On inclusion of water resource management in Earth System models - Part 2: Representation of water supply and allocation and opportunities for improved modeling

Revision summary and point-to-point reply to the reviewers' comments

Ali Nazemi[1] and Howard S. Wheater[1]

[1] Global Institute for Water Security, University of Saskatchewan, 11 Innovation Boulevard, Saskatoon, SK, S7N 3H5, Canada.

I. Letter to the editor and revision summary

Dear Dr. Buytaert

Many thanks for handling our submitted manuscript (hess-2014-257). We revised our manuscript and provided a point-to-point reply to the reviewers' comments. We found the comments extremely constructive. We took all necessary steps to provide a reasonable response to reviewers' comments and incorporate their suggestion into our revision. We believe that the revised manuscript is substantially improved by reviewers' suggestions as well as the comments we received from algorithm developers.

To summarize the revisions made, we revised Section 1 to focus on the main objective of our paper, according to comments made by anonymous reviewer #1. Section 2.1 was extended to include a discussion on natural lakes according to a comment made by anonymous reviewer #1. Section 2.3 was extended and revised according to comments made by anonymous reviewer #1. Section 3.1 was revised according to comments made by both reviewers. Section 3.2 was modified based on a comment made by anonymous reviewer #1. Sections 3.3.1 and 3.3.2 were minorly revised based on suggestions made by algorithms developers, namely Drs Hanasaki and Hadelland, respectively. Section 4 was majorly revised and restructured based on the comments received from both reviewers. Section 5.1 extended based on the suggestions made by both reviewers. Section 5.2 was majorly revised and restructured based on the comment made by both reviewers. Discussions in Section 5.4 were extended and revised based on comments made by both reviewers. Section 5.6 was extended majorly by a new set of discussions as well a new figure and a new table based on comments received from anonymous reviewer #2. Finally, 18 new references have been used and added to the reference list to appropriately address the reviewers' comments.

Below, we first provide a point-to-point reply to the reviewers' comments and then include a marked up revised manuscript. Although the marked up version include most of our revisions, it has some minor differences with the final revised manuscript. Accordingly, we prepared our response to the reviewers comments based on the final revised manuscript attached separately, not the marked up version below this letter. Many thanks for considering our revisions.

II. Point-to-point reply to Anonymous Reviewer #1

We greatly appreciate Anonymous Reviewer #1 for their positive, constructive and thoughtful comments, which led to substantial improvements in the revised version of our manuscript. In the following, the issues raised are addressed point-by-point in the order they are asked. The reviewers' comments are numbered; our reply to each comment is shown immediately below the comment in blue.

1- Although well surveyed, I found some errors in text which misrepresent some formulations or concepts of models (please see below for detail). It is quite challenging for non-developers, if not impossible, to describe models perfectly by only literature review. Here I would like to suggest the authors to make a simple survey of models: contact the main developers of major models and ask to check whether the descriptions on their models are correct.

Many thanks for your suggestion and heads-up on some of the misrepresentations in the submitted manuscript. We corrected all points you highlighted and contacted the main developers to take all reasonable steps to ensure accurate representation of the scheme. Some of the developers have kindly came back to us and we included their comments into the revised version.

2- I found considerable overlaps in contents within this article. It could be attributed to its structure. Actually, the titles of chapters 2-4 read "Available representations of water sources in large-scale models", "Available representation of water allocation in large-scale models", and "Current large-scale modeling applications". In each section, both the reservoir operation and groundwater models are discussed citing the same papers repeatedly. I wonder the overlaps might be drastically reduced if the authors reorganize them into two sections, the reservoir operation and groundwater models.

Many thanks for your comment. We thought a lot on this and tried different variations to organize the content. This was not as easy task and took us a long time, considering the fact that we needed to somehow link the content of Part 1 and Part 2 papers together and keep the same narration style in both papers. The main objective in both papers is to breakdown different aspects of water resource management and describes briefly how various elements are included in large-scale models. This is mainly to inform non-familiar readers about how the big problem of representing water resource management can be divided in to rather stand-alone pieces, which can be then represented through a specific suite of algorithms. In the Part 1 paper, we defined water resource management as an integration of water demand with water supply and allocation, in which water allocation links water demand and supply together. Therefore in this paper, we first breakdown water sources and then focused on algorithms available for representing water allocation. As the main papers cited in this paper include both water supply and allocation (and some also water demand, which are cited in Part 1 paper), such overlaps as you indicated become somehow unavoidable, even if we consider a section solely on surface water and another one only to groundwater supply and allocation. This is due to the fact that most of the cited papers include discussion on both groundwater and surface water. We believe that organizing our discussion in the present form can help non-familiar readers to understand how a specific paper deals with various issues around the representation of water resource management. Indeed, further consultation with original papers is required for further understanding of the algorithms reviewed in this review.

3- The objective of review is a bit unclear. As the title of this paper says, the authors may intend to make use of this review to develop an ESM including human activities based on an atmospheric model and conduct online simulations to study landatmosphere interactions. If this is the case, the paper in the current form might pay too much attention to the application of offline simulations and too less to the problems inherent to ESMs and online simulation (low spatial resolution, biases in atmospheric and hydrological variables, small signal to noise ratio due to large internal variation, etc).

Many thanks for your comment. We noticed that both offline and online effects of water resource management are important and relevant to ESMs, in particular GHMs and LSMs. We do agree that both papers have more discussion related to offline applications; however, this is wholly a reflection of the current literature. In fact, most of the available studies are mainly offline (with exception of irrigation that discussed in Part 1 paper) and we are not aware of any study that incorporates ESMs with full consideration of water resource management for online simulations at the regional or global scale. Nonetheless, we suggest that the ultimate need is to move towards online simulations in a way described in Figure 1. According to your comment, now we have added a substantial discussion on issues around online modelling in Section 5, including incorporating several new references. Please see the revised manuscript **(lines 580 to 696).**

4- The authors partly included discussion on water security in this paper, which confused me. Water security is largely a matter of socio-economic change, policy, institution, and governance, which is out of the scope of this paper. Above all, the review on this topic is insufficient.

Many thanks for your comment. As you truly noted in your comments, our main aim in this paper is to discuss how to represent water supply and water allocation in large-scale models. We highlighted three main practical reasons for this, including quantifying the effect of human-water interactions on terrestrial water cycle and climate as well as addressing the water security concerns at regional and global scales. We did not intend to provide a comprehensive review on water security assessment. Rather, we would like to justify the need of representing water resource management in large-scale models based on emerging issues around water security assessment. From a broader perspective, water resource management and water security are rather interconnected as both are influenced by of socio-economic change, policy, institution, and governance. However as you noted these issues are beyond the scope of this paper. As a result, we modified the discussion related to water security assessment according to your comment to avoid further confusion. Please see the revised manuscript **(lines 87 to 108 and 484 to 557).**

5- P8303, L2, "focus mainly on measuring the annual difference between natural water availability and projected demand as an indicator of water scarcity": I'm wondering this part is of relevance to this review article. This paper basically focuses on the representation of human activities in numerical models rather than its application to water resources assessments. Indeed, dozens of high quality papers have been published on global water scarcity and security, which is largely missing in this article.

Many thanks for your comment. This comment is closely related to the previous comment and comment #14. As we mentioned above we revised the discussion related to water security assessment to keep the focus on the main objective of this paper, which as you mentioned is representation of human water management in large-scale models. Please see the revised manuscript **(lines 87 to 108)**

6- P8304, L19, "10% of the annual runoff": The number may be too small. 8000km3 of storage volume must be accounts for 20% of global annual runoff (approximately 40000 km3/yr).

Many thanks for the heads-up on this. We referred to the original articles as well as Gleick (2000) and you are absolutely right. We highly appreciate your careful reading of our paper. We revised the paper accordingly. Please see the revised manuscript **(lines 147 to 150).**

7- P 8304, L16, "Available representations of water sources in large-scale models": The section includes a subsection "groundwater", while it excludes "surface water". I understand that river and lakes are "natural" processes and do not include explicit human activity, but these are the most fundamental water sources.

Many thanks for the comment. We included a brief discussion about the natural lakes in Section 2.1. Accordingly, Section 2.1 is now titled as "Lakes and reservoirs". Please see the revised manuscript **(lines 142 to 186).** Please note that we already have a brief discussion in Section 2.2 related to river flow abstraction. Please see the revised manuscript **(lines 193 to 215).**

8- P8307, L24, "often groundwater availability is assumed as unlimited local source": Please carefully revisit the original article. For example, Rost et al. (2008) devised a technical term "Nonlocal and nonrenewable blue water (NNBW)" and avoided assuming groundwater is unlimited source.

Many thanks for your comment. You are absolutely right as she did advise that in the 2008 paper. We revised this in the paper. However, from a numerical modelling perspective, these are rather similar. Please see our discussion related to comment #13. Please see the revised manuscript **(lines 235 to 239 and Table 1 in page 55).**

9- P8308, L1, "Wada et al. (2014)": Döll et al. (2014) should be mentioned here as well.

Many thanks for introducing this paper to us. We were not aware of this paper and read it with a lot of interest. Accordingly, we included a brief discussion on this paper. Please see the revised manuscript **(lines 246 to 249).** We also used the reference in some other places of revised manuscript, where applicable.

10- P8310, L14, "Hanasaki et al. (2006) assumed that large reservoirs can supply all downstream demands within 1100km and with lower elevation": When the model of Hanasaki et al. (2006) estimates the monthly release of individual reservoirs, it only uses the information of water demand in downstream. Released water is not always sufficient to "supply the all downstream demands". This kind of details might be difficult to learn from literature review. Voluntary checking by model developers would substantially improve the accuracy.

Many thanks for your comment. We exactly meant what you indicated but we poorly wrote it. What we meant was large reservoirs consider supplying demands that are located within 1100 km and lower elevation. This does not mean that they can fully supply them. Please see the revised manuscript **(lines 309 to 310 and Table 1 in page 55).**

11- P8310, L28, "Irrigation has often been given the highest priority": At least, Hanasaki et al. (2008a) gave priority to domestic and industrial water over irrigation in abstraction of water from river.

Many thanks for your very careful reading and comment. We checked the article and you are completely right: "*The anthropogenic water withdrawal module withdraws the amount of consumptive water use for domestic, industrial, and agricultural purposes from river channels in that order at each simulation grid cell*". However later on, it indicates that "*Withdrawn irrigation water was added to the soil moisture in irrigated areas, and domestic and industrial waters were removed from the system*". We mistakenly took this statement as an indication of priority in the water allocation. Please see the revised manuscript **(lines 320 to 322 and Table 1 in page 55).**

12- P8311, L3, "the deficit is typically shared proportionately to the demands": Because of the reason shown above, the proportion among water sectors is not shared at least in Hanasaki et al. (2008a, 2013a).

Many thanks for the heads-up on this. We corrected this in the paper.

13- P8312, L7, "If the groundwater is considered as an infinite local source (Rost et al. 2008; Hanasaki et al. 2010: : :)": This is not the case for Rost et al. (2008) and Hanasaki et al. (2010). What they assumed infinite was Nonlocal Nonrenewable Blue Water (NNBW) which indicates water sources that are not explicitly represented in their models, namely, water diversion, glacier melting, desalination, and others.

Yes, you are completely right. We corrected this in the revisions. However, from modelling perspective, assuming groundwater or NNBW sources as infinite are quite similar. In fact, (1) both do not consider water shortage; (2) both bring water from outside the modelling domain and (3) the estimation of water withdrawal from either sources wholly depends on how water demand and water supply are estimated at the grid scale. As a result, the errors from these estimations can wholly propagate in to estimation of groundwater or NNBW withdrawals. Please see the revised manuscript (**lines 353 to 359**).

14- P8319, L10, "Impacts assessment and water security studies": It is not very clear what kind of impacts on what are discussed here. For example, the reservoirs influence not only the surface water/energy budget, but also sedimentation (e.g. Syvitsky et al., 2005), ecosystem (Vörösmarty et al., 2010). These issues are not mentioned here.

Many thanks for your comment. In order to avoid further confusions and focus only on the main objective of the paper, we extensively revised this section according to you comment. Please see the revised manuscript **(lines 87 to 108 and 484 to 557).**

15- P8322, L23, "Computational complexities": Personally, I am not very much convinced by this sub-section. It is quite subjective to discuss what is computationally "complex" or "expensive". I am wondering whether this subsection is necessary.

Many thanks for your comment. We removed this subsection; but we modified and incorporated some of the discussion in Section 5.2, which is now dedicated to problems related to online simulations and including groundwater. Please see the revised manuscript **(lines 671 to 681).**

16- P8326, L23, "implement the operation at finer temporal resolution (sub-hourly to few hours rather than daily and monthly)": I am wondering why such finer temporal resolution is needed. The atmospheric processes and reservoirs are primarily connected by the water surface of reservoirs. More specifically, the area and temperature of surface water, if I understood correctly. In most cases, both of them vary slowly, hence the reservoir operation in online modeling might not request such a fine temporal resolution. What I think more important here is that the river inflow to reservoirs by online simulation includes substantial bias compared to offline ones, particularly when it is not assimilated. A fundamental problem here seems to be how to represent reservoirs in a robust manner while the inflow simulation is highly unreliable. An old saying goes "garbage in garbage out".

You are right. This was inaccurate in our discussion and we highly appreciate your careful review of our paper. We revised the discussion accordingly. Please see the revised manuscript **(lines 756 to 769).**

17- Table 1, "Demand-supply dependency": upstream reads downstream.

Many thanks for your comment. We revised the column related to “supply-demand dependency”. Please see the revised manuscript **(Table 1, page 55).**

18- Table 2, "Host model": H07 reads H08 (Hanasaki et al. 2008), and PCR-GLOBW reads PCR-GLOBWB (PCRaster Global Water Balance).

Many thanks for your comment. We corrected these typos. Please see the revised manuscript **(Table 2, page 56).**

19- Table 2 "Discharge data": Does it show the validation data used in earlier studies? It is a bit confusing because many of studies simulated discharge by their models.

Many thanks for your comment. Yes they are mainly for validation except for Wu and Chen (2012) that we indicated that. We added “Validation” before discharge data to avoid confusion. Please see the revised manuscript **(Table 2, page 56).**

III. Point-to-point reply to Anonymous Reviewer #2

We greatly appreciate Anonymous Reviewer #2 for their positive, constructive and thoughtful comments, which led to substantial improvements in the revised version of our manuscript. In the following, the issues raised are addressed point-by-point in the order they are asked. The reviewers’ comments are numbered; our reply to each comment is shown immediately below the comment in blue.

1- I would agree with reviewer #1 that there are a couple of erroneous statements which could be verified by the different modelers.

Many thanks for your suggestion. As indicated in our reply to reviewer #1, we took all reasonable steps to ensure accurate representation of the schemes reviewed. We contacted the main developers. Some of the developers have kindly came back to us and we included their comments into the revised version.

2- the last section suggesting a modeling and testing framework (5.6) seems limited in comparison to the first sections (2,3,4) describing the existing processes. The framework is not put in perspective with respect to the modeling suggestions made in the section 5 subsections. A case study of the suggested framework with one of the example suggested in earlier 5.s section would validate that framework. The point is that if a framework is being suggested in a paper, readers will expect a case study in order to get convinced that this is sound and feasible, even though the paper is already pretty long.

Many thanks for your comment. We try to majorly extend this section using your comments. Please see the revised manuscript **(lines 820 to 928)** In particular, we added a table to summarize the suggested modelling improvements and the spatial and temporal scales at which this is meaningful, and the data required to make it possible in terms of parameterization and validation. We have also added a new figure on how to approach the suggested framework in a sequential manner. We included a very brief discussion on the activities we are currently doing in terms of benchmarking reservoir operation algorithms in the Saskatchewan River Basin, which is a WCRP-RHP. However, we did not provide any detail or simulation results as our investigation is not yet fully finalized and we plan to publish our result in another manuscript.

3- There is a lot of information, which comes in text, and might seem unorganized and sometimes even in opposition to previous call for improvement (especially computational burden and mismatch in space and time scales between LSS, GHS, and management models for example). I would suggest a summary table which specifies for all the suggested improved modeling, the spatial and temporal scales at which this is meaningful, and the data required to make it possible in terms of parameterization and validation at least. I think that this process would make the manuscript easier to properly cite and useful for directions in research.

Many thanks for your comment. We added a new table (**Table 4; see page 58 in the revised manuscript**) in the beginning of Section 5.6 to summarize the suggested modelling improvements and the spatial and temporal scales at which this is meaningful, and the data required to make them possible in terms of parameterization and validation. Please see the revised manuscript **(lines 821 to 837 and Table 4, page 58).**

4- Section 3.3.1: Voisin et al. (2013) actually combines release targets with storage targets, ~ rule curves.

Many thanks for your comment. We consulted with the original article and revised the related discussion accordingly. Please see the revised manuscript **(lines 328 to 334).**

5- Section3.3.2: Although there are advantages to using optimization-based algorithms, the computational burden and need of forecast demand and inflow makes it inappropriate for full online coupling. It is unclear in the paper how the authors see further research on how to integrate them in their vision of future research.

You are absolutely right and we have also noted this in the manuscript and suggested simulation-based algorithms to move forward, especially towards online simulations. However, we feel that we still need to review the existing algorithms for completeness of our review and discuss the pros and cons of both simulation-based and optimization-based algorithms in detail. Moreover, optimization algorithms would be valuable for offline simulation, particularly for integrated impact assessments. We tried to highlight this throughout the revised text. Please see the revised manuscript (e.g., **lines 388 to 393 and 756 to 759**).

6- Section 4: GHMs are used for hydrological application because their hydrology processes are more complex and allow for some calibration. Reservoirs have fixed characteristics and the main driver of uncertainty for reservoir modeling is the bias in the inflow (Muller Schmied et al. 2014). This would need to be put in perspective in terms of direction of research, in the sense that there is a workflow in the modeling improvement; Some things need to be improved first before we can improve other concepts. The idea of workflow could be introduced in the summary table suggested above.

Many thanks for your comment and the reference you introduced. We have incorporated the reference in Section 4, where we discuss the uncertainty related to the inflow to the reservoir. Please see the revised manuscript **(lines 526 to 529 – please also see lines 530 to 535).** We have also suggested a sequential framework to approach model development and testing framework suggested in Figure 2. More specifically, Figure 3 divides the model development into four sequential steps related to (1) benchmarking individual algorithms, data support and host models; (2) building various settings for offline simulations; (3) further improvements and configuring data, algorithms and host models for online simulations; and (4) building various setting for online simulations. Please see the revised manuscript **(lines 889 to 900 and Figure 3, page 61).**

7- Section 5.4: Even in local see regional operational water resources management, different decision support systems are used for handling events at different time scales: i.e. hydropower with a 5 minute market, floods with subhourly to hourly time step, and monthly seasonal water supply. The suggestion to move large scale water management to a sub hourly time scale seems i) irrelevant and ii) in contrast with the need of data for calibration when operation are driven by the market for example, and in constrast with the need to balance computational needs.

Many thanks for your careful reading of our paper. You are absolutely right and the discussion was irrelevant. We have revised the section and also included your discussion on the decision support system in the following call for investing on system identification frameworks. Please see the revised manuscript **(lines 756 to 769 and 784 to 786).**

8- The demand-supply dependency term of "upstream" is confusing. The dependence links the grid to places where water can be withdrawn, i.e. the grid and a couple of reservoir upstream. But those reservoirs are note defined at " 5 grid upstream". Rather, the dependent grid cells are downstream from a reservoir and within 5/10 grid/ 200 km from the impounded river (downstream). Please clarify.

Many thanks for your comment. This issue was noted by reviewer #1 as well. We revised the column to avoid further confusion. Please see the revised manuscript **(Table 1, page 55).**

9- Entries for Voisin et al. are inaccurate: "Dynamic priority in operation" should be changed to irrigation, flood control, hydropowers and others.

Many thanks for careful reading of our paper. We corrected the Table 1 accordingly. Please see the revised manuscript **(Table 1, page 55).**

10- The source of data for Voisin et al. (2013a,b) include USGS, USBR and GRDC as in Haddeland et al. There should be another row for Voisin et al. (2013b) which actually used the Community Land Model (CLM) instead of VIC.

Many thanks for your comment. We included the data sources in the table and added a new row for Voisin et al (2013b). Please see the revised manuscript **(Table 2, page 56).**

On inclusion of water resource management in Earth System models – Part 2: Representation of water supply and allocation and opportunities for improved modeling

Ali Nazemi[1] and Howard S. Wheater[1]

[1] Global Institute for Water Security, University of Saskatchewan, 11 Innovation Boulevard, Saskatoon, SK S7N 3H5, Canada

Correspondence to: A. Nazemi (ali.nazemi@usask.ca)

Abstract

Human water use has significantly increased during the recent past. Water withdrawals from surface and groundwater sources have altered terrestrial discharge and storage, with large variability in time and space. These withdrawals are driven by sectoral demands for water, but are commonly subject to supply constraints, which determine water allocation. Water supply and allocation, therefore, should be considered together with water demand and appropriately included in Earth System models to address various large-scale effects with or without considering possible climate interactions. In a companion paper, we review the modelling of demand in large-scale models. Here, we review the algorithms developed to represent the elements of water supply and allocation in Land Surface Models and Global Hydrologic Models. We noted that some potentially-important online implications, such as the effects of large reservoirs on land-atmospheric feedbacks, have not yet been addressed. Regarding offline implications, we find that there are important elements, such as groundwater availability and withdrawals, and the representation of large reservoirs, which should be improved. Major sources of uncertainty in offline simulations include data support, water allocation algorithms and host large-scale models. Considering these findings with those highlighted in our companion paper, we note that advancements in computation as well as natural and anthropogenic process representations, host models, remote sensing and data assimilation can facilitate improved representations of water resource management at larger scales. We further propose a modular development framework to

consider and test multiple options for data support, algorithms and host models in an integrated model diagnosis and uncertainty assessment framework. We suggest that such a framework is required to systematically improve current representations of water resource management in large-scale models that are relevant to Earth System modeling. A key to this development is the availability of regional scale data. We argue that the time is right for a global initiative, based on regional case studies, to move this agenda forward.

1 Introduction

The water cycle is fundamental to the functioning of the Earth System and underpins the most basic needs of human society. However, as noted in our companion paper (hereafter referred to as Nazemi and Wheater, 2014a), the current scale of human activities significantly perturbs the terrestrial water cycle, with local, regional and global implications. Such disturbances affect both hydrological functioning and land-atmospheric interactions, and therefore, should be explicitly represented in large-scale models. We consider both Land Surface Models (LSMs) and Global Hydrologic Models (GHMs). LSMs generally represent water, energy and carbon cycles, and can be coupled with climate models (i.e. online simulations) for integrated Earth System modeling, or uncoupled from climate models (i.e., offline simulations) for large-scale impact assessment. GHMs are also run in uncoupled mode for impact assessment; however, they have much less detail and focus exclusively on the water cycle. In this pair of papers we focus on the representation of water resources management in these large-scale models, considering water quantity rather than water quality. We note that while historically the effects of water management have largely been neglected in LSMs and GHMs, there has been increasing interest in recent years in their inclusion and a common first step is to estimate the demand for water, in particular associated with irrigation. However, in practice water resource systems are often complex, and associated infrastructure may have competing functional requirements and constraints (e.g. flood protection, water supply, environmental flows, etc.), exacerbated during drought. In this paper, we turn to the issues around water supply and allocation and associated representations in large-scale models.

Major implications are associated with water supply from surface and ground water sources. For instance, large dams and reservoirs can significantly modify downstream streamflow characteristics (e.g., Vörösmarty et al., 2003, 2004; Oki and Kanae, 2006; Wisser et al., 2010;

Tang et al., 2010; Tebakari et al., 2012; Lai et al., 2013; Lehner and Grill, 2013) with large regional variability (see e.g., Pokhrel et al., 2012a). Considering that almost all major river systems in the Northern Hemisphere (except for the arctic and sub-arctic regions) are dammed (e.g., Meybeck, 2003; Nilsson et al., 2005), it can be argued that accurate simulation of continental and global runoff is impossible without considering the effects of reservoirs. Such hydrologic impacts and associated environmental consequences can be studied through offline LSMs or GHMs (see e.g., Döll et al., 2009). There are, however, important implications that require online simulations. For instance, it has been argued that large dams can have important footprints on surface energy (Hossain et al., 2012), with associated effects on land-surface boundary conditions and potential interactions with local and regional climate (MacKay et al., 2009). For understanding these effects, online LSMs, coupled with climate models are required to provide quantitative knowledge of the extent of such impacts in time and space.

Groundwater resources have been also exploited during the "Anthropocene". Every year, a large amount of groundwater is pumped to the land-surface for both irrigative and non-irrigative purposes (e.g., Zektser and Lorne, 2004; Siebert et al., 2010). Such extractions have already caused large groundwater depletions in some areas (Rodell et al., 2007, 2009; Gleeson et al., 2010, 2012; Döll et al., 2014) and changed the surface water balance due to return flows from demand locations to river systems and ultimately to oceans (e.g., Lettenmaier and Milly, 2009; Wada et al., 2010; Pokhrel et al., 2012b). In parallel, a considerable proportion of the surface water, diverted into the irrigated lands, may recharge groundwater (Döll et al., 2012). Also, from a broader perspective, groundwater aquifers (particularly shallow groundwater) can be also an important control on soil moisture and wetlands, and thus influence atmospheric surface boundary conditions (e.g., Maxwell et al., 2007, 2011; Fan and Miguez-Macho, 2011; Dadson et al., 2013). These online effects are widely unquantified at the global scale, as the sub-surface processes below the root zone have been generally assumed to be disconnected from the atmosphere (see Taylor et al., 2013).

In addition to the importance for simulations of terrestrial runoff and storage as well as feedbacks to regional and global climate, representing water allocation practice in large-scale models is urgently required to address various emerging water security concerns including human water supply (e.g. Postel, 1996), ecosystem health (e.g. Vörösmarty et al., 2010), sedimentation (e.g. Syvitsky et al., 2005) and water quality (e.g. Skliris and Lascaratos, 2004). These latter areas are

beyond the scope of this paper, but highlight the need for representing human water allocation in large-scale models for regional and global impact assessments. For instance, the most densely-populated parts of the globe suffer from extremely fragile water supply conditions (e.g., Grey et al., 2013; Falkenmark, 2013; Schiermeier, 2014) and this will be amplified under future climate change and population growth (e.g., Arnell, 2004; Wada et al., 2013b; Rosenzweig et al., 2013). While population growth directly affects water demand, indirect effects include changing land and water management, with associated impacts on the aquatic environment. Similarly, climate change is expected to perturb both water demand and supply, as it also results in greater seasonal and inter-annual variability with increase in the risk of extreme conditions (e.g., Dankers et al., 2013; Prudhomme et al., 2013). Looking to the future, Yoshikawa et al. (2013) argued that current sources can only account for 74 percent of the global net irrigation requirements of the 2050s and supply/demand imbalance will cause a major increase in global water scarcity (Alcamo et al., 2007; Hanasaki et al., 2008a, b, 2013a, b; Schewe et al., 2013). In water-scarce condition, competition for water resources becomes increasingly important and the details of water allocation practice play a key role in the spatial and temporal distribution of water stress. These issues necessitates adaptation strategies to mitigate the effects of water stress and extreme conditions and large-scale models are , therefore, required to assess the effects of various global changes and to examine the impact of alternative management strategies.

Representation of water allocation practice introduces a set of issues associated with management and societal preferences, local and regional differences in decision making, complexity of water resources systems (particularly at larger scales), as well as lack of data support. At local and basin scales, water allocation practice is mainly defined as an optimization problem, in which the aim is to minimize the adverse effects of water shortage and/or to maximize the economic benefits of the water resource system. The advent of search algorithms such as Linear Programming (Dantzig, 1965), Dynamic Programming (Bellman, 1952) and Genetic Algorithms (Goldberg, 1989) has resulted in a wide variety of operational models for water resource management at small basin-scale (e.g., Rani and Moreira, 2010; Hossain and El-shafie, 2013; see Revelle et al., 1969 for the early developments). These small-scale water allocation models, however, typically do not include processes related to water supply and demand and receive these variables as prescribed inputs. Moreover, small-scale operational models often require detailed information about policy constraints and operational management. This information is not generally available over larger

regions and at the global scale. Even if all related information were to be available, the level of complexity within small-scale operational models cannot be supported globally due to high dimensionality in decision variables and computational burdens. These restrictions have gradually resulted in the development of macro-scale algorithms to represent water allocation practice and competition among demands at regional and global scales.

The main objective of this paper is to overview the current literature and to identify the state of available methods and applications for large-scale representations of water supply and allocation in LSMs and GHMs, with relevance to both Earth System modeling and regional and global water management. Section 2 addresses the representation of surface and ground water sources. Section 3 discusses the linkage between available sources and prescribed demands (see Nazemi and Wheater, 2014a) through macro-scale allocation algorithms. Section 4 reviews current large-scale modeling applications and discusses the quality of available simulations. Section 5 merges the findings of Nazemi and Wheater (2014a) with those obtained in Sections 2 to 4, and highlights current gaps and opportunities from an integrated water resources, hydrology and land-surface modeling perspective. This is finalized by suggesting a systematic framework for model development and uncertainty assessment to guide future efforts in inclusion of water resource management in large-scale models. Section 6 closes our survey and provides some concluding remarks.

2.1 Lakes and reservoir

Deleted: R

Deleted: storage

Natural lakes and man-made reservoirs cover more than 2 percent of the global land surface area except for Antarctica and glaciated Greenland (Lehner and Döll, 2004). Lakes and reservoirs are important water sources due to their ability to store and release surface water for human demand. While natural lakes have been historically an important water source for human civilization, man-made reservoirs have been mainly constructed since the last century. Currently, there are more than 16 million reservoirs worldwide (Lehner et al. 2011), retaining around 20 percent of the annual runoff and 10 percent of the total volume of the world's freshwater lakes (Gleick, 2000; Meybeck, 2003; Wood et al., 2011). This makes an important global water resource: Yoshikawa et al. (2013) estimated that reservoirs allocated 500 cubic kilometers only for irrigation during the year 2000, worldwide.

From the large-scale modeling perspective, lakes and reservoirs introduce heterogeneity into land-surface parameterizations, with both offline and online implications. To represent these open water bodies, first they should be identified at the grid and sub-grid scales. The availability of basic data for larger lakes and reservoirs is relatively good (see Lehner and Döll, 2004 for a comprehensive list of data sources). For instance, the Global Lakes and Wetlands Database (GLWD; http://www.worldwildlife.org/pages/global-lakes-and-wetlands-database) includes more than 250,000 lakes globally. In addition, the International Commission of Large Dams (ICOLD; http://www.icold-cigb.net/) and Global Reservoir and Dam (GRanD; http://www.gwsp.org /products/grand-database.html) databases contain information about the location, purpose and capacity of 33,000 and 7000 large dams, worldwide. However, to estimate evaporation, as well as storage and release, more specific physical characteristics, such as storage-area-depth relationships, are required. These data are generally not available and parametric relationships have been used for approximating these properties based on various assumptions (e.g., Takeuchi, 1997; Liebe et al., 2005). Nonetheless, at this stage of model development, reservoir simulations cannot be directly verified, due to the lack of observations of reservoir level and storage (Gao et al., 2012). These data limitations may be largely solved in a relatively near future by upcoming satellite missions – see the discussion of Section 5.3 below.

Depending on their size, lakes and reservoirs can be represented either within channel or sub-grid routing components of host large-scale models. While larger lakes and reservoirs are normally represented within the river routing component and regulate the channel streamflow, smaller bodies are mainly considered within sub-grid parameterizations as an additional pond (e.g., Döll et al., 2003; Wisser et al., 2010). Ideally, natural lakes and reservoirs should differ in their representation due to human management. If human management is neglected, reservoir releases can be represented similar to natural lakes using simple parametric equations that link the reservoir release to reservoir storage (or level) (e.g., Meigh et al., 1999;, Döll et al., 2003; Pietroniro et al., 2007; Rost et al., 2008). Lake algorithms, however, have had limited success in highly regulated basins. This is rather intuitive: for natural lakes, the dynamics of lake storage (and hence discharge) are regulated by climate and inflow variability, whereas the dynamics of reservoir discharge (and hence storage) are mainly controlled by pressures of downstream demands and management

decisions. Moreover, reservoirs are often multi-functional and deal with competing demands with varying priority in time; therefore, simple lake routing algorithms are unable to fully describe reservoir functionality. Alternatively, macro-scale algorithms for reservoir operation are suggested, which attempt to link reservoir releases to inflows, storage and prescribed human demands considering water allocation objectives – see Section 3.3.

Considering online implications, the effects of dams on near-surface energy and moisture conditions and hence land-atmospheric feedbacks can be important for large reservoirs (Hossain et al., 2012). Addressing this issue using coupled LSMs is currently a major gap in the literature and exhibits a challenging problem at the grid scale, since the contribution of dams on the local climate can be masked by regional climate variability and surrounding land cover (e.g., Zhao and Shepherd, 2011).

Deleted: LSS

2.2 Streamflow diversions and inter-basin water transfers

Streamflow diversions of any magnitude require dams or barrages. At smaller scales, these include in-basin water transfers from local streams to nearby demands. In-basin diversions are often represented in large-scale models by instantaneous abstractions (e.g., Hanaski et al., 2008a, 2010; Döll et al., 2009). Hydrologic routing can be alternatively considered for improved representation (e.g., Wisser et al., 2010). It should be noted that a proportion of the diverted flow normally returns to the river systems. Heuristic algorithms have been advised to mimic the mechanism of diversion based on returning the excess water to the river with some lag. Biemans et al. (2011) for instance represented the dynamics of diverted/return flows for irrigated areas by making water available for consumption for 5 days; if unused, it is released back to the river. This can have an important implication for differentiating between the actual use and total withdrawals, in case water is over-allocated.

Deleted: s

Deleted: not

Inter-basin water transfers normally involve major infrastructure and can significantly perturb the regional streamflow regime. For instance, proposed South to North water transfer schemes in China (see Liu and Zheng, 2002; Liu and Yang, 2013) would divert 44.8 billion cubic meters of water annually (http://www.internationalrivers.org/). The associated hydrological impacts are estimated to be as, or more significant than, land-use and/or land-cover changes (Liu et al., 2013). Inter-basin water transfer can be adequately represented by hydrologic routing. Examples are available for some regional applications (e.g., Nakayama and Shankman, 2013a, b; Ye et al., 2013); however, efforts to represent long-distance diversions at the global scale are limited. This is mainly due to data issues regarding the location and specification of diversion channels globally. This could be largely resolved in future due to improvements in remote sensing observations – see the discussion of Section 5.3 below.

2.3 Groundwater

Even large-scale models with detailed water resource management schemes have limited representation of groundwater availability (see Table 1), largely due to the limitations in data related to groundwater storage, withdrawals and sub-surface properties as well as computational difficulties. There have been some efforts to include groundwater in LSMs to describe the aquifer dynamics, land-atmospheric feedbacks and watershed responses, mainly at basin and small regional scales (e.g., Maxwell and Miller, 2005; Maxwell et al., 2005, 2007, 2011; Kollet and Maxwell, 2008; Ferguson and Maxwell, 2010; Miguez-Macho and Fan, 2012). These studies consider a physically-based groundwater store, which can be updated at each modeling time step using a 3D representation of groundwater movement, and linked to land-surface calculations through soil moisture dynamics. Such representations are computationally expensive and limited at the global scale, since temporal and spatial domains should be finely gridded for accurate representations of groundwater movement and soil-moisture interactions, particularly in online studies. To the best of our knowledge, no online study, characterizing the feedback effects between groundwater management and climate, is available at the global scale. Offline representation of groundwater management has mainly been performed in the context of GHMs and involves estimation of available groundwater storage, sub-grid groundwater recharge and groundwater withdrawals. In this section, we focus on groundwater availability and recharge and leave the discussion related to groundwater withdrawals to Section 3.2.

In current representations, often groundwater availability in general, or the nonrenewable and nonlocal blue water (NNBW) in particular, is assumed as an unlimited local source (e.g., Rost et al., 2008; Biemans et al., 2011; Pokhrel et al., 2012a,b). NNBW is a technical term defined as an "imaginary" source that implicitly accounts for nonrenewable fossil groundwater or other water sources that are not explicitly represented in the model. This can cause major uncertainties in estimation of actual withdrawals (see Section 3.2). Efforts have been made to improve this

Deleted:)

Deleted:

assumption. For instance, Strzepek et al. (2012) bounded groundwater availability by considering a threshold for groundwater allocation. Wada et al. (2013a) proposed a conceptual linear groundwater reservoir, parameterized globally based on lithology and topography, to estimate the groundwater availability at the grid-scale using the baseflow proxy. Although this conceptual representation provides an efficient scheme for global simulations, it ignores the baseflow reduction due to groundwater depletion. In a more recent attempt, Döll et al. (2014) continuously simulated the daily groundwater storage using the difference between groundwater recharge and the sum of baseflow and net groundwater abstraction, with base flow declining with decreasing groundwater storage. Both algorithms, however, do not consider inter-grid lateral groundwater movement, which is an important contributor of water availability across various scales. Although lateral groundwater movement is widely studied in aquifer studies at smaller basin and regional scales (e.g., Ye et al., 2013), it is currently a key missing process representation at larger regions and global scales (Taylor et al., 2013).

Groundwater recharge includes the movement of water from the unsaturated soil zone to a saturated groundwater body. There are a number of approaches to represent the vertical water movement in large-scale models, including heuristic methods (e.g., Döll et al., 2003), conceptual “leaky-buckets” (e.g., Wada et al., 2010), or numerical solutions of the physically-based Richards’ equation (Best et al., 2011; D. B. Clark et al., 2011). These approaches are based on various assumptions and are subject to large uncertainties. Heuristic schemes relate the recharge rate to surface runoff, using a set of parameters based on catchment, soil and aquifer characteristics. These representations are often simplistic and may result in large estimation errors, particularly in arid and semi-arid regions (Polcher et al., 2011). Conceptual approaches widely assume a steady-state condition and use the unsaturated hydraulic conductivity to represent groundwater recharge with or without considering capillary rise (van Beek and Bierkens, 2008; Wada et al., 2010; van Beek et al., 2011; Wada et al., 2013a; Ye et al., 2013). In a global study, Wada et al. (2012) used this approach to account for additional recharge from irrigated lands based on the unsaturated hydraulic conductivity at the field capacity. This can be important for representing the excess water diverted from both surface and groundwater sources. Although conceptual representations are efficient for large-scale studies, still limitations remain in these schemes due to large heterogeneities in soil characteristics, a common assumption of steady-state recharge rate, as well as the inherent uncertainty associated with soil hydraulic properties. The physically-based approaches remove the

Deleted: the

Deleted: .

Deleted: to

steady-state assumption; nonetheless as discussed above, they require a detailed numerical scheme for solving a highly non-linear partial differential equation. This is subject to various computational difficulties at larger scales, and invariably there is a gap between the scale for which Richards' equation was developed and the scale at which it is implemented in large-scale groundwater and hydrologic models (Beven, 2006a; Gentine et al., 2012).

2.4 Desalination and water reuse

Water reuse and desalination are currently minor water resources at the global scale and have been widely ignored in large-scale models. Nonetheless, it should be noted that these water sources have local relevance and are important in several water-limited regions (Wade Miller, 2006; Pokhrel et al., 2012a). Wada et al. (2011) estimated that annual desalinated water use is around 15 cubic kilometers globally, of which Kazakhstan uses 10 percent of the total volume. Desalinated water availability can be estimated using a bottom-up approach based on the information available about treatment and water reuse capacity at the grid-scale (Strzepek et al., 2012). These data, however, are limited and uncertain globally. Alternatively, top-down approaches try to downscale the countrywide water reuse data. Wada et al. (2011, 2013a), for instance, downscaled the countrywide data on water reuse and desalination using a gridded population map. Considering that water reuse and desalination will likely be more important in future due to increased water scarcity at the global scale, we suggest more effort in representing these sources, including data collection to support future algorithm developments – see Section 5.3 below.

Deleted:

3 Available representations of water allocation in large-scale models

Water allocation distributes the available water sources among competing demands and should typically include a set of management decisions to systematically (1) link the prescribed demands to available sources of water; (2) determine allocation objectives as well as priorities in case of water shortage; and (3) withdraw the available water based on operational objectives and management constraints. At this stage of model development, there are limited examples for representation of water allocation at larger scales. These studies are offline and have multiple sources of uncertainty. Table 1 summarizes some examples from the recent literature. In this section, we briefly discuss the main requirements and available algorithms for representing the water allocation in large-scale models.

3.1 Main requirements

The first basic requirement is to identify which sources are available to supply the water demands within each computational grid. The majority of current allocation schemes assume that grid-based demands can be supplied from the sources available within the grid locally. This assumption is intuitive and easy to implement, however, it naturally ignores long distance water transfers. Various modifications have been proposed to overcome this limitation. Relative elevation and travel time of water from source to demand have been used to condition demands to available sources upstream. For example, Hanaskai et al. (2006) assumed that large reservoirs can supply downstream demands that are located within 1100 km (based on a travel time of 1 month). Similarly, Wada et al. (2011) considered a criterion of approximately 600 km and Biemans et al. (2011) 250 km. These rules are evidently simplistic but can be easily implemented. They also generally assume steady-state conditions, so that the allocated water can be simply abstracted from the source and added at the demand location at the same time step. Alternatively, routing schemes can provide a more accurate basis for representing the water delivery and avoid this limitation – see the discussion of Section 5.5 below.

The second important issue is to determine objectives of and priorities for water allocation, particularly during shortage. In the absence of access to local operating rules, this requires defining a set of generic rules to assign the relative preference of each demand and to define the purpose of water allocation. Both Irrigative (e.g., Rost et al., 2008; Döll et al., 2009; Wada et al., 2013a) and non-irrigative demands (e.g., Hanasaki et al., 2008a; Strzepek et al. 2010, 2012; Blanc et al., 2013) have been given the highest priority. In cases where multiple demands with the same priority are derived from a unique source of water, the deficit is typically shared proportionately to the demands (e.g., Biemans et al., 2011). Based on priorities and assumptions made regarding water availability, several allocation objectives have been used (see Table 1). It should be noted that water resource management is commonly multi-purpose and allocation objectives and priorities can change within a typical operational year. For example, many reservoirs are designed for two conflicting objectives, i.e. irrigation supply and flood control. To account for this, Voisin et al. (2013a) used rule curves to specifically drop the reservoir storages before snowmelt starts while

maintaining the storage in the reservoir to provide releases for irrigation, water supply and hydropower in the remaining part of the year. More specifically, they developed flood control storage targets to complement the irrigation release targets, with mass balance conservation. They also allowed for a linear drop in storage as a device to represent the operational balance between maintaining storage and releasing flow for hydropower purposes. They showed that this modification can improve the simulation of regulated flow and maintain the spatiotemporal consistency of reservoir levels.

Finally, allocation algorithms are required to estimate groundwater abstractions and reservoir releases at each simulation time step based on allocation objectives and priorities. Groundwater abstraction algorithms are generally limited, due to significant gaps in information about groundwater availability and actual groundwater withdrawals at the global scale. Although current data availability for reservoir levels and storages is also poor, runoff data are relatively available regionally and globally, which can be used for algorithm development and performance assessment through comparison of simulated and observed discharges downstream of reservoirs. Apart from local or national data, data of the Global Runoff Data Centre (GRDC; http://www.bafg.de/GRDC/) have been widely used for validation of macro-scale reservoir operation algorithms.

3.2 Grid-based groundwater abstractions

Groundwater abstractions include both sustainable and unsustainable water uses. While sustainability of groundwater withdrawals is a complex issue, in particular related to environmental impacts of abstraction, the distinction between these for large-scale applications is generally based on the grid-based groundwater recharge, as any abstraction exceeding recharge rate results in groundwater depletion, and therefore, can be considered as unsustainable. So far, groundwater withdrawals have been estimated through either bottom-up or top-down algorithms, both subject to large uncertainty.

In bottom-up procedures, the groundwater abstraction is identified using grid-based estimates of surface and groundwater availability as well as the water demand. If the groundwater and/or NNBW is considered as an infinite sources (Rost et al., 2008; Hanasaki et al., 2010; Wisser et al., 2010; Pokhrel et al., 2012a,b), then the groundwater or NNBW abstraction is equal to estimated

demand minus estimated water availability at the grid scale. In this case, priorities are not inherently considered; however NNBW has the advantage that it explicitly accounts for the water that should come to the system from outside the modeled domain. If the groundwater availability is bounded at the grid or basin scale, then the maximum groundwater withdrawal cannot exceed the local groundwater availability (e.g. Strzepek et al., 2012; Wada et al., 2013a); however, errors in estimations of surface water availability and water demands can still directly propagate into estimation of groundwater withdrawals.

Deleted: surface

Deleted: l

Deleted: its

Deleted: .

Deleted: still

Top-down approaches are based on using recorded regional groundwater withdrawals or downscaling national groundwater abstractions data to finer spatial scales. Siebert et al. (2010) created a global data for irrigation water supply from groundwater abstractions based on FAO-AQUASTAT (http://www.fao. org/nr/water/aquastat/main/index.stm) and other census and sub-national data. In an another effort, Wada et al. (2010, 2012) used the data of the International Groundwater Resources Assessment Center (IGRAC; www.igrac.net) to estimate the countrywide groundwater use for year 2000. These estimates were further downscaled to 0.5°×0.5° grids, based on a global map of yearly total water demand. In a countywide study, Blanc et al. (2013) used the groundwater withdrawal data of the USGS for the year 2005 (USGS, 2011) and repeated the data for every year of simulation. These approaches are also limited by the fact that the actual groundwater pumping might be considerably more than the recorded data (e.g., Foster and Loucks, 2006; Wada et al., 2012) and groundwater withdrawals can have considerable inter-annual variability. Current and upcoming remote sensing technologies can address some of the issues around groundwater data availability – see Section 5.3 below.

3.3 Macro-scale reservoir operation

Current macro-scale reservoir operation algorithms are designed for offline applications and included in large-scale models for characterizing the impacts of reservoirs on terrestrial water storage, runoff and water security. These algorithms can be roughly divided into two general categories based on either simulating the reservoir release using a set of prescribed operational rules or using search algorithms to find optimal reservoir release. In brief, simulation-based schemes are based on a set of functional rules that use initial storage as well as inflows and demand pressure during a typical operational period to simulate releases during the operational period. In contrast, optimization-based algorithms search for optimal releases at each time step given an ideal storage at the end of the operational year, storage at the beginning of the year and forecast inflows and demands during the year. Naturally, optimization-based algorithms are more computationally expensive; nonetheless, they are more suitable for evaluating competition among water demands and effects of policy change, due to the ability to explicitly include multiple allocation objectives to guide the search for optimal releases. In contrast, simulation-based algorithms are more efficient and can be modified to support online simulations – see Section 5.4. Table 2 summarizes some representative examples from the current literature.

3.3.1 Available simulation-based algorithms

Current simulation-based algorithms are heavily influenced by the work of Hanasaki et al. (2006), which was initially proposed for global routing models but extended to GHMs (Hanasaki et al., 2008a, 2010) and LSMs (Pokhrel et al., 2012a,b). The algorithm distinguishes between operational rules for irrigation and non-irrigation purposes. The algorithm also accounts for both inter-annual variability and seasonality in reservoir releases. In simple terms, the total release in a typical operational year is first determined based on the reservoir capacity, initial storage and the annual mean natural inflow to the reservoir. Second, the monthly fluctuations in the reservoir release are parameterized based on annual mean natural inflow, mean annual demand and the prescribed monthly demand. Note that demands are considered as total water withdrawals rather than consumptive uses. Finally, monthly fluctuations are corrected based on inter-annual variability in total reservoir releases (estimated during the first step) to provide actual monthly reservoir releases. The correction, depending on the purpose and size of reservoir, is based on the ratio of initial reservoir storage to total capacity, the ratio of reservoir capacity to annual mean inflow, and/or the monthly mean natural inflows to the reservoir – see Hanasaki et al. (2006) for related formulations.

Deleted: LSS

Hanasaki et al.'s algorithm has been widely used in the recent literature as it provides a generic and flexible framework to represent reservoir operation. Döll et al. (2009) implemented this algorithm for representing operation of large reservoirs within the framework of WaterGAP (Alcamo et al., 2003). They considered some modifications to accommodate losses from the reservoir and to characterize the dynamics of demand pressure on reservoirs based on consumptive uses rather than total water withdrawals. Biemans et al. (2011) modified Hanasaki et al.'s algorithm by extracting the reservoir releases using annual and monthly mean regulated inflows (rather than corresponding natural flows), limiting the demand pressure only to irrigation and changing the release rules during high demand periods. These modifications were further added to the Joint UK Land Environment Simulator (JULES; Best et al., 2011, Clark et al., 2011a) for offline simulations (Polcher et al., 2011). Voisin et al. (2013a) made a regional intercomparison between various simulation-based algorithms for the Columbia River Basin and concluded that deriving releases based on withdrawals rather than consumptive uses results in improved simulations of downstream flows. They also indicated that the choice of natural or regulated inflows depends on the severity of the demand pressure and water allocation: If the overall water demand is high with respect to mean annual inflow, it would be better to drive the algorithm with mean monthly regulated inflow; otherwise it is better to use the natural flow, due to large uncertainties associated with water demand estimates, and therefore, regulated flows. Although this study is limited to one region, it provided an assessment of uncertainties in estimating the reservoir releases due to uncertainties in estimating both inflows and water demand – see the discussion of Section 4.

Deleted: in

Deleted: .1

Existing simulation-based schemes are not limited to the above algorithms. Efforts have been made to simulate the reservoir releases using parametric functions, in which the parameters can be calibrated using observed downstream flows. For example, Wisser et al. (2010) advised a set of functional rules to parameterize the release from large reservoirs using the actual inflow and the long-term mean inflow to the reservoirs. More recently, Wu and Chen (2012) proposed a new algorithm by explicit consideration of operational rule curves, locally specified for each reservoir. In brief, rule curves are a set of pre-defined reservoir levels that divide the total reservoir capacity into different storage zones. These storage zones can be further associated with demands conditioned on the reservoir using various assumptions. The algorithm considers the reservoir operation at a given day as a deviation from mean releases at that day and represents this by a weighted sum of individual variations as the result of allocation for each individual water demand. Demand-specific allocations can be therefore characterized based on rule curves, the available storage, total capacity as well as the history of inflow to the reservoir. Accordingly the total release at any given day can be defined as a parametric function, in which the parameters can be tuned using observed downstream flows. Although they noted that the operational parameters are inherently time-varying, as the purpose of dam can change with time, a systematic scheme for

Deleted: ,

dealing with non-stationary parametric estimation has not been provided. This remains for future efforts – see Section 5.4.

3.3.2 Available optimization-based algorithms

Optimization-based schemes were initially proposed by Haddeland et al. (2006a) and implemented further in Haddeland et al. (2006b, 2007). These algorithms are heavily inspired by small-scale reservoir operation algorithms within the engineering literature, particularly Dynamic Programming (see Voisin et al., 2013a), and strongly rely on estimates of future inflow and demand. Therefore, they are not suitable for online simulations, however they can be valuable for integrated impact assessment over large grids and/or assessment regions in offline mode (see e.g., Strzepek et al., 2010; 2012; Blanc et al., 2013). In brief, the calculation starts by targeting the reservoir storage at the end of a typical operational year based on forecast demands, but without considering forecast inflows. Then, the minimum release at each daily time step is defined based on the natural streamflow at the dam's location to maintain a minimum flow requirement downstream of the reservoir. Accordingly, the maximum allowable daily release is determined based on simulated daily inflow, minimum release, reservoir storage at the beginning of the day and the targeted storage at the end of operational year. Minimum and maximum releases introduce a feasible release range, where a search algorithm can be used to find the optimal monthly releases that provide the minimum deficit during the year and the least violation from the target storage at the end of the year. Adam et al. (2007) slightly changed this algorithm by considering new thresholds for allowable release and storage and used maximization of hydropower revenue as the objective function for reservoir operation.

There are two main issues with the proposed scheme. First, feasible reservoir releases are determined based on forecasts of natural flow at dam location; therefore, the algorithm essentially requires estimating both natural and regulated flow at each simulation time step. Second, a high dimensional search (e.g. 12 releases in the case of a monthly release simulation) must be performed for each operational year, and given the uncertainty in prognostic inflows, this can result in considerable uncertainty in the optimality of actual releases. These issues were noted by van Beek et al. (2011). They modified Haddeland et al. (2006a) algorithm to decrease the complexity and uncertainty associated with the algorithm. Most importantly, they defined the expected inflow for each month prospectively as a function of the flow in the same month of the previous years;

therefore, they omitted using prognostic natural flow forecasts. In order to reduce the dimensionality of search, they considered reservoir release as a harmonic function; therefore, only release at beginnings of the release and the discharge periods needed to be determined. As the actual inflow values become available, the release can be consequently updated so that the final storage at the end of release period can meet the predefined target storage. With respect to determining the reservoir inflow based on naturalized or regulated flows, van Beek et al. (2011) noted that either set-ups can be used, depending on how the observed discharge is simulated at the large-scale. This is due to large uncertainties in simulating the regulated runoff – see the discussion below.

4 Current large-scale modeling application

Water supply and allocation schemes reviewed in Sections 2 and 3 have been used in a wide range of offline applications for estimation of human impacts on the terrestrial water cycle. Despite disagreements between different simulation results, the current literature agrees that the effects of water allocation are more pronounced at finer spatial and temporal scales. For example, Haddeland et al. (2007) studied the impacts of reservoir operation coupled with irrigation on continental runoff and argued that water allocation has resulted in 2.5 and 6 percent increase in annual runoff volume in North America and Asia, respectively. This is almost canceled out by increased evaporation due to irrigation. Nonetheless, as the analysis moves from global and continental to regional and large catchment scales, the effects of water allocation become more profound. For instance, while the mean annual runoff decreased in the western US by around 9 percent during a historical control period, the rate of decrement is around 37 percent in the Colorado River during the same period (Haddeland et al., 2006b). Similarly, the effects of water allocation are more significant at finer time scales. For instance, Adam et al. (2007) noted that reservoirs have a minor effect on annual flows in Eurasian watersheds but have significant seasonal effects by changing the flow timing and seasonal amplitudes (see also Döll et al., 2009; van Beek et al., 2011, Biemans et al., 2011).

These simulations, however, are highly uncertain due to major limitations in algorithms reviewed above, host large-scale models and data support. The efficiency of available water allocation algorithms can be diagnosed by comparing the streamflow obtained from simulations with observations. Currently, macro-scale water allocation schemes cannot fully describe the dynamics

of regulated streamflows and there can be major disagreements between the regulated discharges obtained from different reservoir algorithms (Voisin et al., 2013a). It has been shown that calibration can improve the quality of reservoir operation algorithms (e.g. Wu and Chen, 2012); however, calibration is also associated with uncertainty and can potentially hinder model applications for future projections due to possible temporal and spatial variations in optimal parameters. Hanasaki et al. (2006) as well as Döll et al. (2009) showed that simulation-based algorithms can generally provide improved discharge simulations compared to lake routing algorithms. However, it should be noted that simulations still remain substantially biased in highly regulated catchments (e.g. San Francisco River, US; Syr Darya, Central Asia) and in cold regions (e.g. Saskatchewan and Churchill Rivers in Canada), particularly during high flows (e.g. Hanasaki et al., 2008a; Biemans et al., 2011; Pokhrel et al., 2012a). The simulation algorithm of Wu and Chen (2012) was found to be more accurate in simulating both storage and release compared to simple multi-linear regression and the target-release scheme embedded in SWAT (Arnold et al., 1998); however, it was tested only at the local scale and it is not clear how the algorithm can perform in other regions with different climate, level of regulation and allocation objectives. Very similar conclusions were obtained for optimization-based algorithms. Discharge simulations are generally improved compared to the no reservoir condition (e.g., Haddeland et al., 2006a); however, there are still significant deficiencies in simulating highly regulated flows, particularly in mountainous and cold regions such as Colorado River in the US as well as Yukon and Mackenzie Rivers in Canada (e.g., Haddeland et al., 2006b; Adam et al., 2007). This relates in particular to prognostic reservoir inflows, which remain highly uncertain in these environments; this uncertainty contributes to the uncertainty in assigning optimal reservoir releases, often in dynamic and complex manners (Nazemi and Wheater, 2014b; Muller Schmied et al. 2014).

Deleted: majorly

Deleted: and

From a broader perspective, the current performance of reservoir operation and water allocation algorithms must be seen in the context of the hydrological performance of the host large-scale models, including how well the water demand has been represented (see Nazemi and Wheater, 2014a). Currently, there are large biases in modeling hydrological processes across various scale and runoff estimates remain widely divergent (e.g., Wisser et al., 2010; Hejazi et al., 2013b). More clearly, it has been shown that current simulations systematically underestimate streamflow in the arctic and sub-arctic regions and overestimate the observations in dry catchments; and reservoir operation algorithms mainly improve the timing of the flow, but not the volume (van Beek et al., 2011). While there are many potential reasons for this, one key source of this limitation is the quality of gridded precipitation products (Biemans et al., 2009; 2011). Rost et al. (2008) used different precipitation products to simulate the regulated river discharge and found substantial variations in simulated discharge due to the choice of precipitation data. Moreover, they showed that sometimes the total precipitation estimate could be less than the total observed discharge after abstraction and regulation. Upcoming satellite missions can address some of the issues regarding historical forcing (see the discussion of Section 5.3); however, uncertainty in future precipitation (and other climate variables) should be dealt systematically using multiple climate forcing options based on various combinations of concentration pathways, climate models and downscaling procedures.

Turning from surface water to groundwater issues, almost all available global studies agree on a significant increasing trend in groundwater withdrawal from the late 20th century onward. As an example, Wada et al. (2013a) argued that from 1990 to 2010, the rate of global groundwater withdrawal increased by around 3 percent a year. These results are in relatively good agreement with major observed depletions in some regional aquifers (see Gleeson et al., 2012). However, various quantified assessments and further conclusions such as regarding groundwater-induced sea-level rise remain highly uncertain and show major disagreements due to crude representation of groundwater availability, recharge and withdrawal, as discussed in Sections 2.3 and 3.2 (see e.g., Wada et al., 2010; Pokhrel et al., 2012b; Döll et al., 2014). This highlights an urgent necessity for improving the representation of human-groundwater interactions at larger scales.

5 Towards an improved representation of water resource management in large-scale models

5.1 Ideal representation and remaining gaps

Throughout our survey, we highlighted the importance of including water supply and allocation in conjunction with water demand (see Nazemi and Wheater, 2014a) in models that are relevant to Earth system modeling and/or are required for understanding the effects of water resource management on the Earth System, with both online and offline implications. From an integrated water resource management and land-surface modeling perspective, water demands can be

Moved up [2]: Despite modeling uncertainties and disagreements simulation results, the current literature agrees that the effects of water allocation are more pronounced at finer spatial and temporal scales. For example, Haddeland et al. (2007) studied the impacts of reservoir operation coupled with irrigation on continental runoff and argued that water allocation has resulted in 2.5 and 6 percent increase in annual runoff volume in North America and Asia, respectively. This is almost canceled out by increased evaporation due to irrigation. Nonetheless, as the analysis moves from global and continental to regional and large catchment scales, the effects of water allocation become more profound. 4.1 Quality of regulated streamflow simulations¶
Despite important developments, current macro-scale water allocation schemes cannot fully describe the dynamics of regulated streamflows and there can be major disagreements between the regulated discharges obtained from different reservoir algorithms (Voisin et al., 2013a). It has been shown that calibration can improve the quality of reservoir operation algorithms (e.g. Wu and Chen, 2012); however, calibration is also associated with uncertainty and can potentially hinder model applications for future projections due to possible temporal and spatial variations in optimal parameters. Hanasaki et al. (2006) as well as Döll et al. (2009) showed that simulation-based algorithms can generally provide improved ...

considered as functions of climate, vegetation and soil-moisture as well as socio-economic and policy variables (see Nazemi and Wheater, 2014a). As shown in this paper, water supply is driven by water demands but controlled by natural surface and ground water availability, which determine the maximum possible water allocation. Therefore, water demand and water supply should be systematically linked through a feedback loop, represented by water allocation. This integrated water resource system should be then linked to natural land-surface processes at the grid scale. This is rather intuitive: When considered in a typical grid, water allocation perturbs hydrological and land-surface variables within the grid. In parallel, the combined effects of land-surface and hydrological processes govern the variations in surface and ground water availability, which consequently determine water demand (and accordingly water allocation) in the next simulation step. Figure 1 shows a simplified schematic for this integrated modeling framework, in which grid-based calculations of natural and anthropogenic land-surface are further coupled with climate through grid-based land-atmospheric feedbacks.

Major gaps remain in representing water resource management in LSMs in the way defined above. First, as also discussed in Nazemi and Wheater (2014a), the key consideration in Earth System modeling is the conservation of mass, energy and water; however, this is largely violated in current models that include elements of water resource management (see Polcher, 2014). For instance, considering groundwater or NNBW as unlimited water sources necessitates bringing water to the system from outside the modeling domain, breaking the assumption that the Earth System is a closed system. This has particular importance when understanding the effects of human-water interactions on the climate and sea-level rise is sought.

Deleted: a

Deleted: s

Deleted: of

Deleted: and

Deleted: ,

Second, water resource management often takes place at the sub-grid resolution of current LSMs used for simulations over large regional and global scales (i.e., 50 kilometers and more). Including the elements of water resource management therefore requires moving towards a “hyperresolution” scale (a few kilometers or less) for explicit representation (see Wood et al., 2011) and/or adding new sub-grid parameterizations related to human-water interactions, as illustrated in Figure 1. However, as the resolutions become finer or more sub-grid parameterization are added, modeling complexity, computational burdens and data requirements increase significantly, particularly in online simulation in which finer modeling resolution and better discretization of soil and vegetation is generally required to capture land-atmospheric feedbacks and possible climate responses (see Sorooshian et al., 2011a).

Third, we have noted that all currently available efforts in including water supply and allocation in large-scale models are offline and have been made mainly in the context of GHMs. GHMs provide an efficient platform for algorithm development and testing given the relative lack of computational constraints. However, self-evidently understanding online effects of large reservoir storage and large-scale groundwater pumping needs online simulations using coupled LSMs. At this stage of model development, however, many algorithms originally designed for offline applications might not be suitable for online implementations. An important example is reservoir operation, as both optimization- and simulation-based algorithms have some levels of prognosis that hinder their application in coupled simulations.

Fourth, online applications are associated with complexity in representing various feedbacks and time-scaling mismatch among different LSM component and water resource management. In addition, current performance of online simulations is limited due to significant biases across different components and propagation of these biases throughout the fully coupled system (see Yuqing et al., 2004)

Fifth, we have highlighted major limitations even in offline representation of water resource management at larger scales due to various sources of uncertainty. These uncertainties are due to (1) data support, particularly with respect to precipitation, actual water use and land-surface characteristics; (2) water demand, supply and allocation algorithms, particularly with respect to irrigation demand estimation, reservoir operation and groundwater withdrawals; as well as (3) host large-scale models, particularly with respect to those calculations that determine surface and ground water availability. It should be noted that here we only focus on epistemic sources of uncertainty, which needs to be addressed, quantified, communicated and possibly reduced (see Beven and Alcock, 2012). Table 3 summarizes various aspects of uncertainty related to data support, algorithmic procedures and host models, identified for estimation of water demand (see Nazemi and Wheater, 2014a) as well as water supply and allocation (see Sections 2 to 4) in offline mode. It is often quite difficult to identify the exact source of uncertainty due to complex interconnections between various elements; and currently, a formal framework to test and validate the water resource management components in the face of various sources of uncertainty is not available (see also Beven and Cloke, 2012).

Moved up [3]: From an integrated water resource management and land-surface modeling perspective, water demands can be considered as functions of climate, vegetation and soil-moisture as well as socio-economic and policy variables (see Nazemi and Wheater, 2014a). As shown in this paper, water supply is mainly controlled by natural surface and ground water availability but water demands remain as the key driver of water allocation. Therefore, water demand and water allocation should be systematically linked through a feedback loop. Also, as noted in Section 3.1, various human-water interactions are coupled and linked to available water sources through water allocation practice. This integrated water resource system should be then linked to natural land-surface processes at the grid scale. This is rather intuitive: When considered in a typical grid, water allocation perturbs hydrological and land-surface variables within the grid. In parallel, the combined effects land-surface and hydrological processes govern the variations in surface and ground water availability, which consequently determines water allocation in the next simulation step. Figure 1 shows a simplified schematic for this integrated modeling framework, in which grid-based calculations of natural and anthropogenic land-surface are further coupled with climate through grid-based land-atmospheric feedbacks. ¶

Deleted: we argue that improving the inclusion of water resource management in Earth System models requires more model development efforts in LSSs, particularly towards coupled simulations. ¶

In following sections, we briefly focus on these gaps and highlight the opportunities to address them and move towards the integrated representation proposed in Figure 1.

5.2 Outstanding challenges - closing the water balance and online simulations

At this stage of research, issues around closing the water balance and online simulations are the most fundamental challenges in representing water resource management in Earth System models. Closing the water balance requires considering all the sources of human water withdrawals and uses in the system and integrating them into the host large-scale models. One major gap in representing the water sources is groundwater, which is ignored or crudely represented in most current models. In parallel, as noted above, performing online simulations requires moving towards finer spatial and temporal scales and handling various sources of bias within the integrated system. Although providing an extensive discussion on issues around integrating groundwater models with LSMs as well as online Earth System modeling remains beyond the scope of this paper, here we attempt to briefly point to the main challenges and highlight a few opportunities for future developments.

Technically, the issues around coupling LSMs with groundwater and/or climate models are rather similar. In principle, (1) both require couplers to build an integrated model from independent models; (2) both require refining temporal and spatial resolutions; (3) both substantially increase the complexity of calculations; (4) both need research in terms of improving and adding new algorithms for process representations; and finally (5) both require handling various sources of uncertainty. Research on coupling individual models in an integrated Earth System modeling framework is ongoing and currently there are various coupling strategies available (e.g., Dunlop et al., 2014). One challenge in coupling the elements of water resource management with climate is the mismatch between temporal scales of water resource management and natural cycles in the Earth System. For instance, capturing the online effects of evaporation from reservoirs requires running the climate model with fine temporal resolution; although the reservoir evaporation is mainly a function of reservoir temperature and area, which vary slowly. Research, therefore, should be done to compare and optimize existing coupling strategies to handle such inconsistencies in time scaling.

Deleted: Major gaps remain in representing water resource management in LSSs in a way defined above. Essentially, water resource management often takes place at the sub-grid resolution of current LSSs used for simulations over large region and global scales (i.e., 10 kilometers and more). Including the elements of water resource management therefore requires moving towards a "hyperresolution" scale (a few kilometers or less) for explicit representation (see Wood et al., 2011) and/or adding new sub-grid parameterizations related to human-water interactions, as illustrated in Figure 1. However, as the time-space resolutions become finer or more sub-grid parameterization are added, modeling complexity, computational burdens and data requirements increase significantly, in particular for online simulations. Other important issues for online applications are the complexity in representing various feedbacks and significant biases across different components (including propagation throughout the fully coupled system) as well scaling mismatch among different parts of the earth system and water resource management. This needs fundamental research towards determining the appropriate temporal/spatial scales for including water resource management in LSMs and further integration with climate models (see Yuqing et al., 2004). It should be noted that most of the currently available On important example is online representation of groundwater processes at the global scale. Moreover, current algorithms originally designed for offline applications and might not be suitable for online implimentationsimplementations. An important example is reservoir operation as both optimization- and simulation-based algorithms have some levels of prognosis that hinder their application in coupled simulations. ¶
From offline perspective, major limitations are associated with representing water resource management at larger scales due to uncertainties in (1) data support, particularly with respect to precipitation and actual water use; (2) water demand, supply and allocation algorithms, particularly with respect to irrigation demand estimation, reservoir operation and groundwater withdrawals; as well as (3) host large-scale models, particularly with respect to those calculations that determine surface and ground water availability. It should be noted that here we only focus on epistemic sources of uncertainty, which needs to be addressed, quantified, communicated and possibly reduced (see Beven and Alcock, 2012). Table 3 summarizes various aspects of uncertainty related to data support, algorithmic procedures and host models, identified for estimation ...

One major need for representing groundwater and for online simulations is the necessity for moving towards finer spatial resolutions. This can result in various challenges. First, even if the spatial resolution increases, several sources of heterogeneity would still be ignored, as current LSMs do not consider them. For instance, LSMs usually define plant species based on Plant Functional Types (PFTs), within which all parameters are identical. However, current LSMs recognize only limited PFTs and hence they typically ignore much of the biodiversity. Improvement in LSMs in terms of adding more detail into land-surface parameterization can provide opportunities to represent such sources of heterogeneity. Second, going toward finer modeling resolutions requires improved data support at finer scales. However, fine resolution data are becoming more and more available. For instance, a global 1-km mesh dataset of soil properties has been recently released (cited in Sato et al., 2014); however such datasets are normally obtained from multiple independent sources, which differ in terms of their quality (Liu et al. 2013). More efforts towards producing standardized and accurate data sources can support future fine-grid Earth System modeling. Finally, moving towards finer scales requires a new set of process representations and parameterizations (Hurrell et al., 2013). There are new developments along scale-aware parameterizations (e.g., Hurrell et al. 2009) that can help refine parameterizations for finer spatial scales.

One important issue with online simulations and groundwater modeling is the computational complexities compared to offline surface water simulations (e.g. Hill et al., 2004; Kollet et al., 2010; Wood et al., 2011). Wehner et al. (2008) suggested opportunities to address computational burdens, including hardware design (i.e., building enhanced computer processors for a specific application) and use of distributed and grid systems. A wide range of applications exists for grid and cloud computing systems (see Schwiegelshohn et al., 2010; Lecca et al., 2011; Fernández-Quiruelas et al., 2011). Improved computational power can also provide a basis to explore various model resolutions to identify critical scales for process representations (see Gentine et al., 2012) and to support computationally expensive offline calculations, such as groundwater processes, dynamic crop growth, river routing and model calibration (e.g. von Bloh et al., 2010; Rouholahnejad et al., 2012; Wu et al., 2013).

Understanding and handling various sources of uncertainty requires activities towards evaluating model performance against observations, which includes new diagnostics for systematic assessments of the modeling system. One key challenge is the fact that LSMs are run over large

Deleted: ost

Deleted: O

Deleted: are generally

Deleted: ly

Deleted: expensive

Deleted:). Moreover, capturing online effects of water resource management requires appropriate resolution of process representation (Sorooshian et al., 2011a), which is generally unknown in advance. Implicit schemes therefore require research into appropriate scales of resolution. Explicit consideration of land-surface processes using hyperresolution schemes can in principle overcome this issue; however, such representations require large computational resources

Deleted: (

Deleted:), for example in running coupled LSS runs as well as sensitivity analysis and ensemble predictions

Deleted: (

Deleted: This

grids, whereas validation data for land-surface variables and groundwater can be only obtained at local scales. There are several attempts to overcome this issue. For instance, FLUXNET (daac.ornl.gov/FLUXNET/fluxnet.shtml) coordinates regional and global analyses of observations from micrometeorological tower sites to fill validation gap for online LSMs. Such observation networks can facilitate diagnosing the LSMs efficiency and sources of errors over large geographical scales. Moreover, a large number of combinations of model configurations should be tested to ensure reliability and performance of individual components and characterize the bias propagation from one component to others. For that purpose, it should be noted that increased modeling complexity does not necessarily result in an improved precision; therefore, a systematic approach is required to test, intercompare and falsify modeling options in the light of validation data available. This will be discussed in more detail in Section 5.6.

Deleted: s

5.3 Data support

Deleted: ¶

As noted through our survey, major data limitations exist in representing various aspects of water resource management, which are related to forcing, parameterization, calibration and validation of water demand, supply and allocation algorithms (see also Table 3). At this stage of research, major gaps are noted in spatial and temporal quality and coverage of the data related to climate, hydrology, socio-economy, policy and water resource management that are required to drive or to support large-scale models (see Wood et al., 2011; Gleick et al., 2013; Oki et al., 2013).

Deleted: data

One important opportunity to improve data support is the use of remote sensing technology, which can provide a synoptic view of the state of land-surface and atmospheric variables (see Sorooshian et al., 2011b; Asrar et al., 2013) and a reliable data support for dynamic forcing, parameter estimation as well as evaluation of large-scale models (see van Dijk and Renzullo, 2011; Trenberth and Asrar, 2012). For instance, Landsat missions (http://landsat.gsfc.nasa.gov; see Williams et al. 2006) have captured long-term variations in global land-cover with a temporal resolution of 16 days and spatial resolution of up to 30 meter, which can help to parameterize anthropogenic activities such as crop growth and reservoir area. More recently, passive MODerate Resolution Imaging Spectroradiometer (MODIS; http://modis.gsfc.nasa.gov; see Savtchenko et al., 2004) provide a wide range of land-surface information and have already been applied for various large-scale modeling studies, including validation of online models (Sorooshian et al., 2011a), high resolution parameterization (Ke et al., 2012) and monitoring storage in large reservoirs (Gao et al.,

Deleted: ;

2012). Assimilation of MODIS land measurements with meteorological data and the Penman-Monteith equation has also provided 8-day, monthly and annual evapotranspiration estimates at 1 km resolution globally (Mu et al., 2007, 2011). This can provide a basis to evaluate simulated evapotranspiration over land-surface (see Section 5.4). Another important product is the Gravity Recovery and Climate Experiment (GRACE; http://www.csr.utexas.edu/grace/; see Tapley et al., 2004), measuring changes in the total terrestrial water storage at rather coarser resolutions. GRACE data have already been used in studies related to regional groundwater depletion (e.g., Rodell et al., 2007, 2009), model calibration (Sun et al., 2012) and validation of large-scale simulations (Pokhrel et al., 2012a,b).

Upcoming satellite missions can further support representation of water resources management. For instance, precipitation is a key limitation in hydrological modeling in general, but is also important for irrigation demand and scheduling. The upcoming Global Precipitation Measurement mission (GPM; http://gpm.nasa.gov) will collect data at 10km resolution, every 3 hours, globally. The upcoming Soil Moisture Active Passive mission (SMAP; see Entekhabi et al. 2010) will provide improved global soil moisture measurements every 24 hours without sensitivity to cloud cover. This can be considered as an important data support for irrigation demand algorithms. Another upcoming remote sensing mission is the Surface Water and Ocean Topography mission (SWOT; see Fu et al., 2009; Biancamaria et al., 2010; Durand et al., 2010), which will provide fine-scale measurements of various surface water stores, including reservoirs as well as natural and man-made channels. Such information at the global scale has the potential to revolutionize representation, calibration and validation of algorithms related to estimation of inflow to reservoirs, reservoir releases and inter-basin water transfers.

There are also important improvements in sharing ground-based data and simulation results, including some inspiring grass-root data collection efforts. For example, the International Groundwater Resources Assessment Centre (IGRAC; www.un-igrac.org) assigns an associate expert to each one-degree grid cell to submit monthly groundwater levels. Such data can be a critical source for testing groundwater withdrawal algorithms. Similar grass-root efforts could be made to record other water resource management data, particularly with respect to actual (rather than licensed) water uses, local management policies and water technologies. We also note that sharing of gridded climate forcing and simulation results is important and provides a basis for consistent model intercomparison efforts. One example is the recently finished EU-WATCH program (http://www.eu-watch.org/), which provides forcing and simulation results of WATCH’s Model Intercomparison Project (WaterMIP; http://www.eu-watch.org/watermip).

5.4 Water resource management algorithms

Computational algorithms for representing the elements of water resource management have various sources of uncertainty (see Table 3) and improving the related representations and reducing the modeling uncertainty can be considered as an important avenue for future developments. Some important opportunities include enhancing the simulation-based reservoir operation algorithms for online applications and various applications of calibration, data assimilation and system identification techniques.

- One crucial limitation, as noted above, is in current reservoir operation algorithms for online applications. Simulation-based schemes provide a basis to move forward, however, modifications are required to relax prognostic inputs and to represent the thermal and evaporative functions of reservoirs for online applications. Modeling schemes have been already developed for representing energy balance of natural lakes at sub-grid scale (e.g., MacKay, 2011; MacKay and Seglenieks, 2013) and can be merged with improved simulation-based reservoir operation algorithms to simultaneously characterize reservoir release, storage and evaporation as well as land-atmospheric feedbacks. However, an important question remains in how to address substantial biases in estimation of reservoir release due to the uncertainty in estimation of reservoir inflows, particularly in online simulations. This issue can be partially handled using data assimilation frameworks; but substantial uncertainty remains in future simulation, where assimilation is not possible. Therefore, efforts should be made to represent reservoirs in a robust manner that can handle the inflow biases.

Deleted: (1) implement the operation at finer temporal resolution (sub-hourly to few hours rather than daily and monthly); (2)

Deleted: the need to forecast demand;

Deleted: (3)

Deleted: and

Deleted: would

Deleted: o

Deleted: face

Deleted: stays

- Calibration using observed, simulated or assimilated system behavior can be used to implicitly represent management and sub-grid heterogeneity. One example would be to address diversity in irrigation demand by finding “representative parameters” that match the assimilated evaporation over a typical irrigated grid. Calibration with ability to identify time-varying parameters could also be used to improve the performance of reservoir operation algorithms and provide a basis to account for variations in water allocation practice in time and potentially in space by considering functioning of multiple reservoirs.

- Another opportunity is to improve functional mappings of system response and demand through system identification techniques. These techniques can range from statistical regression models to more sophisticated machine-learning techniques such as artificial neural networks (e.g., Nazemi et al., 2006a) and genetic symbolic regression (e.g., Hassanzadeh et al., 2014). One example would be building functional relationships for estimation of irrigative or non-irrigative water demands and/or uses. Another would be to represent reservoir operations through transfer functions and enhanced rule-based models as well as building different decision support systems for handling operations taking place at different time scales (i.e. hydropower with a 5-minute market, floods with sub-hourly to hourly time step, and monthly seasonal water supply). This can provide an interesting prospect to extract operational rules from observed data and to incorporate soft variables such as social values and expert insights into modeling water resource management (e.g., Nazemi et al., 2002). Having such an improved modeling capability might provide an opportunity to guide representation of adaptive management and may provide a basis to regionalize management policies and operational practices.

Deleted: .

5.5 Host models

Limitations in host models can introduce a wide range of uncertainties (see Table 3). This is due to the fact that water resource management algorithms are fully embedded within the host models and interact with calculations related to land-surface process at the grid scale (see Figure 1). For instance, estimation of antecedent soil moisture affects estimation of irrigation demand. Similarly, estimates of the natural inflows to reservoirs govern the calculations related to reservoir releases and storage. Currently, there are major limitations in representing soil moisture, snow cover, permafrost, evapotranspiration, deep percolation and runoff in large-scale models and they cannot be represented without large uncertainty (Lawrence et al., 2012; Trenberth and Asrar, 2012; Oki et al., 2013). Moreover, host models often contain missing processes. For instance, current host models often ignore the effects of increased CO_2 concentration on irrigation demand. This may result in large uncertainties under climate change effects (see Wada et al., 2013b).

While an extensive review of these issues goes beyond the scope of this paper, we note that substantial efforts continue to be made to include missing processes and to improve current parameterizations of natural and anthropogenic processes in large-scale models, particularly in the context of LSMs. For instance, the Community Land Model (CLM; Oleson et al., 2004; 2008; Lawrence et al., 2011) has been recently improved by new algorithms for representing permafrost (Swenson et al., 2012), agriculture (Drewniak et al., 2013) and irrigation (Levis and Sacks, 2011; Levis et al., 2012). Another important development is the vector-based river routing algorithms (e.g. Li et al., 2013a,b) that can improve the representation of natural and anthropogenic channel processes such as reservoir stores, streamflow diversions and inter-basin water transfers (see Lehner and Grill, 2013). Another key opportunity is the application of data assimilation and/or calibration techniques to reduce parametric uncertainty and to improve prediction capability. Some systematic frameworks for calibration and parameterization of land-surface processes are suggested (Rosolem et al. 2012, 2013). We expect improvements in process representations and parameterizations related to LSMs will increase in near future due to the need that has been already recognized (e.g., Wood et al., 2011; Lawrence et al., 2012; Trenberth and Asrar, 2012; Gleick et al., 2013; Oki et al., 2013; Dadson et al., 2013).

5.6 A framework to move forward

Deleted: ¶

Several improvements need to be made in order to appropriately represent the elements of water resource management in Earth System models. We noted that moving towards including the elements of water resource management in a way described in Figure 1 requires continuous developments in water resource management algorithms, host LSMs, online land-atmospheric coupling and data support. We pointed to the main gaps and provided a brief overview on the opportunities for overcoming these limitations. As far as the algorithms related to representing water resource management are concerned, Table 4 summarizes improvements that need to be made before we can properly represent human-water interaction in Earth System models, along with targeted temporal and spatial resolutions. Modeling resolutions can vary across various elements of water resource managements due to the difference in how different elements affect water and energy balance at the land-surface. For instance, irrigation and crop growth directly affect both energy and water balance at the sub-grid scale, with substantial difference between crop function during a day. Therefore, irrigation should be represented at a fine temporal and spatial resolution to capture potential climate responses. Reservoirs also affect water and energy balance; however, as noted above reservoir area and surface temperature vary slowly and therefore

Formatted: Space Before: 18 pt, After: 6 pt

Deleted: at

there is no need to approach a finer time-scale than the scale needed for representing the water balance and downstream releases.

As noted throughout our survey, a variety of modeling options for representing key elements of water resource management at larger scales is currently available and new details about natural and anthropogenic processes are continually being added to Earth System models. Nonetheless, major limitations exist in current data, algorithms and host models, which induce major biases within components and complicate uncertainty quantification and model tractability. At this juncture, a primary task for model development should be to test and compare different data and modeling alternatives in an integrated system. This requires considering model hierarchy and the links between different components and exploring individual and integrated model space with respect to accuracy, identifiability and capability for generalization. This, in turn, can direct where future attempts should be focused to reduce uncertainties further. Guidelines are available for (1) considering multiple working hypotheses for supporting and representing relevant sub-processes and modeling component; (2) constructing different simulations based on various combinations of the considered options and (3) rejecting them if they fail to describe new data, violate their underlying assumptions and/or can be equally described by simpler models (Clark et al., 2011b; see Popper, 1959). Modular systems, such as the recently released WRF-Hydro (NCAR, 2013), are particularly suitable for building such a framework as they provide a tool for constructing/falsifying different hypotheses for process representations, parameterizations and data support in a unified computational platform.

To address this and to move towards the integrated representation of water resource management in LSMs, suggested in Figure 1, we propose a systematic framework for improving the incorporation of water resource management through building, testing and falsifying various modeling options. Figure 2 shows this framework based on the links between different modeling components. In brief, Figure 2 divides the model development into six components, related to (A) modeling set-up and data configuration, (B) climate modeling, (C) land-surface modeling, (D) water resource management representation, (E) calibration and parametric identification, as well as (F) testing and falsification. The framework starts with prior knowledge (A), coming from the modeling purpose, current modeling capabilities and limitations and the knowledge obtained from previous modeling attempts. According to the prior knowledge and emerging advancements, a range of modeling scales can be selected and multiple working hypotheses can be configured to

represent the data and modeling options in (B) to (E). Depending on the mode and period of simulation, climate data or more generally climate models (B) are required to force or to be coupled with land-surface processes. The land-surface component (C) includes relevant sub-modules related to natural processes, water supply and allocation and irrigative and non-irrigative withdrawals. The anthropogenic activities are controlled by the water resource management component (D), which requires inputs from land-surface and climate components to determine water availability and to estimate various demands with the aid of these and/or other proxies (priori knowledge). Rules for prioritizing, partitioning and allocating water demands are reflected in a management decisions sub-module that further drives water allocation in the land-surface modeling component. Sub-modules within (C) and (D) often contain unknown parameters that need to be identified through prior knowledge or calibration. As a result, calibration and parameter identification algorithms (E) with capability for further uncertainty assessment are a key requirement. Population-based optimization algorithms are particularly suitable for parameter identification as they provide a range of behavioral parameters, which can be analyzed through advanced visualization schemes and provide valuable insights into modeling uncertainty, identifiability and multiple performance measures (e.g. Nazemi et al., 2006b, 2008; Pryke et al., 2007). Moreover, population-based algorithms can provide methodological linkage to uncertainty assessment through various diagnostic tests. Guidelines are provided to test and falsify models through various evaluation criteria such as parametric identifiability (e.g. Beven, 2006b), Pareto optimality (Gupta et al., 1998), predictive uncertainty (Wagener et al. 2004) and limits of acceptability (Beven and Alcock, 2012).

Due to the current stage of model development, there is a need to approach the framework suggested in Figure 2 with a sequential workflow, as certain improvements should be made first before we can improve others. Figure 3 divides the suggested framework into four sequential working packages. First, various options for data support, water resource management (WRM) algorithms and host models should be benchmarked, tested and intercompared individually to highlight their relative suitability in further offline simulation. This would naturally result in falsifying some of the working hypotheses. The selected options then should be mixed-and-matched in an offline mode. The offline simulation efficiency should be then explored and intercompared between various integrated settings to assess the biases propagated across the system and examine the robustness of the individual components in an integrated offline simulation. The non-falsified options in this stage can be further improved and configured for online simulation, which can be then coupled with climate models in a way described in Figure 2.

A key requirement for implementing the suggested framework is the availability of suitable data, at an appropriate scale, for algorithm development and intercomparison. Although global studies are important to improve our knowledge of the Earth System and water security, our ability to conduct a comprehensive global study as proposed in Figure 2 is currently limited due to methodological, computational and funding barriers. We argue that a network of regional case studies, however, could provide access to local data, and a sample of comparative examples to support algorithm intercomparison and further development. We note, for example, the success of model intercomparison projects such as MOPEX (Duan et al., 2006) for hydrological modeling, and suggest that the time is right to develop a similar initiative for the incorporation of anthropogenic effects in hydrological models. One possibility is to draw on the resources of the set of Regional Hydroclimate Projects (RHPs) supported by the Global Energy and Water Exchanges (GEWEX) initiative of the World Climate Research Program (WCRP). As an example, our home river basin in western Canada, the 340,000 km^2 trans-boundary Saskatchewan River Basin (SaskRB), is a GEWEX RHP, embodies a complex large scale water resources system (Nazemi et al., 2013), and poses globally-relevant science and management challenges (see Wheater and Gober, 2013). These require improved representation of water resource management at larger scales to diagnose the changes in the regional discharge, climate and water security as the result of current and future water resource management and climate change. Such RHPs could provide a basis for model development and intercomparison to support inclusion of water resource management in Earth System models for fully coupled global simulations. We have already started to explore various modeling options and the ways of improving individual algorithms (i.e. stage 1 of sequential model development protocol illustrated in Figure 3) throughout the SaskRB. For instance, we have benchmarked several reservoir operation algorithms using observed inflows and assessed the possibility of improving simulation using calibration. We have realized that the efficiency of reservoir operation algorithms can be considerably improved if the assumption of fixed model parameterization is relaxed and the algorithm parameters are identified through calibration against observed reservoir level and discharge. We are about to finalize this study and will present our findings through a technical paper in near future.

6 Summary and concluding remarks

Human water supply and allocation have intensively perturbed the water cycle. We noted that the inclusion of these anthropogenic activities in Earth System models poses a new set of modeling challenges and progress has remained incomplete. Despite some major developments, we noted that current limitations significantly degrade the modeling capability at larger scales, particularly with respect to future conditions, and neglect potentially-significant sources of change to land-atmospheric system. We highlighted important deficiencies related to representing groundwater stores and withdrawals as well online implications of large reservoirs. We also noted that current water allocation algorithms have considerable limitations in representing streamflow in regulated catchments. We argued that these limitations are attributed to uncertainties in data support, water allocation algorithms.

Deleted: and host models and proposed that future water security and impact assessment studies should aim to improve current representations and move to finer spatial and temporal resolutions.

We identified four opportunities for improvements. These are advancements in (1) high performance computing and coupling techniques; (2) remote sensing, data collection and data sharing; (3) calibration algorithms, system identification techniques and assimilation products; and (4) ongoing improvements in host models including both process representation and parameter identification. As there are several options available for data support, water resource management algorithms and host models, we proposed a modular framework for testing various modeling and data options, which can be configured by multiple working hypotheses and implemented in a unified and fully integrated modeling framework. The selected working hypotheses can be tested and falsified on the basis of available information, intercomparison and/or various model diagnosis frameworks. Similar to other recent commentaries (e.g., Clark et al., 2011b; Beven et al., 2012), we believe that such a systematic framework in essential for improving current modeling capability in both offline and online modes and can be pursued using regional case studies, before aiming for fully coupled global simulations. WCRP RHPs are one source of suitable examples to move this agenda forward.

It should be noted that filling current gaps in the inclusion of water resource management in Earth System models requires substantial efforts across a wide range of disciplines, from social and policy sciences to economics and water management, from natural sciences to engineering and mathematical modeling, and from remote sensing to hardware technology and computer science. Interdisciplinary research efforts, therefore, are important. Moreover, for various reasons including funding limitations, the community needs to fully recognize the role of collaboration and explore various opportunities to share data and resources for efficient model developments and for consistent intercomparisons.

Finally, it should be indicated that our survey considered water resource management from a water quantity perspective. Water quality concerns are increasingly associated with growing human water demand and can also impact water supply and allocation. Coupling water quality and quantity in Earth System models is however very much in its infancy and much future effort will be required to fill this gap. We hope that our survey will trigger more attention towards the necessity for improving current Earth System modeling capability to respond to the needs and challenges of the "Anthropocene".

Acknowledgments

The first author has attended NASA's Applied Remote Sensing Training free webminar series (http://water.gsfc.nasa.gov/) and would like to thank Amita Mehta, Evan Johnson and John Bolten for providing useful materials related to remote sensing technology. Financial support for this survey was provided by the Canada Excellence Research Chair in Water Security at the University of Saskatchewan. The authors gratefully acknowledge the constructive comments from two anonymous reviewers and Jan Polcher, which have enabled us to make significant improvements to this paper.

Table 1. Examples for available representations of water supply and allocation in large-scale models

Reference	Water supply				Water allocation		
	Diversions	Reservoirs	Groundwater store	Desalination and reuse	Supply-demand dependency	Priorities in demands	Operational objectives
Haddeland et al. (2006b)	In- and inter-grid abstraction	Macro-scale operation[1]	N/A	N/A	Reservoir can supply up to 5 grids downstream[2]	Irrigation, flood control, hydropower, others	Minimize deficit, maximize hydropower
Hanasaki et al. (2008a)	In- and inter-grid abstraction	Macro-scale operation	N/A	N/A	Reservoir can supply up to 10 grids downstream	Municipal, industrial, irrigation	Allocate available water, share deficit
Rost et al. (2008)	Local abstraction	Lake routing	NNBW assumed unlimited[3]		Local grid	Irrigation only	Meet demand using available water
Döll et al. (2009)	In- and inter-grid abstraction	Macro-scale operation	N/A	N/A	Reservoir can supply up to 5 grids downstream	Irrigation, non-irrigation	Meet total demand[4]
Hanasaki et al. (2010)	Local abstraction	Macro-scale operation/local abstraction	NNBW assumed unlimited		Local grid	Irrigation and livestock only	Meet total demand using unlimited groundwater
Strzepek et al. (2010)	Local abstraction	Macro-scale operation[5]	Countrywide estimates	N/A	Local basin	Domestic, industry, livestock, irrigation	Maximize profitability
Wisser et al. (2010)	In-grid hydrologic routing	Macro-scale operation	Unlimited local source[6]	N/A	Local grid	Irrigation only	Meet total demand using unlimited groundwater
Biemans et al. (2011)	Local abstraction, Heuristic routing	Macro-scale operation	NNBW assumed unlimited[7]		Reservoir can supply up to 5 grids downstream	Irrigation only	Proportional allocation of available water
Wada et al. (2011)	In- and inter-grid abstraction	Macro-scale operation	Countrywide estimates	Countrywide estimates	Reservoir can supply up to 600 km downstream	Irrigation, flood control, hydropower, others	Minimize deficit, maximize hydropower
Pokhrel et al. (2012a)	Local abstraction	Macro-scale operation	NNBW assumed unlimited		Local grid	Irrigation, non-irrigation	Meet total demand using unlimited groundwater
Strzepek et al. (2012)	Local abstraction	Macro-scale operation[5]	Basin-scale threshold	Function of capacity	Local basin	Non-agricultural, Agricultural	Minimize groundwater use and spill
Blanc et al. (2013)	Local abstraction, Heuristic routing	Macro-scale operation[5]	Basin-scale threshold	N/A	Local basin	Non-agricultural, Agricultural	Minimize groundwater use and spill
Hanasaki et al. (2013b)	Local abstraction	Macro-scale operation	N/A	N/A	Local grid	Municipal, industrial, irrigation	Allocate available water, share deficit
Voisin et al. (2013a,b)	In- and inter-grid abstraction	Macro-scale operation	N/A	N/A	Reservoir can supply up to 200 km downstream	irrigation, flood control, hydropower and others	Allocate available water, share deficit
Wada et al. (2013a)	In- and inter-grid abstraction	Macro-scale operation	Conceptual reservoir	Countrywide estimates	Reservoir can supply up to 600 km downstream	Irrigation, non-irrigation	Allocate available water, share deficit

---

[1] Simultaneous operation of multiple dams in a river basin was not considered.

[2] See Haddeland et al. (2006a).

[3] Simulations without assuming unlimited groundwater store were also performed. .

[4] Demand that cannot be allocated in any given day is allocated later in the year or in the next year, when water is available.

[5] A virtual reservoir is considered for each basin.

[6] Shallow groundwater is represented as a runoff retention pool, which delays runoff before it enters streams.

[7] Simulations with considering only surface water availability were also performed.

Table 3. Uncertainties in current offline representations of water resource management in large-scale models

Component	Type of activity	Specification	Data uncertainty	Algorithm uncertainty	Host model uncertainty[1]
Water demand (Nazemi and Wheater, 2014a)	Irrigative demands	Irrigation	Climate forcing; soil, crop, land-use and land management including sub-grid heterogeneities; actual diversions; socio-economy and technological variables; agricultural management	Characterizing the potential evapotranspiration and crop water demand; representing the sub-grid crop diversity, irrigation expansion, crop change, return flows	Estimation of actual evapotranspiration, soil water movement, runoff and canopy losses; considering CO_2 effects
	Non-irrigative demands	Industrial uses	Location, diversity and capacity of uses; actual diversions; downscaling proxies; socio-economy and technological variables	Seasonal variations in industrial water needs; structural and parametric uncertainty in estimation and projection of industrial demand.	N/A
		Energy-related uses	Location, diversity and capacity of uses; actual diversions; downscaling proxies; socio-economy and technological variables	Seasonal variations in energy-related water needs; structural and parametric uncertainty in estimation and projection of industrial demand.	N/A
		Municipal Uses	Population; diversity in uses; actual diversions and uses; downscaling proxies; socio-economy and technological variables	Seasonal variations in municipal water needs, structural and parametric uncertainty in estimation and projection of municipal demand	N/A
		Livestock uses	Heads; socio-economy	Seasonal variations in livestock water need; return flows	N/A
		Environmental flows	Habitat and ecosystem needs in time and space	Over-simplicity of demand calculation	Hydrological processes upstream
Water allocation (see Sections 2 to 4)	Water supply	River diversion	Location of diversion; capacity, slope and other properties of diversion networks	Diversion losses, return flows	Channel routing
		Lakes and reservoirs storages[2]	Precipitation; reservoir location and characteristics; actual storage; small dams	Crude representation of reservoir releases using representations of natural lake, losses from reservoir	Hydrological processes upstream of dams, channel routing
		Inter-basin transfer	Location of diversion; capacity, slope and other water transfer properties; management policies; actual water transfer.	Diversion losses, simplicity of heuristic algorithms	Channel routing, calculation of demands
		Reused water	Location, capacity and actual desalinated water supply	Limited representations	N/A
		Groundwater storage	Soil properties, groundwater movement	Crude representation of groundwater availability, ignoring inter-cell lateral groundwater movements	Estimation of groundwater storage, recharge and discharge, calculation of demand.
	Water allocation practice	Operational objectives	Management policies and local constraints	Limitations of common objective functions; Temporal and spatial variations in operational objective	Estimation of water demand and supply
		Demand-Supply dependency	Management policies and local constraints, topography, diversion channels	Steady-state assumption	Estimation of water demand and supply
		Priorities	Management policies and local constraints	Temporal and spatial variations in priorities	Estimation of water demand and supply
		Reservoir operations	Management policies and local constraints	Simplicity of operational rules in simulation-based approaches, complexity of optimization-based algorithms, prognosis of both approaches	Operational objectives, inflow to reservoirs, water demand
		Groundwater withdrawal	Wells location, groundwater management, actual pumping capacities	Crude representation of groundwater withdrawals based on both top-down and bottom-up algorithms	Groundwater storage, surface water availability, grid-based water demands

---

[1] Uncertainties from host-model also include the uncertainties that can extend from other algorithms, related to water resource management, embedded in host models (see Figure 1).

Table 4. Required developments for including the elements of water resource management in Earth System models (see also Table 3)

Water resource management component	Required algorithmic improvements	Targeted spatial scale	Targeted temporal scale	Data support for parameterization and validation
Irrigation demands	Improving the calculation of crop-specific water demand considering the effect of CO_2, considering soil-water movement and other losses	Hyperresolution and sub-grid scale	Sub-daily/sub-hourly (for online simulations)	Crop and soil diversity, measured or assimilated evaporation over irrigated lands
Non-irrigative human demands	Improving the mapping relationship, representing the diversity of non-irrigative demands	Large grids with the ability to be downscaled into finer resolutions using socio-economic and climate proxies	Yearly and monthly with the ability to be downscaled into finer scales using socio-economic and climate proxies	Water use data, gridded climate and regional socio-economic data
Environmental flow needs	Improving the demand approximation considering the diversity in the aquatic life	Catchment scale	Monthly and less	Aquatic biodiversity and water use, climate information, water temperature, water quality
Lakes and reservoirs	Improving the representation of release and storage, linking hydrologic representation with energy-balance components	Grid and sub-grid	Daily	Reservoir storage and water level, release after reservoirs, storage-area-elevation relationships, operational objectives
Water diversions	Representing in-grid and inter-grid water diversions including losses	Grid and inter-grid	Daily	Water distribution specifications, location of abstractions
groundwater	Improving the representation of groundwater storage and recharge	Grid	Daily (shorter in online simulations)	Soil properties, well locations, pumping capacities
Water resuse and desalination	Improving the representation of water reuse and desalination and the annual dynamics of water supply from each facility	Grid	Yearly with the ability to be downscaled into finer time scales using climate and socio-economic proxies	Location and capacity of facilities, gridded climate, regional socio-economic data
