Abstract

Degree-day factors are widely used to estimate snowmelt runoff in operational hydrological models. Usually, they are calibrated on observed runoff, and sometimes on satellite snow cover data. In this paper, we propose a new method for estimating the snowmelt degree-day factor (DDF_S) directly from MODIS snow covered area (SCA) and ground-based snow depth data without calibration. Subcatchment snow volume is estimated by combining SCA and snow depths. Snow density is estimated as the ratio between observed precipitation and changes in the snow volume for days with snow accumulation. Finally, DDF_S values are estimated as the ratio between changes in the snow water equivalent and difference between the daily temperature and the melt threshold value for days with snow melt. We compare simulations of basin runoff and snow cover patterns using spatially variable DDF_S estimated from snow data with those using spatially uniform DDF_S calibrated on runoff. The runoff performances using estimated DDF_S are slightly improved, and the simulated snow cover patterns are significantly more plausible. The new method may help reduce some of the runoff model parameter uncertainty by reducing the total number of calibration parameters. This method is applied to the Lienz catchment in East Tyrol, Austria, which covers an area of 1198 km^2. Approximate 70% of the basin is covered by snow in the early spring season.

1 Introduction

Mountain watersheds serve as important water sources by providing fresh water for downstream human activities (Viviroli *et al.*, 2003; Langston *et al.*, 2011). As a result of snow and glacier melt, the magnitude and timing of runoff from these watersheds tend to be very sensitive to changes in the climate (Immerzeel *et al.*, 2009; Jeelani *et al.*, 2012). Changes of melt runoff may even affect the sustainable development of downstream cities in the long run (Verbunt *et al.*, 2003; Zhang *et al.*, 2012). Modeling snow and glacier melt runoff processes is therefore quite important for local water supply, hydropower management and flood forecasting (Klok *et al.*, 2001). However, melt runoff modeling in such regions faces two challenges: scarcity of meteorological data and uncertainty in parameter calibration due to limited understanding of the complex hydrological processes.

Melt runoff models generally fall into two categories: energy balance models, and temperature-index models (Rango and Martinec, 1979; Howard, 1996; Kane *et al.*, 1997; Singh *et al.*, 2000; Fierz *et al.*, 2003). Temperature-index models operating on a basin wide scale are much more popular for operational purposes due to the following four reasons (Hock, 2003): (1) wide availability of air temperature data, (2) relatively easy interpolation and forecasting possibilities of air temperature, (3) generally good model performance and (4) computational simplicity. The temperature index model is based on an assumed relationship between ablation and air temperature and calculates the daily snowmelt depth, M (mm/d), by multiplying the difference between daily temperature and the melt threshold value, T-T_o (℃/d), with the degree-day factor of snow, DDF_S (mm/d/℃) (Howard, 1996). T_o is a threshold temperature for snowmelt. The temperature index model implies a consistent contribution of each of the heat balance components (including radiation, sensible heat, latent heat and ground heat fluxes). Any changes in climate conditions and the underlying basin characteristics will affect the relative contributions of the heat balance components and cause variations of the DDF_S (Lang and Braun, 1990; Ohmura, 2001). The study of Kuusisto (1980) in Finland found DDF_S to increase sharply in early April, approximately doubling during this month due to increasing solar radiation. Singh and Kumar (1996) and Singh *et al.* (2000) demonstrated a seasonal decrease of DDF_S with increasing albedo due to seasonal changes of

land surface characteristics. Spatial variations of basin topography, such as elevation, terrain slope, aspect and terrain shading change the spatial energy conditions for snowmelt and lead to significant variations of DDF_S (Marsh *et al.*, 2012; Bormann *et al.*, 2014). Generally, regions with a large contribution of sensible heat flux to the heat balance tend to have low degree-day factors (Hock, 2003). DDF_S are expected to increase with increasing elevation and increasing snow density (Li and Williams, 2008). Forest regions often have lower values of DDF_S than open regions (Rango and Martinec, 1995). The identification of DDF_S has been an important yet complex issue for the application of the temperature-index model for snowmelt runoff modeling.

Quite a few studies estimated the degree-day factor from observed snow water equivalent (SWE) data. Martinec (1960) measured SWE with radioactive cobalt and computed the DDF_S as the ratio between SWE and difference between daily temperature and the melt threshold value. Rango and Martinec (1979, 1995) obtained degree-day factors from empirical regressions with snow density. Kane *et al.* (1997) estimated degree-day factors by calibration against point-measured SWE in a 2.2 km^2 catchment. Daly *et al.* (2000) merged interpolated point-measured SWE with snow covered area derived from satellite data to obtain spatial snow water equivalent and estimated spatially distributed DDF_S by calibration to spatial snow water equivalent. Bormann *et al.* (2013, 2014) coupled the method developed by Sturm et al. (2010) to estimate snow density as the ratio between point-measured SWE and snow depth data with the empirical relationship between DDF_S and snow density of Rango and Martinec (1995) to estimate daily variable DDF_S. In these methods, detailed observations of snow water equivalent in the basin are needed. However, observations of snow water equivalent are only representative of a small subset of the spatial domain, and observations tend to be scarce at high elevations (Hamlet *et al.*, 2005).

Another method of estimating the DDF_S is treating it as a hydrologic model parameter and calibrating it on observed hydrological data. Most commonly, runoff is used for calibrating DDF_S (Hinzman and Kane, 1991; Klok *et al.*, 2001; Luo *et al.*, 2013). The drawback is that catchment runoff is not usually a good indicator of the spatial snow cover distribution (Blöschl *et al.*, 1991a,b; Bach *et al.*, 2003; Liu *et al.*, 2012 etc.). Advances in remotely sensing techniques help provide more practical information for the calibration of

DDF_S. There have been numerous comparisons between satellite snow cover products (e.g. Hall *et al.*, 2000, 2002; Maurer *et al.*, 2003; Lee *et al.*, 2005; Hall and Riggs, 2007). In particular, MODIS snow covered area (SCA) products have been demonstrated to be of good quality and have been widely used in alpine hydrological modeling (Klein and Barnett, 2003; Dery *et al.*, 2005; Andreadis and Lettenmaier, 2006; Wang *et al.*, 2008; Georgievsky, 2009). Subsequently, a number of studies tested the potential of MODIS snow cover data for calibrating and validating snowmelt models (e.g. Dery *et al.* (2005), Tekeli *et al.* (2005), Udnaes *et al.* (2007), Parajka and Blöschl (2008a)). A review is provided by Parajka and Blöschl (2012). The authors generally found that including snow cover data in the model calibration improved the snow simulations. Most of these studies calibrated the DDF_S on combined objective functions involving observed runoff and snow cover data. This makes it hard to obtain spatially variable DDF_S because of the limited availability of spatially distributed runoff data. It is also important to note that the calibration of DDF_S can be significantly affected by other model parameters due to the interdependency of the parameters and the nature of objective functions that reflect the joint effects of all the model parameters in a holistic way. The optimization procedures may there induce significant uncertainties in the parameter estimates (Kirchner, 2006), if insufficient attention is paid to the physical catchment characteristics (including elevation, vegetation coverage, and snow density etc.) affecting the value of DDF_S (Bormann *et al.*, 2014).

In mountain watersheds, distributed hydrologic models are more widely applied than lumped models due to the large spatial variability. Degree-day factors estimated from point measurements or spatially uniform values from calibration are not likely representative for the entire catchment. An increasing need for spatially distributed estimation of DDF_S has been identified (Hock, 1999; Nester *et al.*, 2011). However, only few studies have attempted to develop temperature-index methods in a distributed manner (Cazorzi and DallaFontana, 1996; Williams and Tarboton, 1999; Daly *et al.*, 2000 etc.). Most of them computed the DDF_S as a function of a radiation index, snow albedo, rainfall rate, elevation, snow density or wind speed, which are heavily affected by topography, thus addressing the spatial variability of snowmelt in mountain terrain (Dunn and Colohan, 1999; Hock, 2003). However, due to the complex interactions between atmospheric and surface characteristics affecting the

128 degree-day factor, the relationship between DDF_S and these characteristics is still not very
129 well understood.

130 The objective of this study is to propose a new method for estimating spatial patterns of
131 DDF_S from MODIS data in mountain catchments. In comparison to traditional methods, the
132 DDF_S is not calibrated to observed runoff and snow water equivalent data, but directly
133 estimated from MODIS snow covered area and snow depth data alone. Snow depths can be
134 more widely measured in the field than snow water equivalent. For example, Environment
135 Canada gauges snow depth at 1556 sites, but snow water equivalent only at 27 sites. Similarly,
136 the U.S. Weather Service and the Swiss Service measure many more depths than water
137 equivalents (Johnson and Schaefer, 2002; Zhou *et al.*, 2005; Sturm *et al.*, 2010). The new
138 proposed method differs from existing estimation methods of DDF_S in a number of ways:
139 First, snow water equivalent is estimated from MODIS snow cover, snow depths and
140 precipitation data, so there is no need for snow water equivalent measurements which are
141 difficult to obtain in most mountain watersheds. Second, DDF_S is estimated on a
142 subcatchment scale rather than on a point scale as in most traditional estimation methods.
143 Third, the study extends the idea of partitioning hydrological time series to explore hidden
144 hydrological information of He *et al.* (2014) to the case of snow data. The methodology is
145 tested in a mountain basin in Austria.

146 The remainder of this paper is organized in the following way: Section 2 details the
147 estimation method of spatial snow density and the snowmelt degree-day factor, as well as the
148 stepwise calibration method for the model parameters. Section 3 contains a description of the
149 geographic and hydrological characteristics of the study basin, including the main data
150 sources and data preprocessing. Section 4 presents the main simulation results and
151 comparisons between the hydrologic model performance using DDF_S estimated from snow
152 data and DDF_S calibrated on runoff. Finally, section 5 provides a summary of the study, and
153 discusses possible sources of uncertainty in the results and further applications of the new
154 estimation methods of degree-day factors.

155 **2 Methodology**

156 The main idea of estimating the degree-day factor is as follows. The volume of snow for
157 each subcatchment and each day is estimated using MODIS SCA data and ground-based snow

158 depth time series. The snow volume time series are partitioned in time into three groups,
159 based on the daily air temperatures: days with snow accumulation (when temperatures are
160 below a threshold), days with ablation (when temperatures are above a different threshold)
161 and days where both processes occur (when temperatures are between the thresholds). Snow
162 density is estimated from the days with snow accumulation as the ratio between measured
163 precipitation and changes in snow volume. The degree-day factor is estimated from the days
164 with ablation as the ratio between measured changes in snow water equivalent (product of
165 snow volume and density) and the difference between daily temperature and the threshold
166 value.

167 For comparison, DDF_S is calibrated on runoff using a semi-distributed hydrological
168 model--THREW which has been applied in several studies (Tian *et al.*, 2006,2008,2012; Mou
169 *et al.*, 2008; Li *et al.*, 2012). The calibration follows the stepwise procedure developed by He
170 *et al.* (2014) but was slightly modified because of the local characteristic of the study basin
171 (see Section 2.2). The study basin is divided into 95 subcatchments for the simulations.

172 The estimated degree-day factors are tested by simulations of basin runoff and snow
173 cover patterns. The study period for which the analyses are performed is ten years, 2001-2010.
174 2001 to 2005 is the calibration period and 2006 to 2010 is the validation period.

175 **2.1 Estimation of degree-day factor from snow data**

176 The observed snow data used to estimate the degree-day factor, DDF_S, are snow covered
177 area (SCA) products and ground-based snow depths. Firstly, we obtain the volume per area of
178 snow in each subcatchment and for each day by V_s=SCA • D_s, where D_s is the average snow
179 depth. Since the average snow depths tend to overestimate the snow covered area, therefore
180 the multiplication with SCA is needed to compensate for the biases. In a next step, the change
181 of snow water equivalent (SWE) between two days, $\frac{dSWE}{dt} = \rho_s \cdot \frac{dV_s}{dt}$, is attributed to three
182 snow processes according to Eq. (1a-c).

183
$$\rho_s \cdot \frac{dV_s}{dt} = \begin{cases} P, & \text{for } T < T_S \quad \text{Accumulation} \quad (1a) \\ P_s - M, & \text{for } T_S \le T \le T_R \quad \text{Combination} \quad (1b) \\ -DDF \cdot (T - T_m), & \text{for } T > T_R \quad \text{Ablation} \quad (1c) \end{cases}$$

184 where, ρ_s is the snow density, P is daily precipitation, P_S is daily snowfall, M is daily
185 snowmelt depth, T_S is the temperature threshold below which all precipitation is in the form of

snowfall, T_R is the temperature threshold above which all precipitation is liquid, and T_m is the temperature threshold controlling the occurrence of melt. T_m usually falls between T_S and T_R. Rainfall and snowfall in the temperature window between T_S and T_R are simply estimated as half of the total precipitation. The value of the three temperature thresholds are set as $T_m = T_S =$ 0.0℃ and T_R =2.5℃ in this study following Parajka *et al.* (2007). The V_s time series are partitioned into three segments, i.e. accumulative segment, a combination segment and an ablative segment according to Eq. 1a-c.

The snow density (ρ_s) is calculated from the days with accumulation based on the observed V_s and P according to Eq. 1a. As the snow cover volume can still change after snowfall events due to gravity and condensation, snowfall events that produce a stable snow cover volume are selected for the estimation of snow density. Therefore, snowfall events in the accumulative segment that ended by at least three no-snowfall days, and where the relative difference of the V_s value between the last three no-snowfall days is lower than 10%, are selected for the calculation of snow density. In these events, the cumulative snowfall (ΔP_s) is the sum of the daily precipitation values, and the change of snow cover volume (ΔV_s^*) is the difference of the V_s values between the last no-snowfall day and the first snowfall day. Snow density in each event is obtained as $\rho_s = \Delta P_s / \Delta V_s^*$. This calculation is carried out for each subcatchment. A representative value of the density for each subcatchment is estimated as the average of all event values, neglecting any changes of density during snow melt. While this is a simplification, it should be noted that the melt period is often interrupted by accumulation events, thus the differences between accumulation and ablation densities are not considered to be very large.

The snowmelt degree-day factor DDF_S is calculated from days with ablation based on changes in the snow water equivalent and air temperatures according to Eq. 1c. The change of snow water equivalent between days is calculated as $\Delta V_s \cdot \rho_s$, where the density ρ_s estimated above is used. The degree-day temperature is calculated as the difference between the daily temperature (T) and the threshold value (T_m). Daily DDF_S value are then estimated as $\mathrm{DDF_S} = \frac{\mathrm{d}V_s}{\mathrm{dt}} \cdot \frac{\rho_S}{T - T_m}$. Again, a representative value of the degree-day factor for each subcatchment is estimated as the average of all event values. Both the estimations of snow

density and DDF_S are carried out in the two sub-periods (2001-2005 and 2006 to 2010) separately.

2.2 Calibration of degree-day factor on runoff by a hydrologic model

The runoff generation processes simulated by the THREW model includes subsurface baseflow, rainfall runoff, snowmelt and glacier melt. Rainfall runoff is simulated by a Xin'anjiang module, which adopts a water storage capacity curve to describe the non-uniform distribution of water storage capacity in a subcatchment (Zhao, 1992). The storage capacity curve is determined by two parameters (spatial averaged storage capacity WM and shape coefficient B). Rainfall runoff is generated on areas where the storage capacity is reached. The remainder of the rainfall infiltrates into the soil and becomes an additional contribution to subsurface baseflow which is calculated by two outflow coefficients (KKA and KKD). Snow and glacier melt are simulated by a degree-day model with different degree-day factors (DDF_S and DDF_G, respectively). Precipitation in the snow covered areas is divided into rainfall and snowfall according to two threshold temperature values (0℃ and 2.5℃ are adopted in this study). Between the two thresholds, mixed snow and rain is assumed to occur. Snow water equivalent in each subcatchment is updated daily with snowfall and snowmelt, while the glacier area is assumed to be stable during the study period. The model parameters are grouped according to the runoff generation mechanisms, i.e., a subsurface baseflow group (KKA and KKD), a snowmelt group (DDF_S), a glacier melt group (DDF_G) and a group where rainfall directly becomes runoff (WM and B) (see He *et al.* (2014)). Each parameter group is calibrated separately in a stepwise way by manual calibration. The stepwise calibration is similar to that proposed by He *et al.* (2014). In a first step, the hydrograph is partitioned according to three indices, S_i, G_i, D_i, which are defined as 0 or 1 (Eq. (2)-(4)) according to the water source for runoff generation on each day (subsurface baseflow, snowmelt, glacier melt and rainfall). Next, each parameter group is related to an individual hydrograph partition and calibrated on the corresponding partition separately.

$$S_i = \begin{cases} 1, & \text{if } \max\limits_{j=1\to 95}(T_j) \geq T_m \\ 0, & \text{otherwise} \end{cases} \quad \text{Snowmelt} \quad (2)$$

241
$$G_i = \begin{cases} 1, & \text{if } \max\limits_{j=1\to n}(T'_j) \geq T_m \\ 0, & \text{otherwise} \end{cases} \quad \text{Glacier melt} \quad (3)$$

$$D_i = \begin{cases} 1, & \text{if } \max\limits_{j=1\to 95}(T_j) \geq T_S \ \wedge \sum\limits_{j=1\to 95} P_j \geq 0 \\ 0, & \text{otherwise} \end{cases} \quad \text{Rainfall runoff} \quad (4)$$

242 where, i is the day index, S_i, G_i *and* D_i are the indices indicating the occurrence of snowmelt,
243 glacier melt and rainfall runoff, respectively. Values equal to 1 indicate that snowmelt, glacier
244 melt and rainfall runoff, respectively, can be a water source for runoff generation on that day.
245 Values equal to 0 indicate that this is not the case. T_j is the daily temperature in the
246 subcatchment j, T'_j is the daily temperature in the glacier covered part of subcatchment j, n is
247 the number of subcatchment that are covered with glacier, and P_j is the daily precipitation in
248 subcatchment j. Based on the daily values of the three indices, the daily hydrograph is
249 segmented into four partitions in Eq. (5):

250
$$Q = \begin{cases} Q_{SB}, & \text{for } S_i + G_i + D_i = 0 \\ Q_{SB} + Q_{SM}, & \text{for } S_i - G_i - D_i = 1 \\ Q_{SB} + Q_{SM} + Q_{GM}, & \text{for } G_i - D_i = 1 \\ Q_{SB} + Q_{SM} + Q_{GM} + Q_R, & \text{for } D_i = 1 \end{cases} \quad (5)$$

251 where, Q_{SB} stands for the subsurface baseflow. It dominates the basin hydrograph when both
252 melt water and rainfall runoff do not occur (S_i+G_i+D_i=0). Q_{SM} represents snowmelt, Q_{GM}
253 represents glacier melt water and Q_R represents the direct rainfall runoff. The partition is
254 based on the assumption that the convergence time of drainage in the basin is no longer than
255 one day.

256 The parameter groups are calibrated on different partitions in a stepwise way: The
257 parameter group controlling subsurface baseflow is first calibrated on the Q_{SB} partition. Then,
258 the degree-day factors for snowmelt and glacier melt are calibrated on the Q_{SB}+Q_{SM} and
259 Q_{SB}+Q_{SM} +Q_{GM} partitions separately. Parameters for rainfall runoff are calibrated on the
260 Q_{SB}+Q_{SM} +Q_{GM} +Q_R partition in a last step. We use *logRMSE* as the goodness of fit measure
261 for the calibration of subsurface baseflow and *RMSE* for the calibration of degree-day factors
262 and rainfall runoff parameters. Finally, we combine the simulations of each partition to obtain

the entire daily simulation of basin discharge and evaluate it using *NSE*, *logNSE*, *VE* and a combined performance measure *ME* (Eq. (6)-(9)).

$$NSE = 1 - \frac{\sum_{i=1}^{n}(Q_{obs}(i) - Q_{sim}(i))^2}{\sum_{i=1}^{n}(Q_{obs}(i) - \overline{Q}_{obs}(i))^2} \quad (6)$$

$$logNSE = 1 - \frac{\sum_{i=1}^{n}(\log Q_{obs}(i) - \log Q_{sim}(i))^2}{\sum_{i=1}^{n}(\log Q_{obs}(i) - \log \overline{Q}_{obs}(i))^2} \quad (7)$$

$$VE = 1 - \frac{\sum_{i=1}^{n}|Q_{obs}(i) - Q_{sim}(i)|}{\sum_{i=1}^{n} Q_{obs}(i)} \quad (8)$$

$$ME = NSE + logNSE + VE \quad (9)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(Q_{obs}(i) - Q_{sim}(i))^2} \quad (10)$$

2.3 Evaluation of estimated DDF_S from snow data

The estimated values of DDF_S are evaluated in the study period by applying their value in the THREW hydrological model and comparing the new simulations of runoff and snow cover patterns with those obtained by DDF_S calibrated on runoff. The evaluation is carried out in three basins with different catchment area, elevation and glacier melt contributions to the total runoff. The *ME* values of daily discharge simulation and *RMSE* values of the simulation of the snowmelt dominated hydrograph partition (Q_{SB}+Q_{SM}) in the three basins are used to evaluate the performance of the runoff simulation. The fit between simulated and observed SCA series and spatial snow cover patterns by MODIS is used to assess the simulations of snow cover.

3 Data

3.1 Study area

The methodology is evaluated in the Lienz catchment which is located in East Tyrol, Austria, and covers an area of 1198 km^2. Its elevations range from 670 m a.s.l. to 3775 m a.s.l., and approximately 7% of the region is covered by glacier (Fig. 1). Its annual mean temperature is approximately 1.7 ℃, and annual mean precipitation is about 1164 mm. Snowmelt water is an important water source for local runoff generation, especially in the spring season when approximately 70% of the basin is covered by snow (Blöschl *et al.*, 1990).

The topographic feature of the basin is depicted by a 25 m resolution Digital Elevation Model which is used to divide the study basins into subcatchment units. The three basins (Lienz, Waier and Innergschloess, see Fig. 1) in the study area are further divided into 95 subcatchments, 29 subcatchments and 9 subcatchments respectively for the hydrological modeling. The runoff concentration time can be considered as approximately one day in this catchment (Blöschl *et al.*, 1990).

3.2 Snow data

The MODIS snow covered area (SCA) data used in this study is the daily product, i.e. MOD10A1 and MYD10A1 (V005) (Hall et al., 2006 a, b). It has been downloaded from the website of the National Snow and Ice Data Center (NSIDC, www.nsidc.org). The used data set has a spatial resolution of 500 m and consists of daily snow cover maps from 1 January 2001 to 31 December 2010. The original Terra and Aqua products were merged in space and time to reduce cloud coverage by Parajka and Blöschl (2008b). Only the MODIS SCA data for those days when the cloud coverage of the basin was less than 50% after the merging procedure are used. To obtain a continuous time series of SCA, we implemented a linear interpolation between two valid SCA values.

Snow depth data observed at 1091 stations in Austria (7 stations in the study area) are spatially interpolated by external drift kriging based on elevation. The resulting data product has a spatial resolution of 1 km. Snow depth in each subcatchment is the average value of all the 1×1km pixels inside.

3.3 Hydrologic model inputs

The daily precipitation data are spatially interpolated by external drift kriging from 1091 stations in Austria (7 stations in the study area). The temperature data are interpolated by the least-squares trend prediction method from 221 stations in Austria (6 stations in the study area). Both methods using elevation as an auxiliary variable (see Parajka *et al.* (2005)). Daily streamflow data from three hydrological stations are used, Lienz, Waier and Innergschloess, which drain areas of 1198 km^2, 285 km^2 and 39 km^2 respectively (see Fig. 1). The datasets used in this study consist of two sub-periods, the first is a calibration period from January 1, 2001 to December 31, 2005 and the second is a validation period from January 1, 2006 to December 31, 2010.

4 Results

4.1 Snow density and DDF_S

Based on Eq. (1a) and (1c), we obtained the snow densities and snowmelt degree-day factors (DDF_S) for each subcatchment in the Lienz basin. For example, Figs 2 and 3 show the spatial distribution of the snow density and DDF_S estimated in the calibration period. Figure 2 indicates that subcatchments in upstream have higher snow density and DDF_S values than that in downstream. Figure 3 represents the relationships between snow density and elevation, and DDF_S and elevation. Leaf area index (LAI) data from MODIS land cover products are used to describe the vegetation coverage in each subcatchment in Fig. 3. Each dot stands for a subcatchment, and its size reflects the annual mean LAI over the study period of the corresponding subcatchment. The estimated values of snow density range from approximately 0.1 to 0.6 g/cm^3 with a mean value of 0.3 g/cm^3. The estimated values of DDF_S range from about 1.6 to 4.5 mm/d/℃ with an average of 2.7 mm/d/℃. DDF_S values in the medium sized Waier basin mainly fall into a range of 2.0-3.0 mm/d/℃, while in the smallest basin, the Innergschloess, they fall into a range of 2.0-4.0 mm/d/℃(see Fig. 2). Generally, both the snow density and DDF_S values increase with increasing elevation (see Fig. 3), as would be expected. The value of snow density can be affected by the duration of the snow cover. In high elevation subcatchments, temperatures tend to be lower which leads to more snowfall and more opportunity for compaction and settling which, in turn, tends to result in higher snow densities (Rango and Martinec, 1995). The spatial pattern of DDF_S can be attributed to the interaction of climate and basin topography as well as vegetation: At higher elevations, soils tend to be thin and air temperatures tend to be low, which are unfavorable conditions for the growth of vegetation. Therefore, the share of latent heat of transpiration in the energy balance is lower. Lower temperatures at higher elevation also reduce the share of sensible heat (Musselman *et al.*, 2012). Coupling with a stronger solar radiation due to lower cloudiness, stronger snowmelt is produced at higher elevations relative to the difference between daily temperature (T) and the threshold value (T_m). Higher elevations are also associated with steep terrain which reinforces the melt rate by increasing the solar incident angle on the south facing slopes (Blöschl *et al.*, 1991a,b; Blöschl and Kirnbauer,1992). At lower elevations, climate conditions are favorable for the growth of vegetation, which

produce a higher share of latent heat by transpiration and restrain the snowmelt. On the other hand, higher vegetation canopies may contribute to higher soil water contents which may increase the albedo of the land surface and may reduce the energy available for snowmelt (Kuusisto, 1980). The moist soil can also enhance the temperature gradient and create sharp gradients in sensible heat fluxes (Entekhabi *et al.*, 1996) and allow fast redistribution of soil moisture at small scales (Western *et al.*, 1998). Changes of the heat conditions in the near surface atmosphere in turn may change the soil moisture state and may promote vegetation growth. The spatial variability of snow density and DDF_S is likely the combined result of a number of factors, including slope aspect, wind speed and shading, in addition to elevation and vegetation.

4.2 Transferability in time of the estimated DDF_S

The data set used in this study has been divided into two sub-periods: calibration period from 1 January 2001 to 31 December 2005 and validation period from 1 January 2006 to 31 December 2010. The average annual precipitation is 1126 mm in the calibration period, and 1238 mm in the validation period. The mean daily temperature is 2.28℃ in the calibration period, and 2.59℃ mm in the validation period. Mean daily snow coverage from MODIS is approximately 10% in the calibration period, and about 12% in the validation period. Although the difference of the climate and snow cover conditions in the two periods is small, it can still play a role in the snowmelt processes. Therefore, we re-estimated the value of snow density and DDF_S using the climate data and MODIS snow data in the validation period and compared the new estimated DDFS set with that estimated using data in the calibration period in Fig. 4. The comparison shows that the two estimated sets of DDF_S and snow density (SD) are slight different due to the different climate and snow cover conditions in the two sub-periods. However, the correlation coefficients between the two estimated DDF_S sets and that between the two SD sets are both high, i.e. 0.802 for the DDF_S and 0.720 for the SD (see Fig. 4), which indicates that both the two estimated DDF_S sets and two SD sets are consistent in the two sub-periods. There is no significant systematic bias for the estimated DDF_S and SD. This suggests the transferability in time of the estimated DDF_S in the whole study period. To further test its transferability in time, we applied DDF_S values estimated in one period for the simulation of basin discharge and snow cover in the other period. For example, in the

following Section 4.4, we used the DDF_S set estimated by snow data in the calibration period (2001 to 2005) for the model simulation in the validation period (2006 to 2010).

4.3 Stepwise calibration

Model parameters in the three basins are calibrated on the corresponding hydrograph partitions separately (see He *et al.* (2014)). After the calibration, we combined the simulations of the four partitions and obtained the entire simulation of daily discharge. As an example, the simulation in each step in the largest basin, the Lienz basin, is shown in Fig. 5, using the calibrated degree-day factors for snowmelt and glacier melt as 2.6mm/d/℃ and 3.5mm/d/℃ respectively, as shown in Table 1. The *logRMSE* and *RMSE* values in Fig. 5 suggest that the simulations of each hydrograph partition are very reasonable. The calibrated parameter set was also tested for the validation period (2006-2010), as shown in Fig. 6. Again, the performance is very reasonable as indicated by *NSE and logNSE*. For example, in the Lienz basin *NSE* values are 0.817 and 0.833 in the calibration and validation periods, respectively, indicating the suitability of the calibrated parameter set. The simulation performances for the two sub-basins (Waier and Innergschloess) are also shown in Table 1.

The calibrated DDF_S and DDF_G are slight different in the three basins. DDF_S ranges from 1.0 to 2.6mm/d/℃, and DDF_G ranges from 3.5 to 6.0mm/d/℃. The calibrated DDF_S in the Lienz and Waier basins are similar to those estimated from MODIS and snow depth data in Sect. 4.1, while the calibrated value, 1.0mm/d/℃, in the Innergschloess basin is clearly different from the estimated values that range from 2.0 to 4.0mm/d/℃. Given the role of radiation in this high elevation basin, the value of 1.0mm/d/℃ seems far too low, and the snow data based estimate is much more reasonable.

The runoff simulations in the medium basin (Waier) are the best with an *NSE* value of 0.832 in the calibration period and 0.863 in the validation period. Runoff simulations in the smallest basin (Innergschloess) exhibit a slightly lower performance with an *NSE* value of 0.726 in the validation period. This may be partly due to the remarkably low value of the calibrated DDF_S, i.e. 1.0mm/d/℃. The calibration of DDF_S relies heavily on the observed hydrographs, which may introduce uncertainties in the DDF_S estimates in some cases.

4.4 Evaluation of estimated DDF_S

To evaluate the estimated DDF_S, we replaced the calibrated DDF_S in the model with the

ones estimated from snow data, and reran the hydrological simulation. The other model parameters remained the same as those calibrated in Sect. 4.3. The new simulation results in the three basins are summarized in Table 1. The simulations using the spatially variable DDF_S estimated from snow data tend to perform better than those using the calibrated, spatially uniform DDF_S. In the Lienz and Waier basins, the new simulations are similar to those shown in Sect. 4.3, as demonstrated by the *ME* values in Table 1. For example, Fig. 7 presents the new simulation for the Lienz basin with an *NSE v*alue of 0.810 in the calibration period and 0.826 in the validation period. Both are very similar to the *NSE* values shown in Fig. 6. The mean value of the estimated DDF_S in these two basins are 2.7mm/d/℃ and 2.6mm/d/℃ respectively, both are similar to the calibrated value of 2.6mm/d/℃. It is worth noting that the new simulation in the smallest Innergschloess basin is significantly better, especially in the validation period, considering the *ME* values in Table 1. The mean value of the estimated DDF_S in this basin is 3.2mm/d/℃ which is clearly different from the calibrated value. This suggests that the calibrated DDF_S value of 1.0mm/d/℃ in this small, high elevation basin may not be accurate.

As the DDF_S value has the most sensitive effect on the snowmelt dominated hydrograph partition (Q_{SB}+Q_{SM}), we focus on the simulation of this partition by the two DDF_S sets in Fig. 8. The simulation performance is evaluated using *RMSE*. The first two rows in Fig. 8 show the simulations using calibrated (Fig. 8a-c) and estimated (Fig. 8d-f) DDF_S in the calibration period, and the last two rows present the simulations in the validation period (Fig. 8g-i is for DDF_S calibrated on runoff and Fig. 8j-l is for DDF_S estimated from snow data). The differences of the *RMSE* values obtained by the two DDF_S sets in the Lienz basin (first column) range from 0.132 to 0.347 m^3/s. Considering the relatively higher levels of the discharge, the two simulations can still be regarded as very close. As to the Waier basin (second column), the *RMSE* value obtained by the estimated DDF_S in the calibration period is slightly higher (0.04 m^3/s higher) but much lower (0.263 m^3/s lower) in the validation period. In Innergschloess basin (third column), the *RMSE* values in the calibration period are as close as a slight difference of 0.016 m^3/s, while in the validation period the *RMSE* value obtained by the estimated DDF_S is 0.118 m^3/s lower than that obtained by the calibrated DDF_S. Comparisons of the simulations of the Q_{SB}+Q_{SM} hydrograph partition show a similar

434 performance in the calibration period but a better performance of estimated DDF_S in the
435 validation period. Overall, the comparisons for the three basins shown in Table 1 and Fig. 8
436 suggest that the DDF_S values estimated from snow data by the new method tend to produce a
437 somewhat better runoff simulation performance.

438 We also assess the suitability of the estimated DDF_S values by examining the snow cover
439 simulations in the study basins. The match between simulated snow cover and observed snow
440 cover from MODIS is illustrated in Fig. 9 to Fig.12. The THREW model simulates snow
441 water equivalent (SWE) in each subcatchment. To obtain the snow covered area (SCA) in the
442 basin, we define a threshold value for the simulated SWE (SWE_T), above which the sub unit
443 of the basin (i.e. subcatchment) is considered to be fully covered by snow, and below it the
444 subcatchment is considered snow free. Subsequently, we obtain the simulated time series of
445 SCA of the study basin. For example, Fig. 9 shows the comparison of simulated SCA using
446 DDF_S calibrated on runoff and DDF_S estimated from snow data, and the observed SCA from
447 MODIS in both calibration and validation periods in the Lienz basin. Fig. 10 shows a similar
448 figure for Innergschloess. The black dots in Figs. 9 and 10 are the MODIS observed SCA
449 values on days when the observed cloud coverage in the basin was lower than 20%. The
450 similarity of the simulated SCA and observed SCA (just for the days when MODIS was
451 available) is evaluated using *RMSE*, where *RMSEc* relates to the simulations using calibrated
452 DDF_S and *RMSEe* relates to the simulations using estimated DDF_S. We determine the SWE_T
453 threshold by optimizing the *RMSEc* values in the calibration period in the Lienz basin which
454 resulted in a value of 18 mm. Parajka and Blöschl (2008a) give details on how the threshold
455 can be chosen.

456 Generally, the simulated snow covered areas by the two DDF_S sets are similar and both
457 are close to those observed by MODIS in the Lienz basin. The similarity can be attributed to
458 the similar value of estimated and calibrated DDF_S in this basin. It is interesting that the
459 simulation of SCA by estimated DDF_S (green lines) still has a higher performance as
460 indicated by the lower *RMSEe* values in both calibration and validation periods. As to the
461 simulation in Innergschloess shown in Fig. 10, the simulated SCA using estimated DDF_S
462 (green lines) matches the MODIS observed SCA significantly better than that simulated by
463 calibrated DDF_S (red lines) in both calibration and validation periods. The *RMSEe* values are

464 approximately 0.07 lower than the *RMSEc* values (Fig. 10). This result suggests that the
465 DDF_S values estimated from snow data in this basin represent the snowmelt pattern better
466 than the value calibrated on runoff.

467 Several days with available MODIS data (black dots in Fig. 9) were selected to analyze
468 the snow patterns in Figs. 11-12. The selected days include April 29th, May 7th and June 10th
469 in 2003, and April 27th, May 7th and May 27th in 2008. The snow patterns are expressed as the
470 spatial distribution of simulated SWE using calibrated DDF_S and estimated DDF_S, and the
471 spatial distribution of SCA observed by MODIS. Figs. 11 and 12 show the results for the
472 calibration period and validation period, respectively. Sub-catchments are covered with snow
473 refers to purple surfaces in Figs. 11 and 12. The intensity of the purple color increases with
474 the increasing of the value of snow coverage (SCA) from MODIS or simulated SWE. The
475 green surface in the two figures refers to areas where SCA value from MODIS or the
476 simulated SWE value is zero, i.e. non-snow covered areas. Generally, a higher simulated
477 SWE value corresponds to a higher MODIS SCA value in that subcatchment. All the three
478 snow patterns show a clear snow ablation process from late April to late May. In April, most
479 of the basin area is covered by snow, and the snow water equivalent can be as high as
480 600-700mm, while snow cover almost disappears in late May 2003. May is a snowmelt flood
481 month which is also indicated in Fig. 6 by the abrupt increase of discharge in this month.
482 However, there are some differences between the three snow patterns. In the upstream
483 subcatchments the simulated snow water equivalent using calibrated DDF_S is higher than that
484 using estimated DDF_S. Correspondingly, the simulated sub-catchments are covered with snow
485 using calibrated DDF_S are more than those observed from MODIS (see Figs. 11 and 12 on
486 June 10th, 2003 and May 27th, 2008). In the downstream subcatchments, simulated snow
487 covered sub-catchments by the two DDF_S sets are both less than the observed ones (see Figs.
488 11 and 12 on April 29th, 2003 and May 7th, 2008). Overall, the similarity between the spatial
489 distribution of snow covered sub-catchments simulated using estimated DDF_S and the spatial
490 distribution observed by MODIS is higher than that simulated using calibrated DDF_S, which
491 can be seen for May 7th, June 10th in 2003, and April 27th and May 27th in 2008. MODIS data
492 were one of the inputs to estimating DDF_S, so this result shows the consistency and usefulness
493 of the estimates.

5 Discussion and conclusions

This study proposes a method for estimating snowmelt degree-day factor (DDF_S) based on MODIS snow cover data and snow depth data. DDF_S is estimated in each subcatchment of the study basin separately. The spatial distribution of DDF_S shows a strong correlation with elevation. Subcatchments with high elevations are associated with higher DDF_S values, which can be partly attributed to the interactions of climate conditions, topography and vegetation. The comparisons between simulations using DDF_S estimated from snow data and DDF_S calibrated on runoff in terms of discharge and snow cover patterns show that the estimated DDF_S are indeed more plausible than the calibrated DDF_S. The better performance can be attributed to two advantages of the estimation method: First, using spatially variable snow cover data from MODIS and snow depth data, it is possible to estimate DDF_S in a spatially distributed fashion, while the calibrated DDF_S are lumped values and therefore spatially uniform. Second, the values of DDF_S are estimated directly from observed snow cover data, accounting for snow density, without involving runoff processes. The direct estimation should have a stronger physical basis than the calibration in which the value of DDF_S is influenced by a number of hydrological processes and the interactions of hydrological model parameters (Merz *et al.*, 2011). However, the modeling improvement when using the spatially distributed DDFs should indeed be different for different modeling scales. The modeling scale, i.e. size of fundamental computational unit (sub-catchment in this study), can have a significant influence on the simulation, considering the spatial resolution of MODIS data and the spatial density of gauge stations for precipitation and temperature. Adopting different sub-catchment sizes in the model could be a potential way to analyze the scale effect on the simulation, which can be an issue for further study.

The estimated values of snow density and DDF_S are fully consistent with those estimated by Kuusisto (1980), Rango and Martinec (1995), Parajka *et al.* (2005) and Sturm *et al.* (2010). The values of snow density estimated in Sturm *et al.* (2010) in Canada and the United States fell into a range of 0.19 to 0.51 g/cm^3, and the DDF_S of snowmelt estimated in Parajka *et al.*(2005) in Austria ranged from approximately 0.5 to 5.0 mm/d/℃. The simulations of snow cover patterns show an obvious snow ablation process from late April to late May in the study basin, which was also indicated by Blöschl *et al.* (1990). The performance of the runoff

simulations in this study is also very reasonable (*NSE* almost always >0.8). For example, the runoff simulations of Parajka *et al.* (2007) in 320 catchments in Austria based on automatic calibration gave *NSE* mean values of about 0.75 in calibration period and 0.70 in validation period. Considering that high NSE values are relatively easier to be reached in snowmelt affected basins, the performance of the stepwise calibration method should be evaluated in further studies. It is believed that the actual model performance is similar to that of automatic methods, yet the parameter estimates may be more plausible as different parameter groups are estimated separately, which reduces the problem of parameter interdependence in the calibration process.

It should be noted that the estimated values of snow density and DDF_S are associated with a number of uncertainty sources: the temperature threshold values that determine the occurrence of snowmelt (T_m) and the transition between liquid and solid precipitation (i.e. T_S and T_R) and also the spatial interpolation method of the snow depth data. Usually, the value of T_m falls in between the values of T_S and T_R in mountain basins. As long as the temperature is higher than T_R, the change of snow water equivalent (SWE) can be attributed to snowmelt alone. When the temperature is lower than T_S, basin snow water equivalent will be affected by snowfall alone. The proposed estimation method can be used in mountain basins with variable values of T_m, T_S and T_R in different basins. Reliable snow depth data are important for estimating snow density and DDF_S well. To obtain the spatial distribution of snow depth, measured data in 7 stations in the study area were interpolated here. The interpolation method can play a significant role. Importantly, in this paper we made the assumption that snow density during days of accumulation is similar to the density during days of ablation. This is an assumption that needs further analysis on the basis of detailed snow data. Also the analysis of the sensitivity of the results to other uncertainty sources could be the topic of future work.

Table 1. Performance of discharge simulations in three basins. DDF_S is the snowmelt degree-day factor and DDF_G is the glacier melt degree-day factor. *ME* is the sum of *NSE*, *logNSE* and *VE*. The value of DDF_S estimated from snow data is expressed as the spatial mean value +/- the mean difference of the highest and the lowest value (in space) from the mean value. DDF_S values estimated by the proposed method are shown in bold.

		Lienz		Waier		Innergschloess	
		Calibration Period	Validation Period	Calibration Period	Validation Period	Calibration Period	Validation Period
DDF_S calibrated on runoff	DDF_S(mm/d/℃)	2.6	2.6	2.6	2.6	1.0	1.0
	DDF_G(mm/d/℃)	3.5	3.5	4.2	4.2	6.0	6.0
	NSE	0.817	0.833	0.832	0.863	0.804	0.726
	logNSE	0.851	0.873	0.849	0.871	0.825	0.871
	VE	0.762	0.758	0.739	0.770	0.654	0.585
	ME	2.430	2.464	2.420	2.504	2.283	2.182
DDF_S estimated from snow data	DDF_S(mm/d/℃)	**2.7 +/-1.1**	**2.7 +/-1.1**	**2.6 +/-0.9**	**2.6 +/-0.9**	**3.2 +/-0.3**	**3.2 +/-0.3**
	DDF_G(mm/d/℃)	3.5	3.5	4.2	4.2	6.0	6.0
	NSE	0.810	0.826	0.835	0.845	0.801	0.768
	logNSE	0.845	0.867	0.845	0.869	0.826	0.885
	VE	0.751	0.746	0.740	0.760	0.648	0.628
	ME	2.406	2.439	2.420	2.474	2.275	2.281

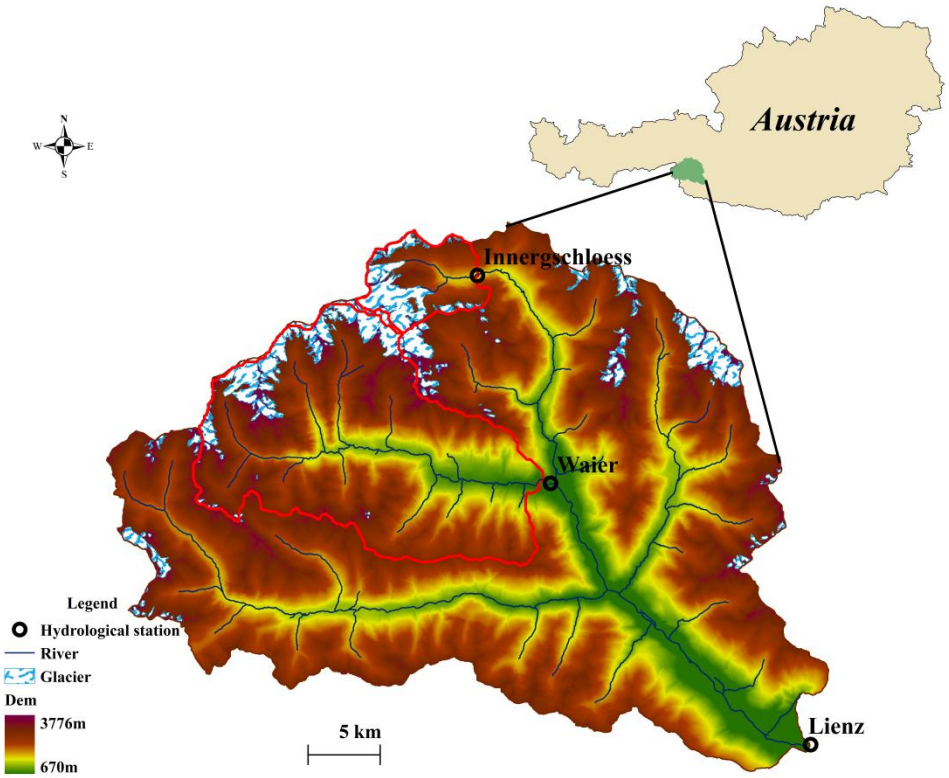

Figure 1. Location of the study area in Austria. Three catchments are analyzed, Lienz, Waier and Innergschloess, with areas of 1190 km^2, 285 km^2 and 39 km^2, respectively. The glacier coverage in the three basins is approximately 7%, 13% and 29%.

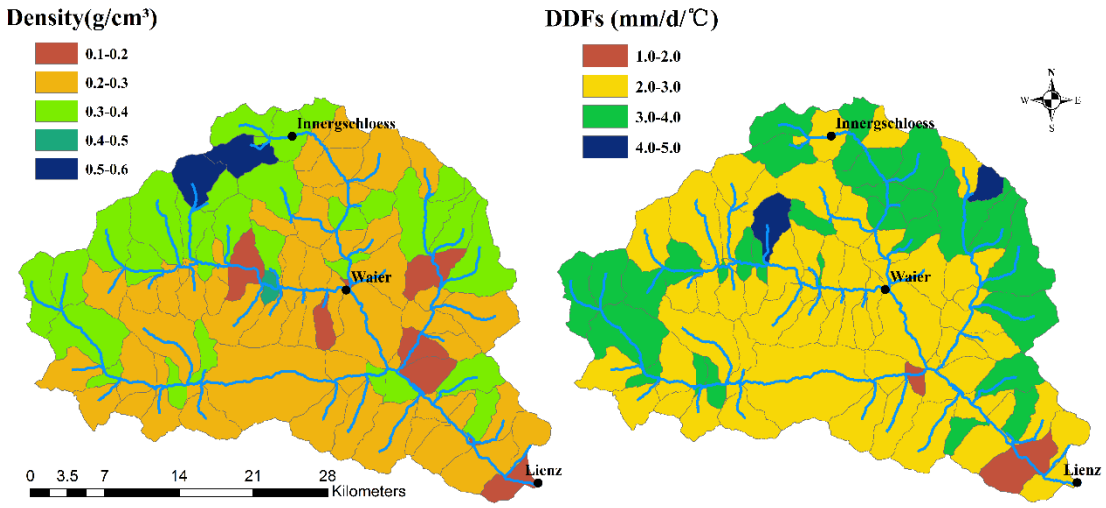

Figure 2. Spatial distribution of the snow density and the snowmelt degree-day factor (DDF_S) estimated by the proposed method in the Lienz basin. Black dots indicate the stream gauges.

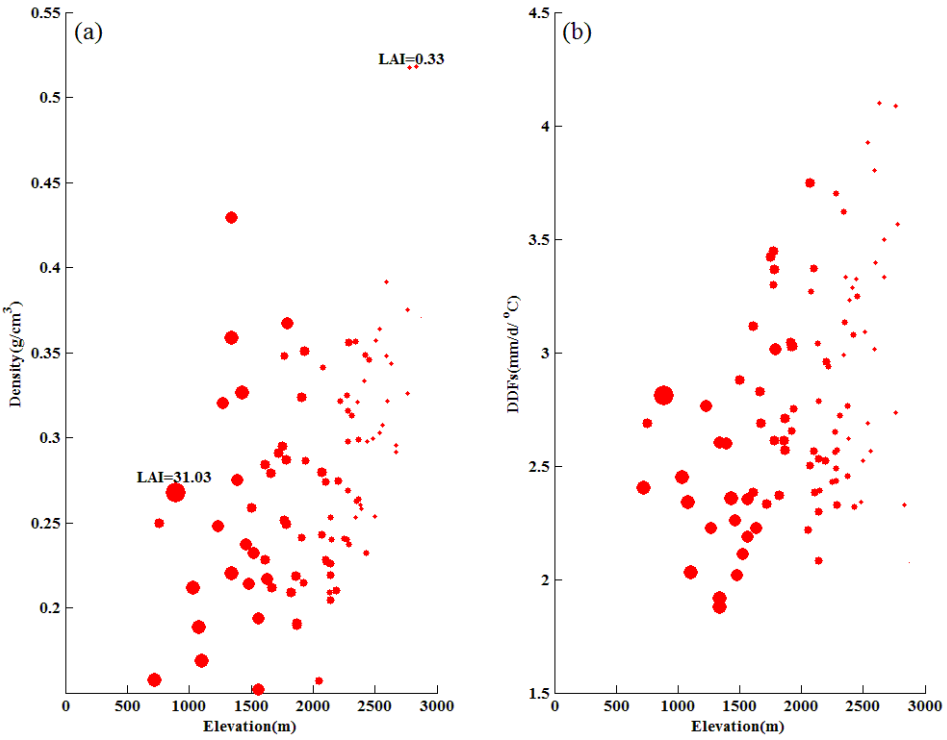

Figure 3. Snow density and snowmelt degree-day factor (DDF_S) estimated by the proposed method plotted against elevation in the Lienz basin. Each dot represents a sub-catchment in the basin. The size of dots increases with increasing of mean leaf area index (LAI) over the study period (2001-2010) which is derived from MODIS. LAI values in the basin range between 0.33 and 31.03.

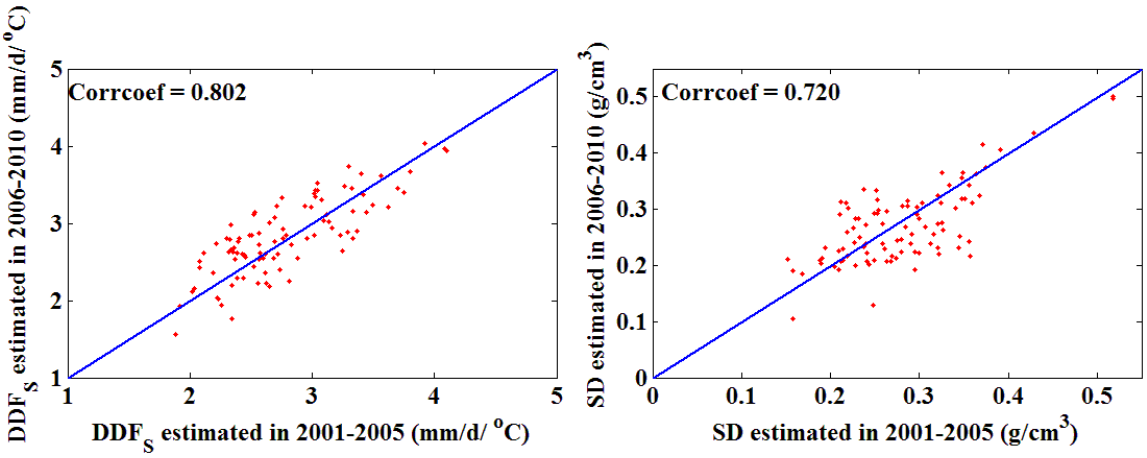

Figure 4. Comparison of the estimated degree-day factor for snowmelt (DDF_S) and snow density (SD) in two sub-periods. "Corrcoef" is the value of correlation coefficient between two estimated sets.

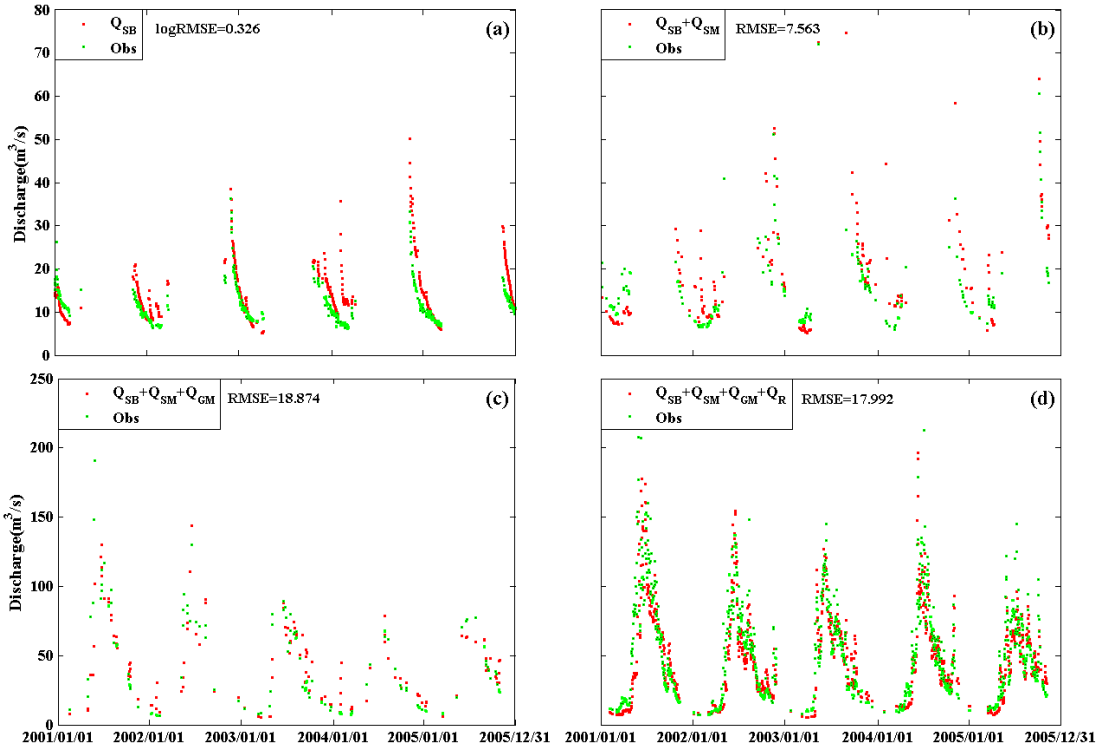

Figure 5. Stepwise calibration results for the Lienz basin in the calibration period. (a) is the first calibration step in which the parameters controlling groundwater baseflow are calibrated, (b) to (d) are the subsequent three steps of calibrating melt factors and rainfall runoff parameters. Q_{SB}, Q_{SM}, Q_{GM} and Q_R are the simulated discharges that are generated by baseflow, snowmelt, glacier melt and rainfall, respectively.

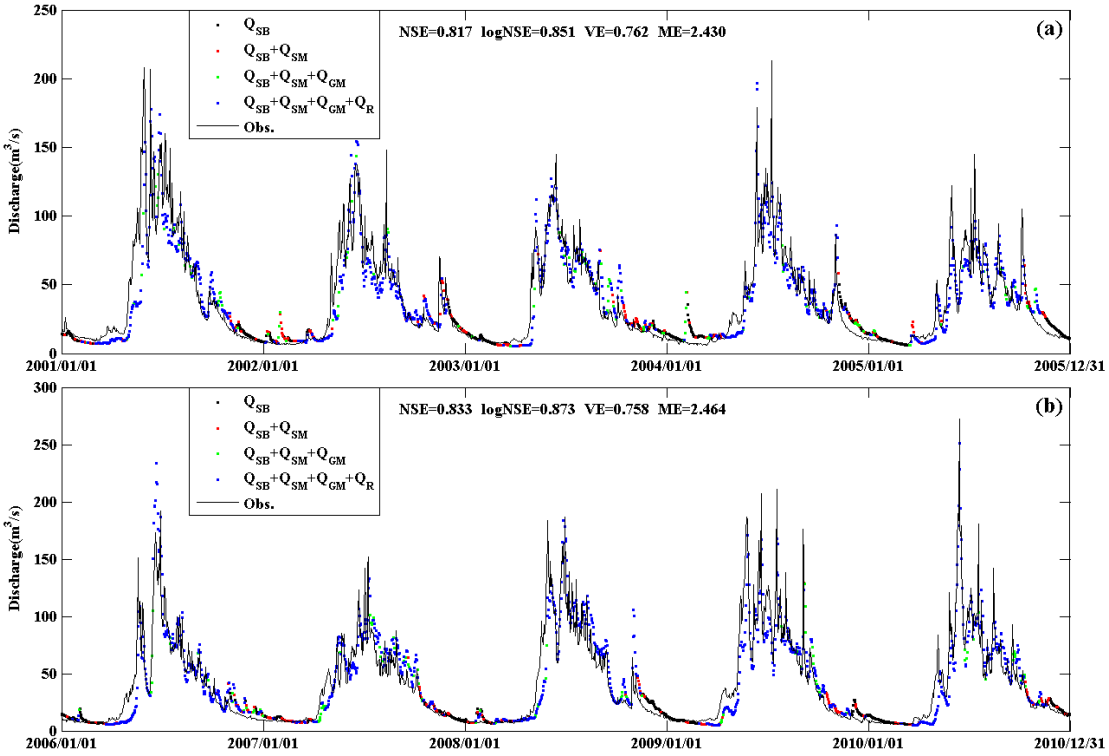

Figure 6. Simulation of daily discharge in the Lienz basin using the snowmelt degree-day factor calibrated on runoff. (a) is for the calibration period and (b) is for the validation period. The entire daily simulated discharge hydrograph has been combined from the simulations of different runoff segments. Q_{SB} stands for the simulated runoff generated by groundwater baseflow, Q_{SM} and Q_{GM} indicate simulated runoff generated by snow and glacier melt, and Q_R is the simulated runoff generated by rainfall directly. Performance measures of the simulations are shown at the top of each panel.

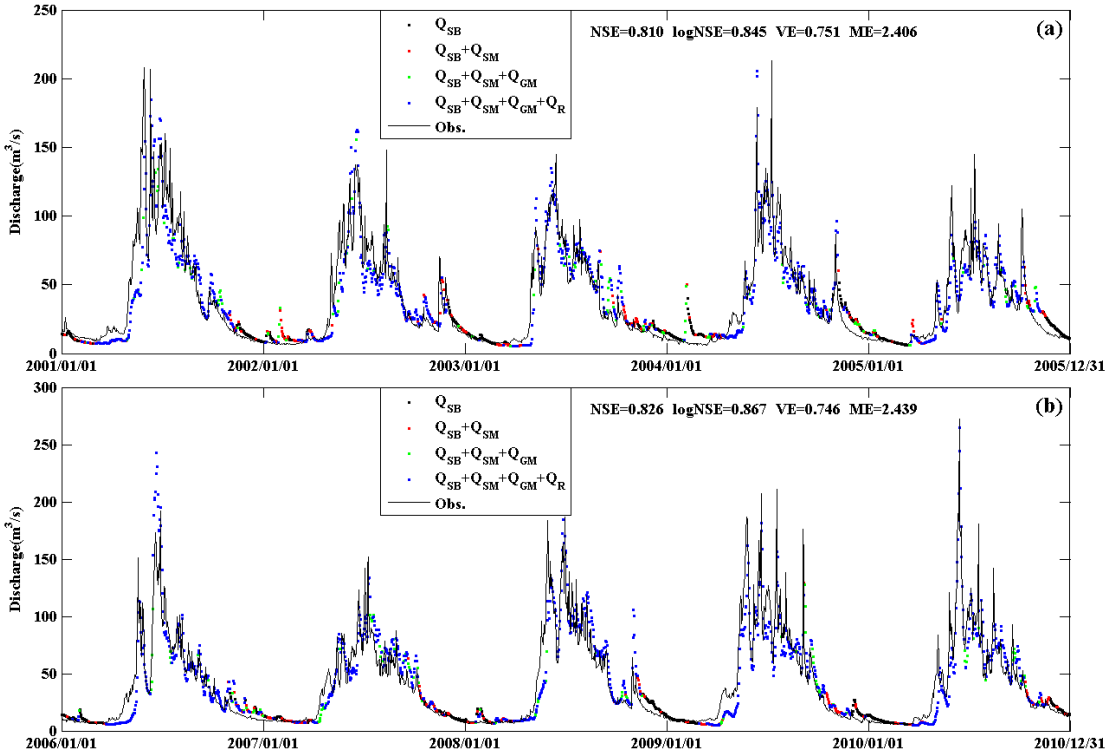

Figure 7. Same as Fig. 5 but using snowmelt degree-day factors estimated from snow data.

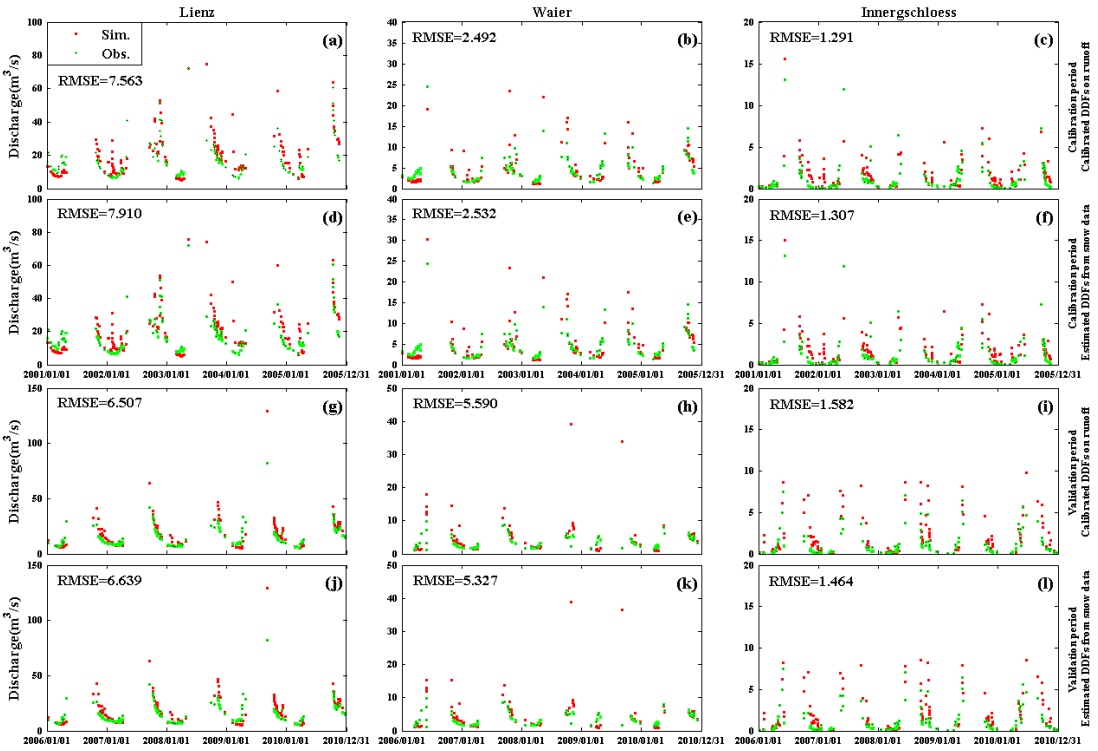

Figure 8. Simulations of discharge segments generated by groundwater baseflow (Q_{SB}) and snowmelt (Q_{SM}) in the three basins. (a)-(c) are simulations for the calibration period using DDF_S calibrated on runoff, (d)-(f) are simulation for the calibration period using DDF_S estimated from snow data, (g)-(i) are simulations for the validation period using DDF_S calibrated on runoff, (j)-(l) are simulations for the validation period using DDF_S estimated from snow data. The discharge simulations are evaluated using the *RMSE* (m^3/s).

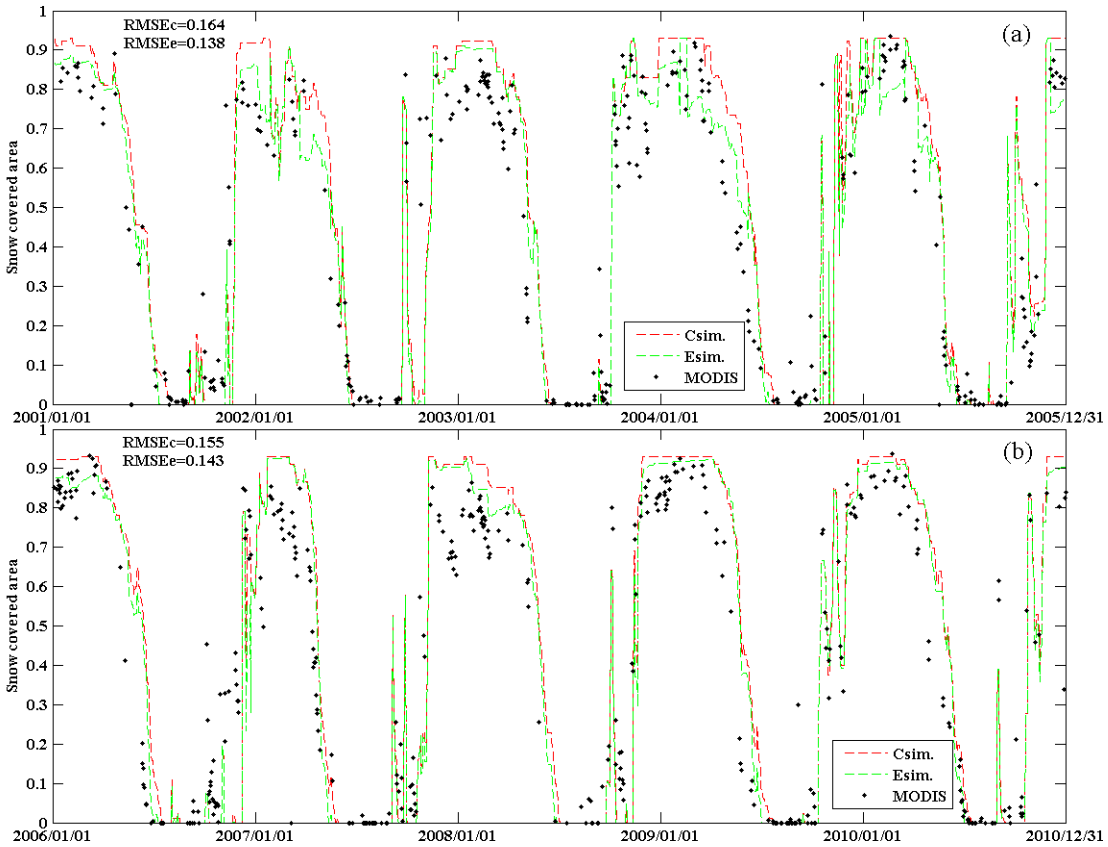

Figure 9. Simulations of the snow covered area (SCA) time series for the Lienz basin (1190 km^2). Red lines (Csim.) represent the SCA simulation using the snowmelt degree-day factor (DDF_S) calibrated on runoff; green lines (Esim.) represent the SCA simulation using snowmelt degree-day factors estimated from snow data. Black dots are the MODIS observed SCA values. (a) is for the calibration period and (b) is for the validation period. The simulations are evaluated by *RMSEc* for the calibrated DDF_S and *RMSEe* for the estimated DDF_S.

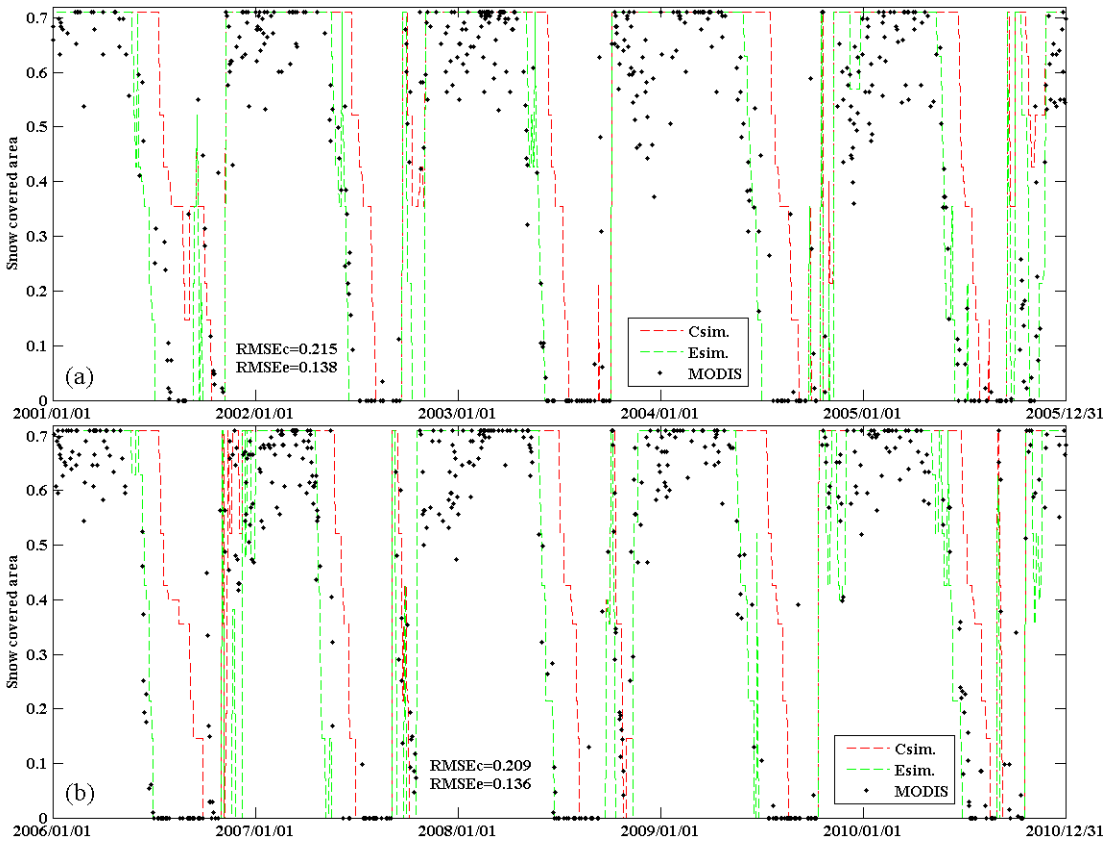

Figure 10. Same as Fig. 8 but for the Innergschloess basin (39 km^2).

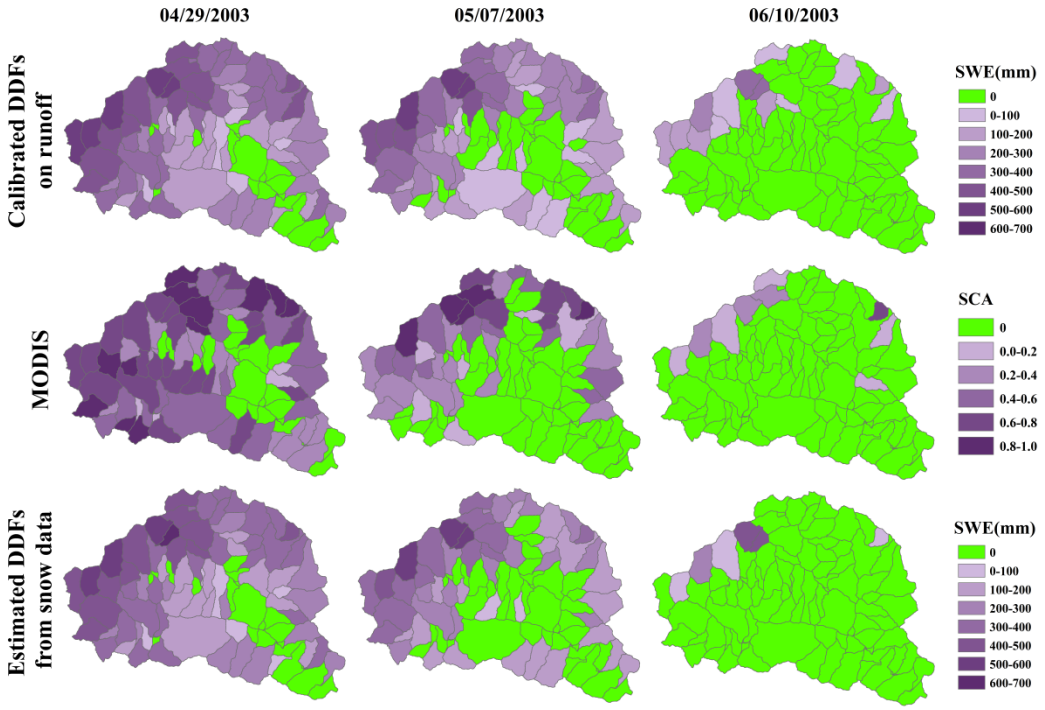

Figure 11. Simulations of snow patterns on three days within the calibration period (April 29th, May 7th and June 10th , 2003). The top row shows simulated snow water equivalent (SWE) using DDF_S calibrated on runoff, the middle row shows snow covered area (SCA) observed by MODIS, and the bottom row shows simulated snow water equivalent using DDF_S estimated from snow data.

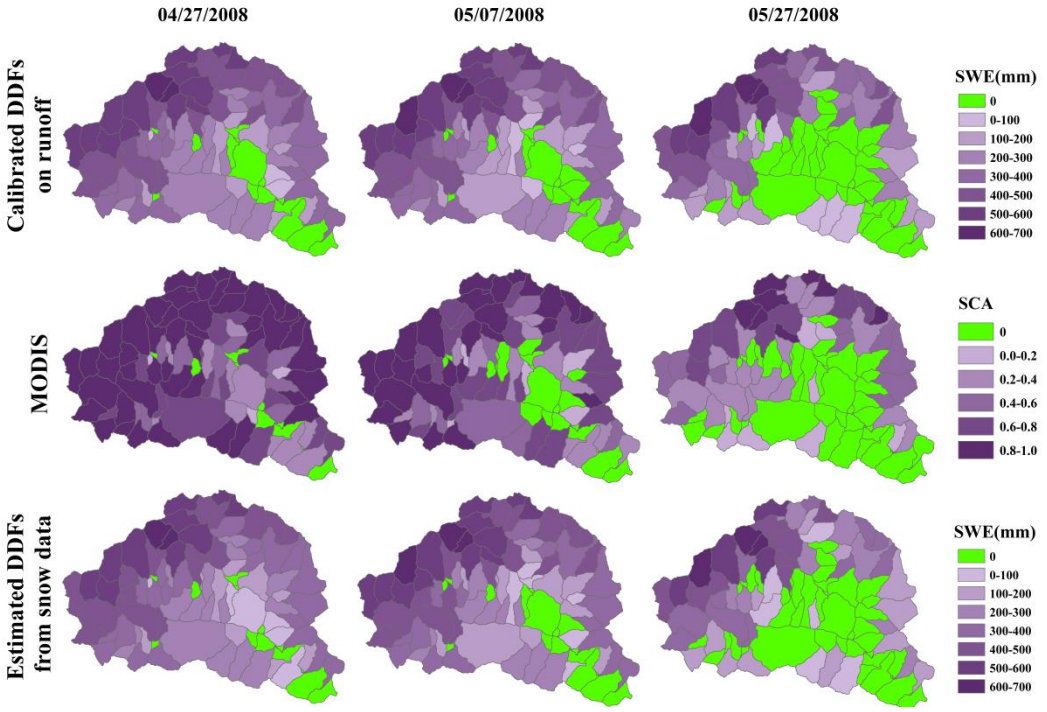

Figure 12. Same as Fig. 10 but for three days within the validation period (April 27th, May 7th and May 27th, 2008).
