Responses to Reviewer #3 (report #2).

1) Figure A would be a nice supporting evidence to add.

Reply: Agree. We have included it as Fig. 4 and added some explanations in lines 168-171.

2) The authors misunderstood my specific comment 1). The problem with “soil water” and “soil water redistribution” is not with “water”, but with “soil” and “redistribution”. In this study, the flow that is being simulated with the new parameterization is not of “soil water” per se, because it has not mixed with soil yet. It is a bulk flow within the root channel. “Soil water/moisture redistribution” implies that water gets mixed with soil in one particular place, and then gets picked up somehow to be re-deposited to another place. That’s not what is happening in this study. Maybe change the sentence to “ …. in the form of bulk flow through the stem-root flow mechanism …”?

Reply: Now we get it. The point is well taken. We have modified the first sentence in the abstract accordingly as “Rainfall that reaches the soil surface can rapidly move into deeper layers in the form of bulk flow through the stem-root flow mechanism.”

Stem-root flow effect on soil-atmosphere interactions and uncertainty assessments

Abstract

Rainfall that reaches the soil surface can rapidly move into deeper layers in the form of bulk flow through the stem-root flow mechanism. This study develops the stem-root flow parameterization scheme and coupled this scheme with the Simplified Simple Biosphere model (SSiB) to analyze its effects on land-atmospheric interactions. The SSiB model was tested in a single column mode using the Lien Hua Chih (LHC) measurements conducted in Taiwan and HAPEX-Mobilhy (HAPEX) measurements in France. The results show that stem-root flow generally caused a decrease in soil moisture at the top soil layer and moistened the deeper soil layers. Such soil moisture redistribution results in substantial changes in heat flux exchange between land and atmosphere. In the humid environment at LHC, the stem-root flow effect on transpiration was minimal, and the main influence on energy flux was through reduced soil evaporation that led to higher soil temperature and greater sensible heat flux. In the Mediterranean environment of HAPEX, the stem-root flow substantially affected plant transpiration and soil evaporation, as well as associated changes in canopy and soil temperatures. However, the effect on transpiration could be either positive or negative depending on the relative changes in the soil moisture of the top soil versus deeper soil layers due to stem-root flow and soil moisture diffusion processes.

Key words: stemflow, root flow, soil moisture, evapotranspiration, land-atmospheric interaction, SSiB

刪除: via vertical redistribution of soil moisture

1. Introduction

The water stored in the land system is a key factor controlling many physical processes and feedback between the land and atmosphere. Soil moisture is a source of water for the atmosphere through processes that lead to evapotranspiration, including bare soil evaporation, plant transpiration and evaporation from other surfaces such as leaves, snow, etc. The rainfall redistribution process in forest systems affects soil moisture amount and its distribution (McGuffie et al., 1995; Chase et al., 1996; Chase et al., 2000; Zhao et al., 2001). Rain water entering the forest is redistributed via several pathways before reaching the forest floor, e.g., some is intercepted by the canopy and some reaches the soil as throughfall. A significant amount of rainwater intercepted by the canopy can flow down along tree stems and reach the forest floor in a process termed stemflow. The efficiency of stemflow varies with plant species, seasons, meteorological conditions, rainfall intensity, and canopy structure (Levia and Frost, 2003; Levia and Germer, 2015). Johnson and Lehmann (2006) summarized various field measurements and showed that the fraction of precipitation that becomes stemflow ranges from 0.07% to 22%.

In contrast to the throughfall that infiltrates slowly through the top soil, stemflow can continue via the root system (hereafter called the "stem-root flow") and quickly reach deep soil layers and the water table (Liang et al., 2007; 2009). It has long been recognized that the stem-root flow can help to store water in deeper soil layers and thus create favorable conditions for plant growth under arid conditions (Návar, 1993; Li et al., 2009). Soil moisture redistribution by stem-root flow not only affects

vegetation growth but also land evapotranspiration and runoff (Neave and Abrahams, 2002). Furthermore, the enhanced water penetration can significantly alter groundwater recharge. Taniguchi et al. (1996) showed that in a pine forest, the stem-root flow contributed approximately 10–20% of annual groundwater recharge even with a stemflow-to-precipitation ratio of only 1%.

Stem-root flow effects have not been considered in most land-surface schemes of climate models. Tanaka et al. (1996) developed a model to evaluate the effect of stem-root flow on groundwater. This model is yet to be implemented in current land surface models. Li et al. (2012) pointed out that stemflow hydrology and preferential flow along roots are intimately linked, but direct integration of these processes into land models, to our knowledge, has not been reported.

In this paper, we parameterized the stem-root flow processes in a land surface model named the Simplified Simple Biosphere Model (SSiB; Xue et al., 1991), and analyzed how stem-root flow affects soil moisture and whether this effect is significant enough to influence atmospheric processes. Soil moisture data from two sites, located at Lien Hua Chih, Taiwan (LHC) and Bordeaux/Toulouse, France (from the HAPEX-Mobilhy experiment, hereafter called HAPEX), were collected for model evaluation. The two sites represent different climate regimes and terrestrial ecosystem, and stem-root flow modifies their surface energy and water processes in somewhat dissimilar ways.

2. Methodology

2.1 The stem-root flow model

In the original SSiB land surface model (Xue et al., 1996), vertical soil moisture movement is described by the diffusion equations:

$$\begin{aligned}\frac{\partial\theta_1}{\partial t} &= \frac{1}{D_1}\left[P + Q_{12} - E_{SE} - b_1 E_{TR,1}\right]\\ \frac{\partial\theta_2}{\partial t} &= \frac{1}{D_2}\left[-Q_{12} + Q_{23} - b_2 E_{TR,2}\right]\\ \frac{\partial\theta_3}{\partial t} &= \frac{1}{D_3}\left[-Q_{23} + Q_3 - b_3 E_{TR,3}\right]\end{aligned} \quad (1)$$

where the subscripts 1, 2 and 3 are indices of the top, middle, and bottom soil layers, respectively; θ is the soil moisture content, expressed as a fraction of the saturated value; D is soil thickness; P is effective precipitation flux on the soil surface, composed of the direct throughfall and the throughfall from leave-intercepted rainfall (cf. Fig. 1); $Q_{ij} = -k[\partial\Psi/\partial z + 1]$ is the flux of water between the i^{th} and j^{th} layers, and is defined to be positive in an upward direction; Ψ (in m) is the soil water potential; E_{SE} is the evaporation rate of bare soil; i is the soil layer index; $E_{TR,i}$ is the transpiration rate in soil layer; b_i is the proportionality factor that accounts for root distribution; Q_3 is the water flux entering the water table. The similar approach has been used by many land surface models. Note that the middle soil layer can be divided into more sublayers with similar formula as used for the middle layer. In these equations, the transfer velocity Q_{ij} considers only the soil diffusion flow. This study develops the parameterizations that include the stem-root flow mechanism which provides a "bypass" for water to channel through the soil on root surfaces (Fig. 1). The stemflow reaching the top soil layer, q_0, is often represented as a fraction of the total precipitation (or, more precisely, the leaf drainage) such that direct rainfall entering the soil becomes

$$P' \equiv P - q_0. \quad (2)$$

By relating the stemflow to leaf drainage, there is an implicit threshold for stemflow initiation that corresponding to the threshold of leaf drainage.

After entering the soil, the root flow is divided into a downward transfer flux q_z (within the root system) and a lateral transfer flux q_x (from the root surface to the soil). These two fluxes can be parameterized as following:

$$q_{z,i} = \alpha_z A_i h_i V_s \tag{3}$$

$$q_{x,i} = \begin{cases} \alpha_x R_i A_i K(\Psi_i) \left(\frac{\Psi_i - \Psi_s}{D_{\text{eff}}}\right), & \text{if } h_i > 0 \\ 0, & \text{if } h_i = 0 \end{cases} \tag{4}$$

where α_z and α_x are proportionality coefficients; A_i (in $m^2\ m^{-3}$) is the total root surface area density that varies with vegetation types (Böhm, 1979; Zhang et al., 2005; Li et al., 2013); h_i (in m) is the thickness of water on the root surface; V_s (in m s^{-1}) is the terminal velocity of root flow; R_i (in m) is the root length; K (in m s^{-1}) is the hydraulic conductivity of the soil; Ψ_s (in m) is the soil water potential at saturation; Ψ_i (in m) is the soil water potential; and D_{eff} (in m) is the effective thickness of the water-soil interface. Derivation of D_{eff} is described in the appendix. Due to a lack of observational data, we used a vertically uniform root distribution. However, different root depths were used based on the measurements (100 cm for LHC and 140 cm for HAPEX). Note that $q_0 = q_{x,1} + q_{z,1}$ according to the mass conservation principle. From Eqs. (1), (2), and (4), we have:

$$\begin{aligned} \frac{\partial \theta_1}{\partial t} &= \frac{1}{D_1}\left[P' + Q_{12} - E_{SE} - b_1 E_{TR,1} + q_{x,1}\right] \\ \frac{\partial \theta_2}{\partial t} &= \frac{1}{D_2}\left[-Q_{12} + Q_{23} - b_2 E_{TR,2} + q_{x,2}\right] \\ \frac{\partial \theta_3}{\partial t} &= \frac{1}{D_3}\left[-Q_{23} + Q_3 - b_3 E_{TR,3} + q_{x,3}\right] \end{aligned} \tag{5}$$

95 The changes in root surface water thickness h_i obey the mass conservation principle and thus are
96 controlled by the vertical and horizontal fluxes of root flow. Its tendency can be described as:

97 $$\frac{dh_i}{dt} = \begin{cases} \frac{(q_{z,i-1} - q_{z,i} - q_{x,i})}{A_i R_i}, & \text{if } h_i > 0 \\ 0, & \text{if } h_i = 0 \end{cases} \quad (6)$$

98 Equations (5) and (6) represent the water budgets in the soil and root flow systems, respectively, and
99 they are linked through the term q_x in Eq. (4).

100 Stemflow input into the first soil layer (q_0) is represented as a fraction of the leaf drainage (LD),
101 which is the portion of precipitation that is intercepted by the canopy minus leaf evaporation and can
102 be calculated in SSiB. LD is similar to canopy drip in some other models, and is represented mainly
103 as a function of the leaf area index (LAI). The ratio of q_0 to LD depends mainly on plant type, as well
104 as meteorological conditions such as wind speed (Levia and Frost, 2003; Johnson and Lehmann, 2006;
105 André et al., 2008; Siegert and Levia, 2014). Unfortunately, there is still insufficient information to
106 determine the ratio of q_0 and LD. We conducted a series of sensitivity tests with systematically
107 varying ratio between the q_0 to LD to assess the uncertainty.

108 The stem-root flow parameterization was tested using the offline SSiB, which is a simplified
109 version of the land-biosphere model developed by Sellers et al. (1986). The model recognizes 12
110 different vegetation types according to Dorman and Sellers (1989), and is set up with 3 soil layers and
111 1 canopy layer. The SSiB model has 8 prognostic variables: soil wetness for 3 layers; temperature at
112 the canopy, ground surface and deep soil layers; snow depth at ground level; and water intercepted by
113 the canopy. An additional variable – h_i – was added for each soil layer to account for the stem-root

114 flow mechanism. An implicit backward scheme was used to calculate the temperature tendency in the
115 coupling of the lowest atmospheric model layer with SSiB, such that energy conservation between the
116 land surface and the atmosphere was satisfied. Soil temperature was calculated using the
117 force-restore method, and water movement in the soil was described by the diffusion equation as
118 shown in Eq. (5).

119 Following typical offline simulation procedures for single-column land surface model, in situ
120 atmospheric data were applied to drive the SSiB model in 30 min time resolution. These specified
121 variables include pressure, temperature, humidity, wind speed, net radiation and rainfall. Soil
122 conditions were initialized with each site's measurement data. The spin up time for coupled land
123 surface model typically ranges from a couple of months to over a year, but can be shorter when
124 running in off-line (single column) mode and with good initial soil conditions (de Goncalves et al.,
125 2006; Yang et al., 2011; Lim et al., 2012; Angevine et al., 2014). Our simulations applied
126 measurement data for model initialization, and the results show that the soil conditions reached
127 physical balance within a few weeks. So, at the last 10 months results of our simulations are
128 reliable.

129 2.2 Experimental design and site information

130 Two sites with different climate and vegetation conditions were selected to test the stem-root flow
131 parameterizations in the SSiB model. The first is a site with warm-to-temperate mountain rainforest
132 condition from the Lien Hua Chi (LHC; 23°55'N, 120°53'E), Taiwan. LHC is located in the Central

133 Mountain Range of Taiwan, with a hilly terrain and a mean altitude of 770 m above sea level in the
134 surroundings. The average annual rainfall at LHC is 2317 mm, with rain falling predominantly in late
135 summer and early autumn (Fig. 2). With ample rainfall, LHC is covered with dense forest with an
136 average canopy height of approximately 17 m. The vegetation cover is comprised of mixed
137 evergreens and hardwood species, including *Cryptocarya chinensis*, *Engelhardtia roxburghiana*,
138 *Tutcheria shinkoensis*, and *Helicia formosana*. The soil has a loamy texture with an average bulk
139 density of 1.29 g cm^{-3} and a porosity of 0.53 over the top 1.0 m (Chen, 2012). Soil moisture
140 measurements were collected at depths of 10, 30, 50, 70 and 90 cm.
141 The second is the HAPEX-Mobilhy data collected at the Caumont site (SAMER station No. 3;
142 43°41'N, 0°6'W) with an elevation of 113 m above sea level and relatively flat terrain. This site has a
143 Mediterranean climate, with an annual rainfall of 856 mm, most of which occurs in spring and winter
144 (Fig. 3). In contrast to the LHC site with dense forest, the HAPEX site is covered mostly with short
145 and sparse soya crops, and the surface albedo stays nearly constant at 0.20 throughout the year
146 (Goutorbe et al., 1989). The soil type is mainly silt, mixed with sand and clay (see Table 1). Soil
147 moisture content was measured every 10 cm from the surface to a depth of 1.6 m using neutron
148 sounding probes on a weekly basis (Goutorbe, 1991; Goutorbe and Tarrieu, 1991). Note that the
149 HAPEX data have higher vertical resolution in the soil column but lower temporal resolution
150 compared with the LHC data. To simplify comparisons, the soil moisture data were converted into
151 three vertical layers. For the HAPEX data, the top (SM1), middle (SM2) and bottom (SM3) layers

correspond to the 0–20 cm, 20–50 cm, and 50–150 cm depths, respectively. For LHC, SM1 corresponds to a depth of 10 cm, SM2 is the average of the 30 cm and 50 cm soil layers, and SM3 corresponds to a depth of 90 cm.

Figures 2 and 3 show the seasonal variations of precipitation and soil moisture at different depths. It is generally expected that soil moisture response to rainfall should be faster in the upper than in the lower layers. However, the LHC measurements (Fig. 2) showed that the soil moisture fluctuation was stronger in the middle layer than in the upper layer during the dry season when the soil moisture was not saturated. Fluctuations were not obvious in rainy seasons when SM2 and SM3 are almost saturated. This phenomenon is likely an indication of the preferential flow due to the root flow mechanism. This phenomena, however, was not observed in the HAPEX data (Fig. 3), which may be due to the coarse temporal resolution (weekly) of the data or a weaker root flow effect from the soya crop, and the latter will be discussed later. Figure 4 shows the correlation between hourly changes in precipitation and soil moisture at LHC in 2010. The correlations are higher at deeper layers and during stronger rainfall intensities. Such a relationship is a good indication of the stem-root flow mechanism.

To test the response of soil moisture to precipitation in these two sites using the modified SSiB model, a set of parameters have to be selected. These include the soil and terrain properties listed in Table 1, as well as the monthly LAI coefficients in Table 2. In addition, some parameters in Eqs. (3)-(6) have to be decided. Two required but little-known parameters are the root-flow velocity V_s

171 and the stemflow to leaf drainage ratio (SLR; i.e., q_0/LD). The root-flow velocity V_s is related to root
172 structure and soil texture, but such information is very limited. Studies have indicated that water flow
173 in the root-channel is approximately 100 times higher than the soil diffusion flow (Beven and Germann,
174 1982; Liu et al., 1994; Jarvis and Dubus, 2006; Köhne et al., 2009; Gerke, 2014). The maximum soil
175 diffusion flow can be represented by the saturated hydraulic conductivity, which was measured as
176 $4x10^{-6}$ m s^{-1} at HAPEX and $1x10^{-6}$ m s^{-1} at LHC. Therefore, we set the root-flow velocity V_s as
177 10^{-4} m s^{-1} in the simulation, and will discuss the associated uncertainty later.
178 The SLR value depends on a number of parameters as discussed in the previous section. This
179 study evaluated SLR-introduced uncertainty by conducting sensitivity tests with systematically
180 varying SLR from 0 to 100%, and identified optimal value that yielded the best soil moisture profiles
181 compared with the observations. The optimal SLR value for the HAPEX experiment was
182 approximately 50%, compared with 90% for the LHC case. These values reflect the large contrast in
183 leaf coverage and plant type between the two sites. In these experiments, we set A_i to 0.5 m^2 m^{-3}
184 based on the Li et al. (2013) and the proportionality coefficients, α_z and α_x, are set to 1. The
185 uncertainty discussion for V_s and SLR should include the uncertainty caused by these parameters.
186 When more observational data are available, we could revisit these issues further. All simulations
187 used integration time step of 30 minutes.
188
189 3. Effect of stem-root flow on soil moisture

The modified SSiB model was used to simulate the intra-annual variations in soil conditions for the 2010 LHC case and the 1986 HAPEX case. For the LHC case, the simulation well captured the soil moisture increase associated with precipitation events followed by rapid drying (Fig. 5). Changes in SM1, SM2 and SM3 all reached the 95% confidence level in all seasons. In many instances, the simulated soil moisture fluctuation was stronger in the middle layer than in the top or bottom layers, as found in the observations. The shading shows the range of values enclosed by the two extremes of SLR (i.e., 0% and 100%). Results with other SLR ratios (not shown) generally lie within these limits but may occasionally fall out of bound, indicating some nonlinearities. When SLR is zero, which has no stem flow effect and is referred to as the control run in this paper, the soil moisture of the middle layer is very low and fluctuates less in response to rainfall events (Fig. 5). The simulation generally underestimated the soil moisture in the bottom layer even with the root-flow mechanism. In the top layer, the model overestimated soil moisture in spring and winter, but underestimated it during autumn. Such discrepancies are generally less substantial when the stem-root flow mechanism is included, as indicated by the generally lower bias and root-mean-square error shown in Table 3. The possible causes of error will be elaborated in the discussion section.

For the HAPEX case, the simulations also well captured the seasonal cycle as well as the sharp fluctuations in the top layer (Fig. 6). The responses of SM2 and SM3 to the stem-root flow are statistically significant (>95% confidence) during late summer and autumn (the main growing season and relatively dry soil); whereas the responses in SM1 reached only 94% confidence level. Without

刪除: 4

刪除: 4

刪除: 5

212 the stem-root flow mechanism, soil moisture was generally overestimated in the two upper layers and
213 underestimated in the bottom layer, except during April and May when all layers were too dry. When
214 stem-root flow with SLR=50% was considered, the model performed better in all layers (see Table 3).
215 Stem-root flow with a much higher SLR (e.g., SLR=100%) produced worse results for soil moisture in
216 the surface and middle layers. Note that SLR=50% produced the driest middle layer, indicating that
217 the stem-root flow effect is nonlinear because both stem-root flow and diffusion, as well as their
218 interactions, play role in soil moisture variations. Note that SSiB does not consider the potential role
219 of plant uptake, which might be potentially important in the middle layer. In the bottom layer, more
220 accurate soil moisture was obtained with SLR=100%, but this does not necessarily mean that the
221 stem-root flow was underestimated. The overestimation of soil moisture in SM1 and the
222 underestimation in SM3 in spring may be coupled, due to mechanisms that are missing in our model.
223 This issue will be elaborated in the discussion section.

224 It is also worth mentioning that both the observation and simulation showed weaker soil moisture
225 fluctuations in the middle than in the surface layer, a feature very different from the LHC case. It is
226 likely that there is a weaker stem-root flow associated with plant and soil types in the HAPEX case.
227 Figures 5, and 6 demonstrate that the strength of the stem-root flow is greater in LHC, with associated
228 changes in soil moisture of up to 0.1 m^3 m^{-3} compared with the maximum changes of 0.05 m^3 m^{-3} at
229 HAPEX. This is simply because LHC has more intense rainfall than HAPEX.

4. Effect of stem-root flow on energy flux

The results in last section show that stem-root flow can alter the vertical profile of soil moisture. It is important to know whether such a modification has significant effects on evapotranspiration and associated interactions between the land and atmosphere. The soil moisture in the top soil layer in the LHC case generally decreased due to stem-root flow, except in some instances (e.g., mid-September, the later dry season) when the enhanced moisture storage in the deep layers replenish the moisture in the drying surface soil through moisture diffusion. The changes in plant transpiration, however, were insignificant (red curve in Fig. 7a), as this process is associated with soil moisture not only in the top layer but also in the deeper layers that are within the reach of the root system. Therefore, the effect of surface layer drying on transpiration may be compensated by the moistening of the lower layers. Soil moisture in these layers are well above the wilting point to support the normal transpiration. Meanwhile, the drying of the surface soil resulted in less soil evaporation (Fig. 7a), which heavily relies on soil moisture near soil surface, and thus weaker the total latent heat release (see Table 4 for the mean and maximum changes in daily temperatures and energy fluxes). This led to a higher soil surface temperature and consequently stronger sensible heat flux (blue curve in Fig. 7b), which resulted in warmer air (magenta curve in Fig. 8b) and thus stronger rainwater evaporation from the leaf surface (green curve in Fig. 7a).

In the HAPEX case, the stem-root flow caused a general drying of the top soil, except for a brief period in mid-October (Fig 8a). However, responses in soil evaporation were not as straightforward

删除: 6

删除: 6

删除: 7

删除: 6

删除: 7

as in the LHC case. For example, in late July (just after the start of the growing season) there was a spike in the evaporation but a reduction in the moisture of the top soil layer (blue curve in Fig 8a). As wind speed is the same for both cases, the increase in soil evaporation must be due to either a higher soil temperature and/or a lower water vapor density in the air near the soil surface. This was indeed the case (magenta and black curves in Fig. 8b) and found to be driven by changes in transpiration.

Soil moisture in the HAPEX case was generally much lower than in the LHC case and occasionally fell below the wilting point. The stomatal resistance that controls transpiration is very sensitive to the soil moisture near the wilting point. As such, a slight decrease in the moisture of the top soil layer can dramatically reduce transpiration. When soil moisture approached the wilting point in late July, plant transpiration reduced sharply in response to the stem-root flow effect (red curve in Fig. 8a). Such a change in plant transpiration caused an increase in the air temperature near the soil surface (magenta curve in Fig. 8b) and a decrease in air humidity, which increased soil evaporation (blue curve in Fig 8a). In early August, however, soil moisture accumulated in the bottom layer through the stem-root flow (cf. Fig. 6c) and the stomatal resistance began to decrease such that transpiration recovered and soon dominated the overall evapotranspiration throughout the rest of the growing season. The increased transpiration also caused a reduction in air temperature and surface temperature and thus the associated sensible heat flux (blue curve in Fig. 8b). During late August to mid-September, surface soil moisture was so low in some instances (cf. Fig 6a), transpiration was shutdown with or without the stem-root flow effect. In these instances, the net energy flux was

controlled by soil evaporation (Fig 8b).

5. Discussion

The above analyses indicate that stem-root flow affects the energy flux mainly through changing the balance between surface soil evaporation and sensible heat fluxes in the humid environment of LHC, and through changing plant transpiration and sensible heat fluxes over the relatively dry environment at HAPEX. The associated changes in annual energy flux to the atmosphere are strongly positive at LHC, but nearly balanced at HAPEX. However, the magnitude of the changes of the individual energy flux component was significantly higher for HAPEX (peaked at approximately -67 and +51 W m^{-2} for transpiration and sensible heat, respectively) than for LHC (peaked at approximately -16 and +31 W m^{-2} for evaporation and sensible heat, respectively) due to its drier Mediterranean environment.

Another interesting contrast between the two cases is the relationship between sensible heat and total heat (sensible heat plus latent heat). In the LHC case, the responses of sensible heat and total heat to the stem-root flow are generally of the same sign (Fig. 7b), whereas they have opposite signs in the HAPEX case (Fig. 8b). Furthermore, the net change in heat flux is dominated by sensible heat at LHC but by latent heat at HAPEX. Budyko (1974) proposed two main evapotranspiration regimes: soil moisture-limited and energy-limited. As summarized by Seneviratne et al. (2010), when soil moisture remains above a critical value, the fraction of evapotranspiration of the total energy flux is

删除: 7

删除: 6

删除: 7

307 independent of the soil moisture content (energy-limited regime); below the critical soil moisture value,
308 the soil moisture content provides a first-order constraint on evapotranspiration (soil moisture-limited
309 regime). Therefore, the evapotranspiration responses to the stem-root flow as discussed above imply
310 that HAPEX is in the soil moisture-limited regime, whereas LHC is in the energy-limited regime.
311 Note that this regime separation needs to take into account the contribution of deep soil moisture to
312 transpiration.

313 Regarding the partition of water transport, recent studies (e.g., Jasechko et al., 2013; Good et al.,
314 2015; Wei et al., 2015) explored the dominant role of transpiration in ecosystem evapotranspiration.
315 The results of this work partially concur with these studies. In other words, the stem-root flow in the
316 plant-soil system could enhance the transpiration, and reduce the soil evaporation, which regulated the
317 partition of evapotranspiration. A number of PILPS studies, including the PILPS-HAPEX
318 experiment (Boone and Wetzel, 1996; Henderson-Sellers, 1995; Shao et al., 1996; Xue et al., 1996)
319 consistently demonstrated that the current land model parameterizations have the weakness in
320 simulating the soil moisture in the dry season. This study by introducing a parameterization on the
321 stem-root flow mechanisms, wish to help solve this deficiency. With the stem-root flow mechanism,
322 the soil moisture will redistribute in vertical, leading to better simulated results in each layer, which
323 is important for the evapotranspiration partition.

324 By including the stem-root flow mechanism, the land surface model appears to better simulate the
325 vertical distribution of soil moisture. However, significant discrepancies still exist in the model based

on comparisons with observed data. The discrepancies may be associated with uncertainties in soil-related physical parameters, such as a few that we listed in the earlier sections. For example, a wide range of values have been reported in the literature for the parameter V_s. In the above simulations, we assigned $V_s = 10^{-4}$ m s^{-1}, which is probably at the low end of the documented values. An additional simulation was performed using a 10-fold higher V_s value (i.e., $V_s = 10^{-3}$ m s^{-1}), and the resulting soil moisture changes were similar to those presented in Figs. 5 and 6 with differences of only a few percent and thus are barely legible in Figs. 9 and 10. When a smaller value of $V_s = 10^{-5}$ m s^{-1} was used, the effect of stem-root flow on soil moisture was similar but the magnitude of the changes was reduced by approximately 50%. These sensitivity tests give an indication of the uncertainties associated with V_s.

Even with the maximum V_s, the simulated soil moistures at the bottom layer are still lower than observed. More realistic values for other soil physical parameters and/or optimizations of these parameters are required. Xue et al. (1996) pointed out that land surface models such as SSiB are quite sensitive to soil-type dependent parameters such as the hydraulic conductivity at saturation and the coefficient used to calculate soil water potential. Such parameters can vary significantly from place to place, and sufficient information to assign appropriate values is usually lacking. This is particularly true for LHC where the soil types exhibited a rather inhomogeneous vertical distribution, and some humus layers could exist to retard surface drainage. Another critical issue is the treatment of water flow across the bottom soil layer. In our current model, soil moisture can leave the bottom

删除: 8

删除: 9

layer with a fixed efficiency, but no recharge from the water table below is allowed. These issues might cause the model to underestimate the soil moisture in the bottom layer (regardless of the presence of stem-root flow), which occurred in both the LHC and HAPEX simulations (cf. Figs. 5c and 6c). On the other hand, the overestimation of soil moisture in SM1 and the underestimation in SM3 in spring at LHC (Fig. 5) could also be explained by missing mechanisms such as hydraulic redistribution (cf. Brooks et al., 2002), which provides a bypass of soil moisture through the inside of the root rather than the exterior surface of the root as in the case of stem-root flow transport. On the other hand, the overestimation of the middle-layer soil moisture at HAPEX may be partly contributed from the plant uptake process which was not considered in this study. Besides, due to a lack of observational data, we used a uniform vertical distribution of root, which might be the other issue on different effects on two sites from stem-root flow. In recent years, U.S. Department of Energy has supported a number of projects to measure the root vertical distribution. With more data becoming available, we should be able to more realistically assess its effects. Henderson-Sellers (1996) indicated that a full evaluation of land surface model's simulation against observations can be established only when the initial conditions and all soil parameters are known precisely. Because this study lacks of process-level data, so the improvement should be more prudent to represent. Since this exploratory study focuses on introducing the stem-root flow mechanisms in a land surface model and test its possible impact, we will not further test the uncertainty due to other parameters in this paper. We hope more relevant measurements (such as the root distribution, stemflow to leaf

371 drainage ratio, and root flow velocity) will provide useful information to study these issues further.

372

373 6. Conclusion

374 In this study, a stem-root flow mechanism, which provides an efficient water channel for rain to
375 penetrate into deep soil, was formulated and implemented into an offline version of the SSiB
376 land-atmosphere model. The model was used to simulate soil moisture variation at two sites with
377 different climate and ecology conditions: LHC with a mountain rainforest climate and HAPEX with a
378 Mediterranean climate. The results showed that the inclusion of the stem-root flow mechanism
379 substantially improved the capability of the model to simulate vertical soil moisture profiles.
380 Stem-root flow generally caused a drying of the top soil layer (upper 20 cm) and a moistening of the
381 bottom layer (below 50 cm) in the model. On a few occasions, such as after a long dry period, the
382 surface layer may be less dry than without the stem-root flow due to greater water supply from the
383 lower layers. The middle soil layer at LHC was also moistened and, in many instances during rainfall
384 events, the moisture in this layer fluctuated more intensely than in the top layer in response to the
385 stem-root flow. However, in the HAPEX case, the middle layer became dryer with less fluctuation.
386 Due to differences in plant and soil types, the strength of the stem-root flow was greater at LHC than at
387 HAPEX.

388 The change in soil moisture associated with the stem-root flow leads to significant modifications
389 in heat and moisture fluxes between the land and atmosphere. The general drying of the surface soil

390 leads to reduced soil evaporation and thus increased soil temperature. Plant transpiration at LHC was
391 not significantly affected by the stem flow because the soil moisture content was maintained well
392 above the wilting point. Therefore, the stem-root flow related to energy flux between the soil and
393 atmosphere is mainly controlled by sensible heat. In this sense, LHC may be considered as having an
394 energy-limited evapotranspiration regime. In contrast, the HAPEX soil (especially the top layer) was
395 generally dryer and sometimes fell below the wilting point. Plant transpiration can thus be
396 substantially affected by the stem-root flow. Changes in transpiration lead to changes in air
397 temperature, which, in turn, influence soil temperature. This effect is stronger than that resulting from
398 the soil evaporation associated with changes in the soil moisture of the top soil layer. At the HAPEX
399 site, evapotranspiration was more soil moisture-limited than energy-limited, and its net change in heat
400 flux associated with the stem-root flow was dominated by latent heat. While the stem-root flow effect
401 on soil moisture was weaker there than at LHC, the energy flux exchanges were actually stronger due
402 to the sensitive transpiration process.

403 Through the impact on soil moisture profiles, stem-root flow can significantly affect evaporation
404 and transpiration processes. The associated changes in moisture and energy fluxes between the land
405 and atmosphere may affect boundary-layer stability and convective processes. As evapotranspiration
406 returns as much as 60% of the precipitation back to the atmosphere over land (Oki and Kanae, 2006),
407 the stem-root flow mechanism may be a key factor in controlling the surface water budget and
408 hydrological cycle. The enhanced storage of water in deep soil layers may have a long-term effect on

409 the climate system. These issues are worthy of further investigation through more relevant
410 observations and testing by coupling the stem-root flow mechanism with global climate models.

412 **Acknowledgment**: This study was supported by the Ministry of Science and Technology of the
413 Republic of China on Taiwan through project MOST-100-2119-M-002-023-MY5. Dr. Y. Xue's
414 support is from U.S. NSF AGS-1346813. We are also grateful to Dr. S. Sun for technical assistance
415 on SSiB, Drs. M.-H. Li and Y.-Y. Chen for providing observation data, Dr. W.-L. Liang for helpful
416 suggestions, and the National Center for High-performance Computing for computer time and
417 facilities. We also deeply appreciate three reviewers' efforts to provide insightful and constructive
418 comments and suggestions to improve and revise the paper.
419
420 **Appendix.** Derivation of D_{eff}
421 The parameter D_{eff} in Eq. (4) was derived in a similar fashion as in Zimmerman and Bodvarsson
422 (1991). As shown in Fig. A1, the part of soil next to the root flow absorbs water and form a thin,
423 saturated boundary of width λ. A gradient of soil moisture is formed in the transition zone (of
424 width δ), with soil water potential decrease from the saturated state, Ψ_s, to that of the bulk soil, Ψ_w.
425 Diffusion of soil moisture toward the bulk soil is directly proportional to this gradient.
426 The soil moisture horizontal (*x*-direction) movement can be express as following:
427 $$\rho \frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x}\left[K(\Psi)\frac{\partial \Psi}{\partial x}\right] \quad \text{(A1)}$$

删除: NSC–100–2119–M–002–023–MY5

删除: and

格式化: 字型: (中文) +本文中文字型 (新細明體)

where ρ is soil porosity; θ is the ratio of soil moisture content to its saturated state; K (in m s^{-1}) is the hydraulic conductivity of the soil; and Ψ (in m) is the soil water potential. Equation (A1) is subject to the following initial and boundary conditions:

$$\theta(0,t) = 1,\ \theta(x,0) = \theta_w\ ,\ \theta(x \to \infty, t) = \theta_w\ . \tag{A2}$$

The first condition means that, when the root-flow occurs, soil at the root-soil interface (x = 0) is saturated. The next two conditions specify the initial bulk soil moisture content, θ_w, and this value remains unaffected by the root flow at a far distance from the root-soil interface throughout the integration time period.

The hydraulic conductivity and water potential of the soil can be represented with the empirical relationship of Clapp and Hornberger (1978):

$$K(\Psi) = K_s(\Psi / \Psi_s)^{-\frac{3}{b}+2} \tag{A3}$$

$$\Psi = -\Psi_s\theta^b\ , \tag{A4}$$

where K_s (in m s^{-1}) is hydraulic conductivity at saturation; b is an empirical constant dependent on the soil type. By introducing a similarity variable η and two normalized variables $\widehat{\Psi}$ and $\widehat{\mathrm{K}}$:

$$\eta \equiv \sqrt{\frac{\rho}{K_s\Psi_s t}},\ \widehat{\Psi} \equiv \frac{\Psi}{\Psi_s},\ \text{and}\ \widehat{\mathrm{K}} \equiv \frac{K}{K_s}, \tag{A5}$$

Eq. (A1) can be transformed into

$$\frac{d}{d\eta}\left(\widehat{\mathrm{K}}\left(\widehat{\Psi}\right)\frac{d\Psi}{d\eta}\right) + \frac{\eta}{2}\frac{d\theta}{d\eta} = 0, \tag{A6}$$

whereas the initial and boundary conditions in Eq. (A2) reduced to

$$\theta(0) = 1,\ \ \theta(\eta \to \infty) = \theta_w \tag{A7}$$

Zimmerman and Bodvarsson (1991) showed that the solution for Eq. (A6) with conditions in Eq. (A7) can be approximated as:

$$\begin{cases} \theta = 1, & \text{if } 0 \le \eta \le \lambda \\ \theta = 1 - (1-\theta_w)\frac{\eta-\lambda}{\delta}, & \text{if } \lambda < \eta \le \lambda + \delta \\ \theta = \theta_w, & \text{if } \lambda + \delta < \eta < \infty \end{cases} \quad \text{(A8)}$$

where

$$\delta = 2\sqrt{\frac{b}{1+\frac{2}{b(1-\theta_w)}}} \quad \text{and} \quad \lambda = \frac{\delta}{b(1-\theta_w)} \quad \text{(A9)}$$

That is, within the root-soil boundary ($0 \le \eta \le \lambda$), θ is saturated (=1); whereas in the transition zone ($\lambda < \eta \le \lambda + \delta$), θ decreases linearly from 1 to θ_w. Here, δ is the "effective thickness" of diffusion in the η cooridnate, and it can be revert back to the *x* coordinate using the similarity conversion in Eq. (A5):

$$D_{\text{eff}} = \delta\sqrt{\frac{K_s\Psi_s t}{\rho}} \quad \text{(A10)}$$

By applying the actual rainfall duration for *t* into Eq. (A10), we calculated the mean values of D_{eff} = 0.005 m for the HAPEX site and D_{eff} = 0.03 m for the LHC site.

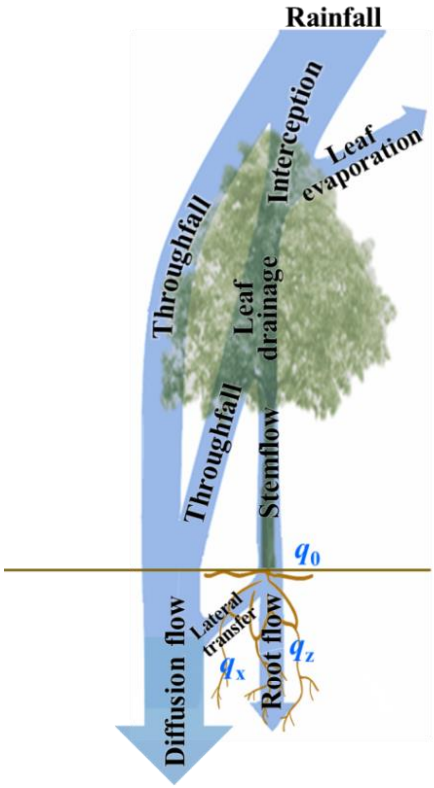

Figure 1. Stem-root flow conceptual diagram. Leaf drainage in the model can be separated into throughfall and stemflow. Following the stemflow path, rainwater can continue via the root system to reach deep soil layers and the water table. The stemflow that reaches the soil top, q_0, is divided into a downward transfer flux (i.e., the root flow) q_z and a lateral transfer flux q_x (from the root surface to the soil), and the two transfer fluxes regulate the root flow thickness.

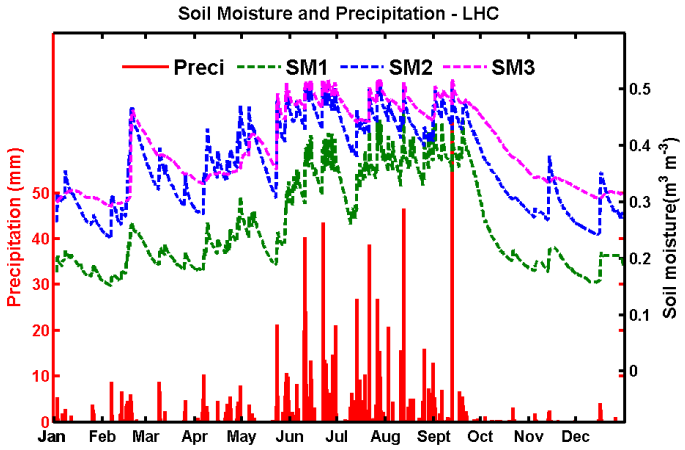

Figure 2. The hourly soil moisture (curves, right axis) and precipitation (red bars, left axis) observed at LHC during 2010. SM1, SM2 and SM3 represent soil moisture at 10 cm (green-dashed curve), 40 cm (blue-dashed curve; average of 30 cm and 50 cm observations) and 90 cm (magenta-dashed curve), respectively.

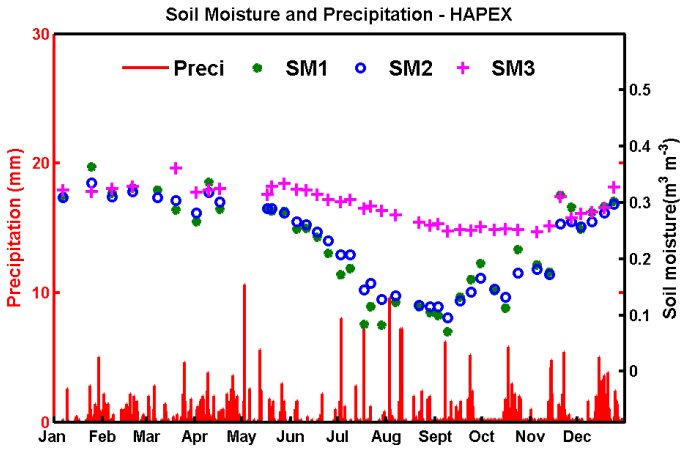

Figure 3. The weekly soil moisture (symbols, right axis) and hourly precipitation (red bars, left axis) observed at HAPEX during 1986. SM1 SM2 and SM3 represent the mean soil moisture in the 0–20 cm (green dot), 20–50 cm (blue circle), and 50–160 cm (magenta cross) layers, respectively.

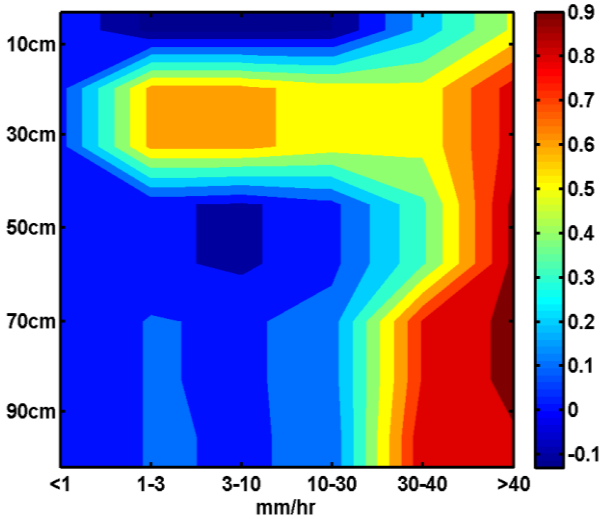

Figure 4: Correlation between hourly changes in precipitation and soil moisture at the Lien-Hua Chih station in 2010. The ordinate is the soil depth and the abscissa is the rainfall intensity. Color shading indicates the correlation coefficient with values shown in the color bar to the right.

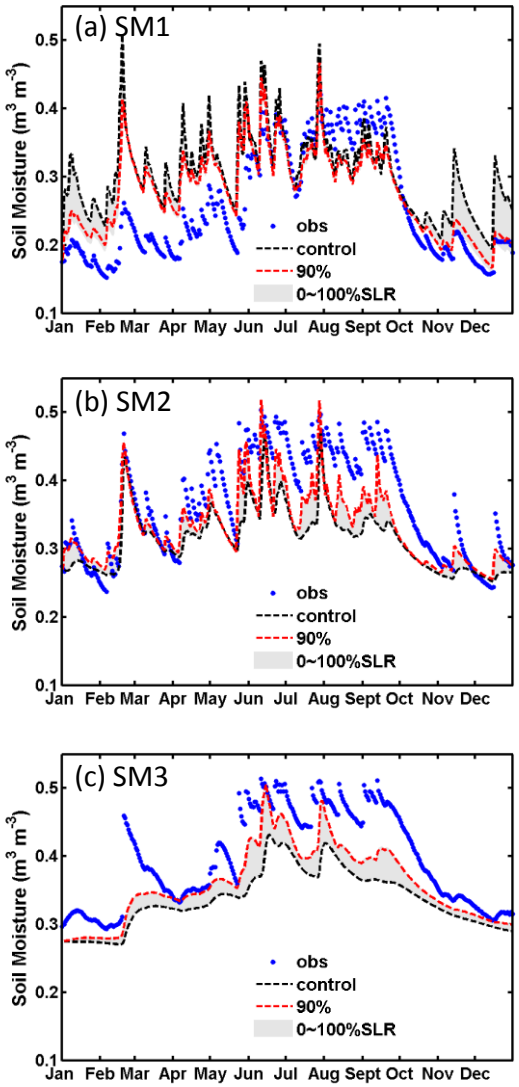

Figure 5. Simulated and observed soil moisture for the LHC site at depths of (a) SM1 (0-20 cm), (b) SM2 (20-70 cm), and (c) SM3 (70-170 cm). Observed results are shown as blue dots. Simulations with SLR=0 (i.e., control run, without stem-root flow) and SLR=90% are shown as black-dashed and red-dashed curves, respectively. The area of grey shading enclosed by SLR=0% and 100% indicates the possible range of the stem-root flow effects. All simulation results are daily averages.

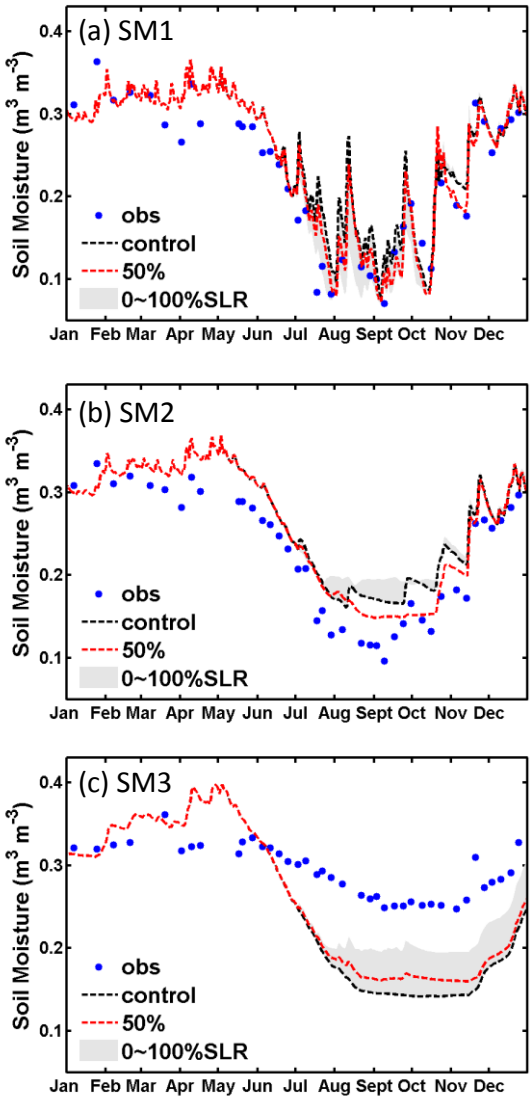

Figure 6. Same as Fig. 5, but for the HAPEX case at depths of (a) SM1 (0-20 cm), (b) SM2 (20-50 cm), and (c) SM3 (50-160 cm). Red-dashed curves are results with SLR=50%.

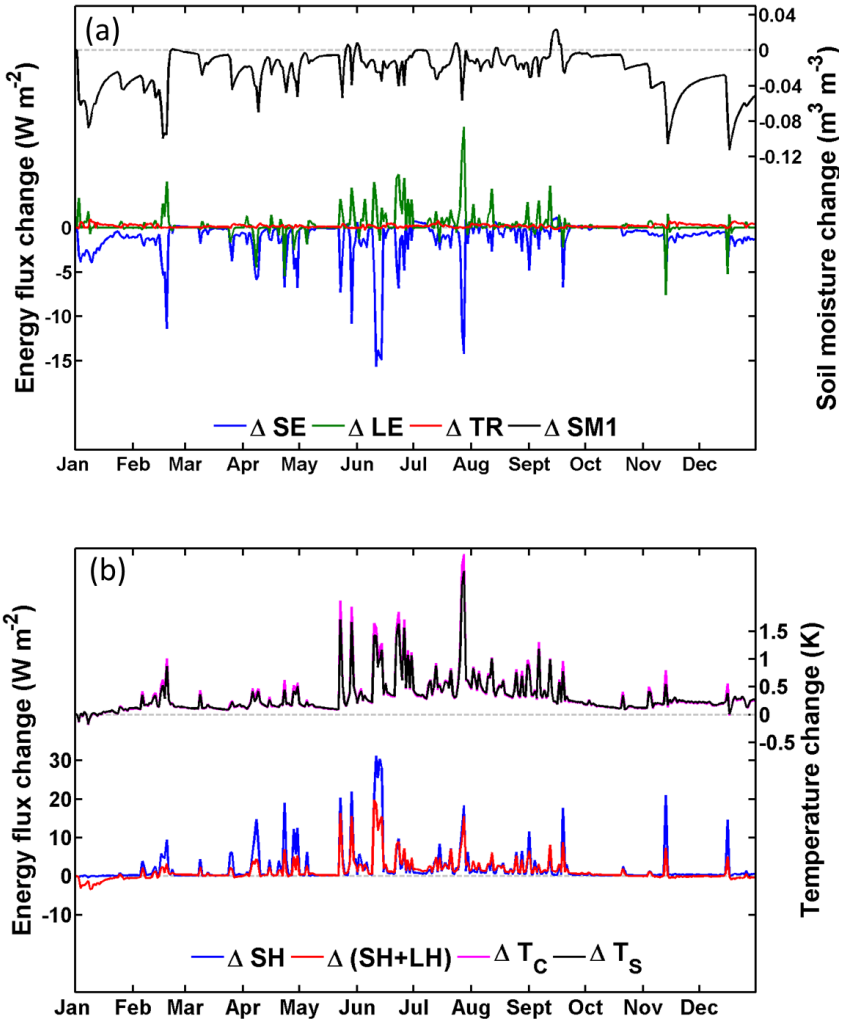

Figure 7. Difference in daily mean heat fluxes and soil moisture due to stem-root flow at the LHC case. (a) Changes in soil evaporation (SE; blue curve), leaf evaporation (LE; green curve), transpiration (TR; red curve) and soil moisture of the surface layer (SM1; black curve; right axis); (b) Changes in sensible heat (SH; blue curve), total heat (sensible heat plus latent heat (SH+LH); red curve), canopy air temperature (T_C; magenta curve; right axis) and soil temperature (T_S; black curve; right axis). Grey dashed lines indicate the zero baseline.

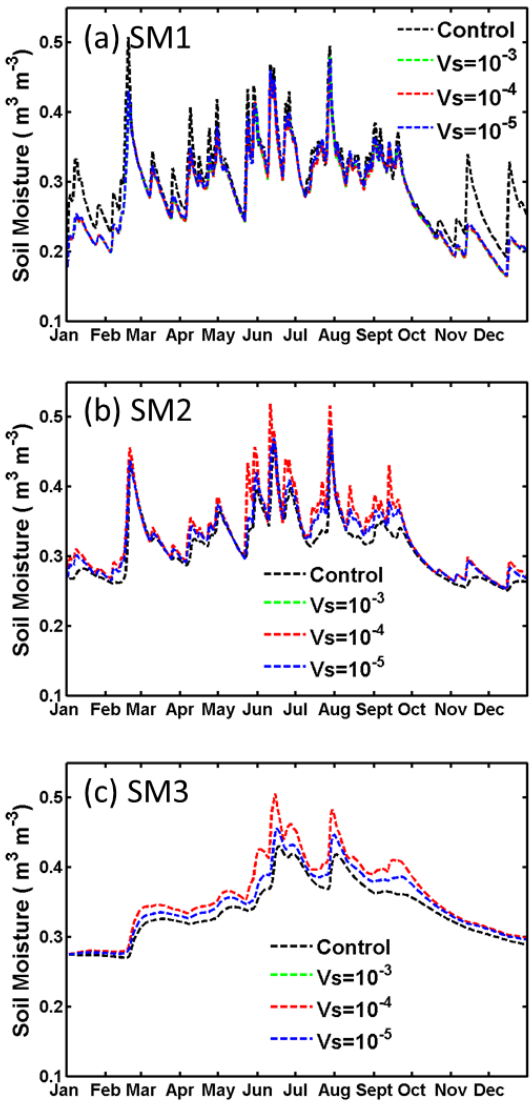

Figure 9. Sensitivity test on V_s for the LHC case with optimal SLR=90% at depths of (a) SM1 (0-20 cm), (b) SM2 (20-70 cm), and (c) SM3 (70-170 cm). The green-dashed, red-dashed and blue-dashed curves are for $V_s = 10^{-3}$, 10^{-4}, and 10^{-5} m s^{-1}, respectively. Also shown in black-dashed curves are the control run results (i.e., SLR=0).

683 Figure A1. Schematics of the root flow-soil boundary and soil moisture transition for the

684 parameterization of horizontal water flux q_x. The red-dashed line represents the analytical solution,

685 and the black-solid line represents the parameterization. Soil moisture is saturated ($=\theta_s$) in the

686 root-soil boundary (width λ), and decreases linearly in the transition zone (width δ) before reaching

687 that of the bulk soil (θ_w).
