},i} - \mathbf{TN}_{\text{sediment},i} \quad (1)$$

$$24 \quad \mathbf{TP}_i = \mathbf{TP}_{i-1} + \mathbf{TP}_{\text{input},i} - \mathbf{TP}_{\text{plant},i} - \mathbf{TP}_{\text{exchange},i} \quad (2)$$

$$25 \quad \mathbf{TN}_{\text{plant},i} = \mathbf{TN}_{\text{uptake},i} + \mathbf{TN}_{\text{rhiz,deni},i} - \mathbf{TN}_{\text{release},i} \quad (3)$$

$$26 \quad \mathbf{TP}_{\text{plant},i} = \mathbf{TP}_{\text{uptake},i} - \mathbf{TP}_{\text{release},i} \quad (4)$$

$$27 \quad \mathbf{TN}_{\text{sediment},i} = \mathbf{TN}_{\text{sedi,deni},i} + \mathbf{TN}_{\text{exchange},i} \quad (5)$$

28 where  $\mathbf{TN}_i$  and  $\mathbf{TP}_i$  are total amounts of nutrients in month  $i$  ( $10^2$  t);  $\mathbf{TN}_{\text{input},i}$  and  $\mathbf{TP}_{\text{input},i}$  are  
 29 the amounts of nutrients input in month  $i$ ;  $\mathbf{TN}_{\text{plant},i}$  and  $\mathbf{TP}_{\text{plant},i}$  are the amounts of nutrients  
 30 removed by the contribution of plants;  $\mathbf{TN}_{\text{sediment},i}$  is the amount of nitrogen removed by the

1 contribution of sediment;  $TN_{\text{uptake},i}$  and  $TP_{\text{uptake},i}$  are the amounts of nutrients absorbed by  
2 plants;  $TN_{\text{release},i}$  and  $TP_{\text{release},i}$  are the amounts of nutrients released due to rhizome decay;  
3  $TN_{\text{exchange},i}$  and  $TP_{\text{exchange},i}$  are the amounts of nutrients removed through the exchange with  
4 sediments; and  $TN_{\text{rhiz,deni},i}$  and  $TN_{\text{sedi,deni},i}$  are the amounts of nitrogen removed by biological  
5 denitrification at plant rhizosphere and sediment, respectively.

6 In Baiyangdian Lake, the majority of plant uptake of nutrients occurs by the common reed,  
7 the dominant species in the region. Reeds absorb nutrients mainly through their rhizome  
8 system (Haslam, 1972; Ailstock et al., 2001). Only a small amount of nutrients is absorbed  
9 from the atmosphere by their leaves and can be ignored. This study divides reed growing area  
10 into two zones, one is submerged zone and another is terrestrial zone. Nutrients absorbed by  
11 reeds in submerged zone mostly come from water body, because most nutrients in the  
12 sediment is unavailable for biotic use and available nitrogen mainly occurs in soluble form in  
13 the lake water and interstitial sediment water (Wetzel, 2001). These reeds in submerged zone  
14 are considered effective for water quality restoration, while those growing in terrestrial zone  
15 mostly absorb nutrients from the soil and they are considered noneffective for improving  
16 water quality. As monthly water level fluctuating, the area of reeds in submerged zone will  
17 vary accordingly. Reeds absorb nutrients for developing their aboveground and belowground  
18 tissues. The latter mainly refers to their perennial rhizome system. During the growing season,  
19 belowground tissues absorb nutrients for growth. When reeds senesce, the aboveground part  
20 dies and translocates some nutrients to the belowground part, if they are not harvested (Juneau  
21 and Tarasoff, 2013), and the belowground part enters dormancy and stores nutrients for new  
22 tissues in the next year (Grandi et al., 1992; Juneau and Tarasoff, 2013).

23 The amounts of nutrients absorbed by the aboveground part annually can be calculated by  
24 multiplying TN or TP concentrations in reed tissues and their aboveground biomass. The  
25 nutrient concentrations and aboveground biomass can be measured by experiment. However,  
26 for the perennial, belowground part, it is much more complicated to calculate the annual  
27 amounts of nutrients absorbed because it is difficult to distinguish which tissues developed in  
28 the current growing season, and the annual biomass increment of old tissues is also hard to  
29 measure (Karunaratne et al., 2004). To better calculate the annual increment of belowground  
30 biomass, some research has built a relation between annual net production of belowground  
31 tissues and maximum aboveground biomass (Valk and Bliss, 1971; Fiala, 1976). Based on  
32 Fiala's research (1976), the average annual value of net production of belowground reed

1 tissues would be 45% of the maximum aboveground biomass. The concentrations of TN and  
2 TP in the belowground tissues are relatively constant during the growing season (Quan et al.,  
3 2007). These two concentrations can be measured by experiment. On the basis of the  
4 increment of belowground biomass, the nutrients absorbed by belowground tissues can be  
5 obtained.

6 Besides absorbing nutrients, reeds also release nutrients to the lake when they senesce. In this  
7 study, the aboveground part will be harvested after the growing season, while the  
8 belowground part will be retained in the lake. Some tissues of the belowground part will die  
9 and release nutrients, and others will be dormant until the next growing season (Chapin et al.,  
10 1990; Grandi et al., 1992). According to research by Grandi et al. (1992), the rhizome  
11 mortality of reeds is about 30%, and the release of their nutrients should be considered in this  
12 study.

13 The field simulation experiment was conducted in Baiyangdian Lake during the growing  
14 season from April to November 2010. The rhizome breeding method was used for reed  
15 cultivation and the experiment was exposed to full sun and ambient temperatures (Huett et al.,  
16 2005). The reed rhizomes, water, and sediment for the simulation experiment were all  
17 sampled from the lake at the beginning of April. According to the control group without reeds,  
18 an average of  $57.6 \text{ mg m}^{-2}$  TN and  $6.5 \text{ mg m}^{-2}$  TP could be removed from the water body by  
19 the contribution of sediments. The efficiency of rhizosphere denitrification is approximately  
20 twice that of sediments because the plant rhizosphere environment supports a higher potential  
21 for the exchange of aerobic and anaerobic processes that facilitate denitrification (Højberg et  
22 al., 1996). From the experiment group with growing reeds, the amounts of nutrients absorbed  
23 by different parts throughout the growing season can be obtained as shown in Table 1.

24 During the growing season, the lake area was divided into two zones: a zone without reeds  
25 and with reeds. The area of the zone with reeds varies with harvesting activity and water level  
26 fluctuation. Plant uptake and denitrification in reed rhizospheres occur in the zone with reeds,  
27 while denitrification in the sediment occurs in the whole lake area. The equations to calculate  
28 plant uptake and denitrification can be shown as follows.

$$29 \quad \mathbf{TN}_{\text{uptake},i} = (\mathbf{tn}_{\text{above,upt},i} + \mathbf{tn}_{\text{below,upt},i}) \times \mathbf{A}_{\text{plant,sub},i} \quad (6)$$

$$30 \quad \mathbf{TP}_{\text{uptake},i} = (\mathbf{tp}_{\text{above,upt},i} + \mathbf{tp}_{\text{below,upt},i}) \times \mathbf{A}_{\text{plant,sub},i} \quad (7)$$

$$31 \quad \mathbf{TN}_{\text{rhiz,deni},i} = \mathbf{tn}_{\text{rhiz,deni},i} \times \mathbf{A}_{\text{plant,sub},i} \quad (8)$$

$$1 \quad \mathbf{TN}_{\text{sedi,deni},i} = \mathbf{tn}_{\text{sedi,deni},i} \times \mathbf{A}_{\text{submerged},i} \quad (9)$$

2 where  $\mathbf{tn}_{\text{above,upt},i}$  and  $\mathbf{tn}_{\text{below,upt},i}$  are the amounts of TN absorbed by aboveground parts and  
3 belowground parts of reeds in unit area in month  $i$ ;  $\mathbf{tp}_{\text{above,upt},i}$  and  $\mathbf{tp}_{\text{below,upt},i}$  are the amounts  
4 of TP absorbed by aboveground parts and belowground parts of reeds in unit area;  $\mathbf{tn}_{\text{rhiz,deni},i}$   
5 and  $\mathbf{tn}_{\text{sedi,deni},i}$  are the amounts of TN removed through biological denitrification at plant  
6 rhizosphere and sediments in unit area;  $\mathbf{A}_{\text{submerged},i}$  is the area of submerged zone in the lake;  
7  $\mathbf{A}_{\text{plant,sub},i}$  is the area of plants in submerged zone of the lake.

### 8 **2.3 Water quantity balance calculation**

9 Besides the amounts of nutrient, water quantity is another crucial factor that affects water  
10 quality. Water sources include inflows from upstream and rainfall supplement. Consumption  
11 of water occurs through outflows, permeation, and evapotranspiration, which includes water  
12 surface evaporation and plant transpiration. Baiyangdian Lake is a semi-closed water system  
13 with no natural outflows (Yang, 2011), so water consumption by outflows can be ignored. On  
14 this basis, the water balance equation to research monthly water quantity variations can be  
15 built as shown below.

$$16 \quad \mathbf{W}_i = \mathbf{W}_{i-1} + \mathbf{W}_{\text{inflow},i} + \mathbf{W}_{\text{rainfall},i} - \mathbf{W}_{\text{eva},i} - \mathbf{W}_{\text{per},i} \quad (10)$$

17 where  $\mathbf{W}_i$  is the lake water volume in month  $i$  ( $10^8 \text{ m}^3$ );  $\mathbf{W}_{\text{inflow},i}$  is water inflows in month  $i$   
18 ( $10^8 \text{ m}^3$ );  $\mathbf{W}_{\text{rainfall},i}$  is supplementary water from rainfall in month  $i$  ( $10^8 \text{ m}^3$ );  $\mathbf{W}_{\text{eva},i}$  is total  
19 evapotranspiration volume in month  $i$  ( $10^8 \text{ m}^3$ ); and  $\mathbf{W}_{\text{per},i}$  is the volume of water consumed  
20 by permeation in month  $i$  ( $10^8 \text{ m}^3$ ).

21 In Baiyangdian Lake, the inflows are mainly controlled by upstream reservoirs. The monthly  
22 average water released for Baiyangdian Lake is  $0.05 \times 10^8 \text{ m}^3$  (Yang, 2011). This region's  
23 annual average precipitation is 461.9 mm, with most of this precipitation falling between June  
24 and September. The permeability coefficient in Baiyangdian Lake is 3 mm every day (Beijing  
25 Normal University, 2011).

26 Evapotranspiration in lakes is a complex process. Outside the growing season, water surface  
27 evaporation decides the total evapotranspiration volume. During the growing season the lake  
28 has to be divided into two zones to calculate total evapotranspiration volume. In the zone  
29 without plants, only water surface evaporation needs to be considered. In the zone with plants,  
30 both water surface evaporation and plant community transpiration need to be considered.

1 Surface evaporation in the zone without reeds and the total evapotranspiration in the plant  
2 growing zone during the growing season for Baiyangdian Lake are shown in Table 2. Reed  
3 transpiration in March and April is negligible. In October and November it also does not need  
4 to be considered because all reeds are harvested before October. From December to February,  
5 the lake is frozen and water surface evaporation can be ignored.

## 6 **2.4 Development of an optimisation model**

7 Before the model development, several basic assumptions should be listed as the base for the  
8 model.

9 1. Nutrients distribute uniformly in space. Spatial difference of the lake water quality is not  
10 considered.

11 2. The growth conditions are the same for reeds in different zones of the lake. The efficiency  
12 of nutrient removal by reeds has no spatial diversity.

13 3. The common reed is the dominant plant species in Baiyangdian Lake. The growing area of  
14 reeds is much larger than the total area of other plants. Thus the common reed is the only  
15 plant species considered in this study.

16 In Baiyangdian Lake, reeds begin to germinate at the end of March or the beginning of April  
17 every year. People usually plant reeds at this time. In this study the initial planting area is  
18 optimised for this time. Nutrient removal and evapotranspiration of reeds in March and April  
19 are negligible and can be ignored. After April, reeds will grow quickly from May to  
20 September. Both the amounts of nutrients absorbed and water evapotranspiration are large  
21 during this time. In October, reeds will stop growing and release nutrients to the lake, so the  
22 harvest of aboveground reed tissues should be finished before this time. All months from May  
23 to September are the potential optimal time to harvest reeds. In this study, a certain proportion  
24 of reeds would be harvested at the end of each month from May to September. The harvest  
25 ratios of these months should be optimised. In summary, the reed planting area in March or  
26 April and harvest ratios from May to September are variables that need to be optimised in the  
27 model.

28 In actual conditions, plant density is very difficult to quantify and control. The reed rhizome  
29 system has high reproductive capacity (Lavergne and Molofsky, 2004), so it is almost  
30 impossible to artificially control reed density throughout the reed growing season. Thus, the

1 reed density in this study is set as the current density in the reed growing zone of Baiyangdian  
 2 Lake. It is assumed that nutrients distribute uniformly in the lake, so nutrient concentrations  
 3 can be calculated based on the amounts of nutrients and lake water volume. After nutrient  
 4 balance and water quantity balance analysis of Baiyangdian Lake in previous sections, the  
 5 relations between nutrient concentrations and reed management can be built.

6 Baiyangdian Lake is expected to satisfy the standard for Grade III of the Chinese water  
 7 quality scale according to the requirement of local government, i.e., the concentrations of TN  
 8 and TP are required to be no higher than  $1.0 \text{ mg L}^{-1}$  and  $0.05 \text{ mg L}^{-1}$ , respectively. These two  
 9 values are defined as the target values ( $C_{\text{target}}$ ). In this study, we attempt to make water quality  
 10 meet the target by reed growth management. If water quality could not meet the requirement  
 11 in some periods, it was expected to be as close to the target concentrations as possible. To  
 12 better show the gap between actual water quality and the target, a new gap index,  $\delta$ , will be  
 13 defined. When the actual concentration of nutrients is not higher than the target value, the gap  
 14 index is zero. Otherwise, the index has to be calculated as the relative error. The equations are  
 15 shown as follows.

$$16 \quad \delta = \begin{cases} 0 & (C_{\text{actual}} \leq C_{\text{target}}) \\ (C_{\text{actual}} - C_{\text{target}}) / C_{\text{target}} & (C_{\text{actual}} > C_{\text{target}}) \end{cases} \quad (11)$$

17 where  $\delta$  is the gap index for some nutrient;  $C_{\text{actual}}$  is the actual nutrient concentration in the  
 18 lake ( $\text{mg L}^{-1}$ );  $C_{\text{target}}$  is the target concentration ( $\text{mg L}^{-1}$ ). It is obvious that water quality is  
 19 better when the gap index is smaller.

20 An optimisation model for macrophyte management of water quality restoration will be  
 21 developed in this study. For TN and TP, a monthly gap index can be obtained. The average  
 22 value of the index over a year for each nutrient indicates the water quality for that year. The  
 23 objective of the model is to make water quality meet the target and make the gap index as  
 24 small as possible. The best result for the lake would be if the index remained zero throughout  
 25 the year.

26 The objective of the model is as follows:

$$27 \quad \min \bar{\delta} = \min(\bar{\delta}_{\text{TN}} + \bar{\delta}_{\text{TP}}) \quad (12)$$

28 where  $\bar{\delta}$  is the total gap index used to show the water quality for a year, and  $\bar{\delta}_{\text{TN}}$  and  $\bar{\delta}_{\text{TP}}$  are  
 29 the monthly average gap indexes for TN and TP, respectively.

## 1 **2.5 Scenario creation and model solution**

2 Reeds grow well at elevations between 0.64 m above the water level and 1.01 m below the  
3 water level in north China (Pagter et al., 2005; Cui et al., 2006). Beyond this range, the  
4 growth of reeds is significantly suppressed. Reed area control normally occurs at the end of  
5 March or beginning of April, when reeds are seedlings. The average water level at this time is  
6 7.8 m. Considering the suitable water depth for reeds ( $-0.64$  m to  $1.01$  m), the possible  
7 surface area for reed growth is  $197$  km<sup>2</sup>, which accounts for about 60% of the greatest surface  
8 area ( $308$  km<sup>2</sup>) of Baiyangdian Lake.

9 The planting area can be optimised as a discretionary value below  $197$  km<sup>2</sup>, and then  
10 managers can define the boundaries of the planting area according to the optimal results.  
11 However, defining boundaries in the actual lake environment is a complex process, which  
12 includes two main tasks. First, we need to define the boundaries on a topographic map. Then  
13 measurements need to be made to determine the actual boundaries in the lake. If the optimal  
14 area varies randomly below  $197$  km<sup>2</sup>, managers need to define the boundaries accordingly  
15 every year. This work is time consuming. In this study, several scenarios for different planting  
16 areas are created. Managers can define the boundaries for each of these scenarios at once. In  
17 the following years, managers only need to choose the best scenario and do not need to  
18 redefine the boundaries. This method may reduce the accuracy of the optimal result, but it is  
19 much easier to implement in practice. Six scenarios will be created, for reed areas of 60%  
20 ( $185$  km<sup>2</sup>), 50% ( $154$  km<sup>2</sup>), 40% ( $123$  km<sup>2</sup>), 30% ( $92$  km<sup>2</sup>), 20% ( $62$  km<sup>2</sup>), and 10% ( $31$  km<sup>2</sup>)  
21 of the lake surface. The harvest ratios under each scenario will be optimised in the model. The  
22 gap index will also be obtained from the model under the optimal harvest scheme for each  
23 scenario.

24 We apply an Adaptive Genetic Algorithm to solve the optimisation model. AGA is one kind  
25 of global optimisation algorithm, which is widely used in various scientific computing fields.  
26 It can generate solutions to optimisation problems using techniques inspired by natural  
27 evolution, such as inheritance, crossover, selection, and mutation. In recent years, AGA has  
28 been used in the field of environmental science and water resources management (Kaini et al.,  
29 2012). In this study, the fitness of AGA is to make the total gap index of one year as small as  
30 possible. There are five optimization variables, which are the reed harvest ratios from May to  
31 September. After modelling all scenarios, we can determine the best reed planting area and

1 harvest scheme, under which the most satisfactory water quality will be attained in  
2 Baiyangdian Lake.

3

### 4 **3 Results**

5 Pollution in the lake deeply affects the optimal results of the model. The reed management  
6 scheme may vary yearly because the pollution level will change. The model in this study  
7 covers one year, considering the water quality both in the reed growing season and the rest of  
8 the year. The year runs from May in one year to April of the following year. Although reeds  
9 begin to grow at the end of March, nutrient removal and evapotranspiration in March and  
10 April are negligible. Reeds begin to affect water quality in May every year. The water quality  
11 from January to April is affected by the reed management scheme of the previous year. Thus,  
12 setting May as the beginning month for the model is more rational.

13 This study used the average level of pollution in Baiyangdian Lake for recent years. Six  
14 scenarios were created for the model. The initial reed area was set as 185 km<sup>2</sup> (scenario 1),  
15 154 km<sup>2</sup> (scenario 2), 123 km<sup>2</sup> (scenario 3), 92 km<sup>2</sup> (scenario 4), 62 km<sup>2</sup> (scenario 5), and 31  
16 km<sup>2</sup> (scenario 6). For each scenario, optimised harvest ratios from May to September and the  
17 total gap index of the year will be obtained through AGA. Total gap index shows the water  
18 quality level in the model year. After modelling, the harvest ratios for each scenario are  
19 optimised, as shown below (Table 3).

20 From Table 3, we find that almost all reeds are expected to be harvested at the end of June for  
21 each scenario. Under these harvest schemes, water quality is the most satisfactory. This  
22 phenomenon can be explained by the two opposite effects of reeds on water quality.  
23 Compared with other months, the most nutrients are absorbed by reeds in June and  
24 evapotranspiration is not very high. After June, evapotranspiration of reed community greatly  
25 increases. Water consumed by evapotranspiration in July is about two times more than that in  
26 June, and severely damages water quality. Although reeds absorb some nutrients in July, the  
27 amount absorbed is less than half of that in June. Therefore, reed growth after June has more  
28 negative effects on water quality, making the end of June the best time to harvest them.

29 The total gap index of water quality is also obtained for each scenario after modelling (Table  
30 4). All the gap indexes are calculated under the optimal harvest scheme. From Table 4, the  
31 obvious difference between the maximum and the minimum gap index under different

1 scenarios shows that planting area has a profound effect on water quality. Scenario 3 has the  
2 lowest total gap index, indicating that the water quality in this scenario is closest to the target  
3 and that a planting area of 40% of the lake surface (123 km<sup>2</sup>) and harvest of 99% at the end of  
4 June is best for the water quality of Baiyangdian Lake.

5 The differences among the gap indexes for scenarios 4, 5, 6 are large, while the differences  
6 among the first three scenarios are small. This indicates that reed area has a significant effect  
7 on water quality when the planting area is less than 40% of the lake surface. When the area is  
8 larger than 40%, most incremental reeds will be planted at the lakeshore, and the effect of  
9 incremental reeds on water quality restoration will be inapparent. Thus the effect of reed area  
10 variation on water quality is not obvious when the area is larger than 40%. Although scenario  
11 3 is the optimal scheme, the gap index is not zero. This indicates that the water quality of the  
12 best scenario cannot completely meet the target of Grade III on the Chinese water quality  
13 grade scale. Macrophyte management alone is unable to maintain satisfactory water quality  
14 throughout the year for the current conditions of Baiyangdian Lake.

15

## 16 **4 Discussion**

### 17 **4.1 Effect of initial reed area on water quality**

18 In order to show the significance of macrophyte management on water quality, the  
19 comparison between optimal result and current situation is conducted. The current reed area  
20 in Baiyangdian Lake is 80 km<sup>2</sup>. According to the results of this study, the optimal reed area is  
21 123 km<sup>2</sup>. Lake water quality throughout the year for these two planting areas is compared (Fig  
22 1). Both these two curves in the figure are extrapolated based on the nutrient balance and  
23 water quantity balance investigated in this study. In both these situations reeds are harvested  
24 at the end of September, according to prior research (Zhao et al., 2012). The time period in the  
25 figure runs from the beginning of May in one year to the same time in the following year. It is  
26 clear that water quality under the optimal reed area is better than that of the current situation.  
27 The water quality improves in May and especially in June. This is due to the increased  
28 amount of nutrients absorbed by reeds in June and the low evapotranspiration. With the  
29 exception of these two months, water quality steadily deteriorates. Although reeds still  
30 remove nutrients from July to September, water quality does not improve because of the high

1 evapotranspiration. Water quality under the current reed area is unable to meet the target all  
2 year. In the optimal situation, water quality can meet the target from July to December.

3 From the figure, we can find that the nutrient concentrations in the optimal situation reach  
4 zero in July, which means that nutrients in the lake are not enough to maintain all reeds  
5 growing in June. When this condition occurs, the optimisation program can calculate the  
6 acceptable area for reed growing in this month and acquiescently consider that the redundant  
7 reeds should be harvested at the end of this month, which means that the area of reeds  
8 harvested in this month should not be smaller than the area of redundant reeds.

## 9 **4.2 Effect of harvest scheme on water quality**

10 A new harvest scheme, indicating that reeds should be harvested at the end of June, is also  
11 proposed in this study. The effects of two different harvest schemes (at the end of June or end  
12 of September) on water quality are compared under the same initial reed area (123 km<sup>2</sup>) (Fig  
13 2). The water qualities are the same in May and June, after which the variation trends for TN  
14 and TP are different for the two harvest schemes. If reeds are harvested at the end of June, the  
15 TN concentration is lower than under the other scheme, while the TP concentration is higher.  
16 The difference in TN is greater than that of TP, so June is chosen as the optimal harvest time  
17 based on the objective of the optimisation model in this study. This result gives us guidance in  
18 choosing a harvest scheme. If the main nutrient of a lake is TN, harvesting reeds in June will  
19 be better. If the main nutrient is TP, harvesting reeds in September will be more rational.  
20 Choosing a harvest scheme should be based on the actual conditions or the management target  
21 of the lake.

22 In the optimal situation meaning that the reed area is 123 km<sup>2</sup> and harvest occurs in June,  
23 water quality can meet the target from July to December. In other months, the water quality is  
24 much closer to the target than it is under the current reed area. If lake water quality is  
25 expected to meet the target all year, the period from January to June needs more attention.

## 26 **4.3 Effect of parameter simplification**

27 Water balance calculation is an important fundament for developing the optimisation method  
28 in this study. Lake water volume is mainly affected by several factors, such as  
29 evapotranspiration, precipitation, permeation and upstream reservoir operation. In this study,  
30 average values were used to set these parameters according to statistical data of past years. It  
31 is significant to consider the influence of parameter variations on final result (Bullock and

1 Acreman, 1999). All these parameters are about water quantity balance, so considering  
2 variation for one of them is enough to reflect the influence. Among these parameters, water  
3 release from upstream reservoirs is the most uncertain. Thus, the influence of water release  
4 from upstream on final result is discussed.

5 Through adjusting the volume of water released from upstream reservoirs, no obvious varying  
6 tendency is found for reed management regime, while the lake water quality varies obviously.  
7 When the annual volume of water released reaches  $1 \times 10^8 \text{ m}^3$ , the gap index of water quality  
8 in the year is about 0.16, which means the water quality is very close to the target. The water  
9 qualities of upstream reservoirs are relatively much better, so water release can dilute the  
10 nutrients and decrease their concentrations directly. Besides this, water volume of a lake has  
11 direct relations with its water surface area and water depth. The water surface area decides the  
12 zone where sediment denitrification occurs and the water depth affects available zone for reed  
13 growing in the lake (Ishida et al., 2006; Lawniczak et al., 2010). The influence mechanism of  
14 water release on the water quality restoration is complicated, so the influence of parameter  
15 variation on reed management regime has no obvious rule.

16

## 17 **5 Conclusion**

18 This study proposed an optimisation model for macrophyte management of water quality  
19 restoration in a shallow lake. Using the optimisation approach, an optimal planting area and  
20 monthly harvest scheme can be obtained. Baiyangdian Lake was used as a case study, with  
21 common reed as the dominant plant. After modelling, it was found that water quality was  
22 closest to the standard for Grade III of the Chinese water quality scale when the initial reed  
23 area was controlled as 40% of the lake surface ( $123 \text{ km}^2$ ) and 99% were harvested at the end  
24 of June.

25 Although the optimal reed management scheme has been determined, the water quality of  
26 Baiyangdian Lake could not meet the target. The period from January to June is the main  
27 challenge to satisfactory water quality. If water quality is expected to meet requirements  
28 throughout the year, some other restoration measures are needed besides macrophyte  
29 management. Water release from upstream reservoirs also has a significant influence on water  
30 quality, and the operation schedule of reservoirs has not yet considered this influence. Future  
31 research on water quality restoration should consider the effects of water release from

1 upstream reservoirs and try to propose a management scheme to ensure lake water quality  
2 meets the target all year.
