12 *Abstract*

13 Analysis of hydrochemical behaviour during storm events can provide new insights into the process
14 controls on nutrient transport in catchments. The examination of storm behaviours using hysteresis
15 analysis has increased in recent years, partly due to the increased availability of high temporal
16 resolution datasets for discharge and water quality parameters. A number of these analyses involve
17 the use of an index to describe the characteristics of a hysteresis loop in order to compare storm
18 behaviours both within and between catchments. This technical note reviews the methods for
19 calculation of the hysteresis index (HI) and explores a new more effective methodology. Each method
20 is systematically tested and the impact of the chosen calculation on the results is examined.
21 Recommendations are made regarding the most effective method of calculating a HI which can be
22 used for comparing data between storms and between different water quality parameters and
23 catchments.

24

25 *1. Introduction*

26 The analysis of hysteresis patterns is a key tool for the interrogation of in-stream physical and chemical
27 responses to storm events, which have been shown to be important periods for the transport of
28 nutrients and sediment within catchments (Bowes et al., 2003;Jarvie et al., 2002;Jordan et al.,
29 2007;Burt et al., 2015;Evans and Johnes, 2004). In the context of this paper, hysteresis is defined as
30 the nonlinear relationship between discharge and concentration of nutrients or sediment. When
31 discharge-concentration data are plotted a cyclic pattern is often observed, the size and shape of the
32 loop is dependent on the the lag in response between the discharge and water quality variables.
33 Quantification of hysteresis allows multiple storm behaviours to be examined between and within
34 catchments as well as under varying antecedent conditions, for discharge and a wide range of
35 hydrochemical parameters. This can provide insight into catchment function, allowing the
36 development and testing of process-based hypotheses. This type of analysis has been used in recent
37 years by many authors investigating nutrient concentration-discharge relationships in catchments of
38 differing environmental character (e.g. Bowes et al., 2015;Darwiche-Criado et al., 2015;Cerro et al.,
39 2014;Rodriguez-Blanco et al., 2013;Oeurng et al., 2010;Eder et al., 2010;Evans and Johnes, 2004) but,
40 traditionally, has been used for the examination of turbidity or suspended sediment data (e.g. Ziegler
41 et al., 2014;House and Warwick, 1998;Williams, 1989;Tena et al., 2014;Klein, 1984;Whiting et al.,
42 1999). Hysteresis analysis has been used to support the investigation of the temporal variations in
43 nutrient transport to streams as a means of characterising the likely contributing source areas and
44 flow pathways linking source to stream in complex landscapes (Outram et al., 2014;Bowes et al.,
45 2015;Lloyd et al., 2016a). Hysteresis patterns with similar characteristics can be observed for a variety
46 of different reasons, however it is generally assumed that clockwise hysteresis, caused by
47 concentrations increasing more rapidly than discharge during the rising limb, suggests a source close
48 to the monitoring point. Conversely, anti-clockwise hysteresis generally signifies a longer lag between
49 the discharge and concentration peak, suggesting that the source was located further from the
50 monitoring point. Williams (1989) provides a detailed summary of different shape hysteresis plots and
51 the possible underlying mechanisms.

52 For hysteresis analysis to be effective and easy to interpret there is a need to develop a robust method
53 of classifying storms according to their hysteretic behaviour. Many papers have classified storms into
54 clockwise or anticlockwise responses, and described the strength of the hysteresis as small or large
55 (Bowes et al., 2015;Evans and Davies, 1998;Butturini et al., 2008). Other authors have used an index
56 approach, which allows a dimensionless quantification of the hysteresis, and thus, comparison of
57 hysteresis indices between catchments of differing size, morphology and hydrological function. An
58 index approach is also useful as it provides information about both the direction and strength of the

59 hysteresis. Hysteretic indices proposed by Butturini et al. (2008) provide semi-quantitative methods
60 to describe whether the measured parameter is enriched or diluted during a storm event and to assess
61 the area inside the hysteresis loop, along with its direction. Langlois et al. (2005) propose a
62 quantitative method which involves splitting the discharge hydrograph into the rising and falling limb
63 and fitting regression lines to each dataset. The hysteresis index is calculated as the ratio (rising:falling)
64 of the areas under the regression curves. Whilst this index provides a quantitative solution, the
65 authors suggest that the method should only be applied to simple uni-directional loops, i.e. not those
66 which exhibit figure-of-eight or more complex behaviours. A quantitative index was also proposed by
67 Lawler et al. (2006), which uses the ratio of the turbidity (or other parameter) concentration on the
68 rising and falling limb, at the mid-point in the discharge. The mid-point in discharge is defined as 50%
69 of the range in discharge during the storm event. This index has been used by a number of other
70 authors (McDonald and Lamoureux, 2009; Outram et al., 2014), as it is flexible and can be applied to
71 hysteresis loops of all shapes. However it is not without limitations. In a recent paper, Aich et al. (2014)
72 highlight that the index of Lawler et al. (2006) in its current form becomes skewed at higher
73 concentrations, with a smaller index calculated for loops of the same shape and area in the case of
74 storms commencing at a higher concentration (Figure 1a). In addition, the calculation of the index
75 using only the mid-point (50%) in discharge can be problematic. Lawler et al. (2006) state that the mid-
76 point was used as it avoids the often noisy sections at the beginning and end of the loops. However,
77 the result of the calculated index may be misleading in many figure-of-eight scenarios, especially those
78 which cross close to the mid-point in discharge (see Figure 1b). The example shown in Figure 1b
79 illustrates that a hysteresis index (HI) calculated at the mid-point in discharge would suggest that there
80 was very little hysteresis, even though there is a strong effect but in different directions during
81 different periods of the storm event. As suggested by Lawler et al. (2006), the HI can be calculated at
82 multiple increments through the flow range and an average HI value gained. Against the above
83 background, this technical note reports the impact of the chosen method on the index values
84 generated from a series of storms of varying size and hysteretic shapes, using an adapted version of
85 the Lawler et al. (2006) index (HI_{LA}). The paper also introduces a new method for calculating the
86 hysteresis index (HI_{new}) and, as a result of this analysis, suggests a recommendation for the most
87 appropriate calculation for a HI for storm-driven nutrient transport in catchments.

88 *2. Methodology*

89 *2.1 Datasets*

90 The example uses a series of storms extracted from high-temporal resolution (15-min) data collected
91 on the River Wylfe at Brixton Deverill (Wiltshire, UK) as part of the Defra Demonstration Test

92 Catchment project (McGonigle et al., 2014) from March 2012 to March 2014. Detailed descriptions of
93 the field site and the datasets are available in previously published work (Lloyd et al., 2016a;Lloyd et
94 al., 2016b) . For the purposes of this study, discharge data were obtained from the Environment
95 Agency gauge (Gauge Number 43806) and turbidity data were collected using a YSI 6-series sonde,
96 which was cleaned and calibrated once a month over the monitoring period. Turbidity (measured in
97 Nephelometric Turbidity Units (NTU)) was chosen for this study as it is the most widely examined
98 parameter in terms of hysteresis and the storms selected from the data set exhibit a wide range of
99 turbidity values and hysteretic shapes. A total of 66 storms were extracted for this analysis from the
100 two year observational data. A storm was classified as an increase in discharge of more than 20%
101 above baseflow and the end of the storm was determined by either a return to baseflow conditions
102 or when discharge began to rise again if another storm occurred before the system had returned to
103 baseflow conditions. Previous work had quantified the uncertainty associated with the discharge and
104 turbidity measurements (Lloyd et al., 2016a;Lloyd et al., 2016b) and this provided 100 resampled
105 iterations of each measured parameter for every storm, accounting for observational uncertainties,
106 for this analysis. Figure 2a-f(l) shows some example storms, where the boxes represent the 5th- 95th
107 percentile uncertainty range for each data point.

108 2.2 Lawler et al. (2006) method and modification

109 The HI was then calculated according to the standard method of Lawler et al. (2006) (HI_L) for
110 combinations of all 100 iterations of each of the storms to provide a distribution of HI when the mid-
111 point in discharge was calculated (50%). The Lawler et al. (2006) method was also adapted (HI_{LA}),
112 where HI was calculated at every 25%, 10%, 5% and 1% increments of the discharge (see Figure 3 for
113 visualisation) as shown below:

114 if $T_{RL} > T_{FL}$ (clockwise hysteresis):

$$115 \quad HI_L = \left(\frac{T_{RL}}{T_{FL}} \right) - 1 \quad (1)$$

116 Or, if $T_{RL} < T_{FL}$ (anti-clockwise hysteresis):

$$117 \quad HI_L = \left(-1 / \frac{T_{RL}}{T_{FL}} \right) + 1 \quad (2)$$

118

119 Where: T_{RL} is the value of turbidity at a given point in flow on the rising limb of the hydrograph and T_{FL}
120 is the value on the falling limb.

121 When multiple sections per storm were calculated, the average value was taken to represent the HI
 122 of the complete storm event. In some cases there were no corresponding values on both the falling
 123 and rising limbs, when this occurs the maximum number of available pairs of data were used to
 124 calculate the index. This usually only occurred at lowest discharges and when a large number of
 125 intervals were being analysed. This meant that the number of missing pairs was small compared with
 126 the available pairs (<5%) and as a result had little impact on the overall calculation. The analyses were
 127 completed for both the raw data and for normalised storms to assess the impact of the different
 128 analysis methods on the HI values obtained. The data were normalised using the following equations:

$$129 \quad \text{Normalised } Q_i = \frac{Q_i - Q_{min}}{Q_{max} - Q_{min}} \quad (3)$$

$$130 \quad \text{Normalised } T_i = \frac{T_i - T_{min}}{T_{max} - T_{min}} \quad (4)$$

131 Where: Q_i/T_i is the discharge/turbidity at timestep i , Q_{min}/T_{min} is the minimum storm parameter value
 132 and Q_{max}/T_{max} is the maximum storm parameter value.

133 2.3 Proposed new Hysteresis Index method (HI_{new})

134 A new method of calculating a HI was also tested (HI_{new}) with the aim of eliminating the impact of a
 135 changing baseline value on the ratio as multiple measurements are taken from the same storm. The
 136 new index uses the difference between the turbidity values on the rising and falling limbs of the
 137 normalised storms, rather than a ratio, and effectively normalises the rising limb at every
 138 measurement point, thereby resulting in an index between -1 and 1.

$$139 \quad HI_{new} = T_{RL_{norm}} - T_{FL_{norm}} \quad (5)$$

140 As with the other methods, the analysis was carried out using different intervals of discharge (25%,
 141 10%, 5% and 1%) and the mean was used as the final HI value for the storm. The impact of this number
 142 of chosen intervals of discharge on the magnitude of the resulting HI was tested.

143 The resulting distributions of HI values for each method were then scrutinised using boxplots.
 144 Differences between the distributions of data for each storm were analysed statistically using ANOVA
 145 where normality and variance assumptions were met, and the non-parametric alternative Kruskal-
 146 Wallis-H on ranked data where the ANOVA assumptions did not hold. When a significant difference
 147 between the groups was detected, a pairwise Tukey test was used to establish which of the groups
 148 were contributing to the effect. The main aim of the analysis was to determine the point at which
 149 sufficient intervals of discharge were used so that there was no statistically significant difference
 150 between the different datasets for each storm.

151 3. Results and discussion

152 A total of 66 storms were analysed using the three methods for calculating the HI, which included 35
153 anti-clockwise loops, 11 clockwise loops, 12 figure-of-eight loops which were mainly anti-clockwise
154 and, 8 figure-of-eight loops which were mainly clockwise (loop shapes were identified by visual
155 inspection). The peak turbidity during the storms ranged between 10 and 392 NTU (mean = 91 NTU)
156 and the starting values were between 2 and 31 NTU (mean = 8 NTU). Figure 2 shows six example
157 storms (a-f, panel I) from the range of behaviour identified above, each with varying shape and size.
158 Table 1 summarises the number (and percentage) of storms tested which can be adequately
159 represented by calculating the HI values using each of the different discharge interval frequencies
160 stated in Section 2.2.

161 Figure 2a-f(II) shows the distributions of HI values (using HI_L) measured at only 50% of discharge are
162 often very different from the analyses which measure multiple sections across the loop (HI_{LA}). The
163 more complex the shape of the loop, the more measured sections are needed to represent it
164 adequately. The analysis shows that by using 5% increments of discharge (19 sections), 98% of the
165 storms analysed showed stable distributions and therefore no significant changes were observed
166 when additional increments were included. While including more increments of the loop in the
167 analysis does improve the HI results, it does not solve all of the issues highlighted earlier. Both HI_L and
168 HI_{LA} are sensitive to the size of the storm and, as a result, for a similar pattern in hysteresis but a larger
169 magnitude of storm, a comparatively smaller value would be calculated for the index, as shown in
170 Figure 1a. This means that the results generated for a series of storms are very difficult to interpret
171 and it is difficult to compare between individual storms and catchments. By normalising the storms as
172 described above and continuing to use the HI_{LA} method, the comparability of the outputs between
173 storms is improved as they are all assessed on the same scale. However, if multiple increments of
174 discharge are included, which has been shown to be beneficial, then effectively each of the individual
175 measured sections of the storm need to be normalised, otherwise the problem is reduced but not
176 eradicated. This problem is illustrated in Figure 1c, which shows an example of an idealised and
177 normalised storm where the width of the loop remains constant through most of the storm. However
178 at different quantiles of flow, HI value varies due to the loop gradient, the HI is inflated towards the
179 lower and reduced at higher quantiles of discharge. The HI_{new} was designed to overcome this problem.
180 The new index uses the difference between the normalised turbidity values on the rising and falling
181 limb at each increment of discharge rather than the ratio, thereby directly quantifying the width of
182 the loop.

183 Figure 4 shows how the new index effectively normalises the rising limb and examines the relative
184 behaviour of the falling limb, thereby identifying the proportion of the storm occurring in a clockwise
185 or anti-clockwise phase. For this new method to be robust, it is necessary to normalise the data as

186 described earlier before the analysis. Figure 2a-f(III) show the example storms in their normalised
187 forms. The new index produces a value between -1 and 1, where 0 represents no hysteretic pattern
188 and positive values clockwise and negative values, anti-clockwise hysteresis. A figure-of-eight storm
189 will be represented as a weighted average of the intervals of discharge measured when the storm was
190 in a clockwise phase and when it was in an anticlockwise phase. Therefore, for example, if the storm
191 exhibits anti-clockwise behaviour for a large proportion of the storm event the average HI_{new} will
192 produce a negative number. It should be noted that in the unusual case that an exactly symmetrical
193 figure-of-eight storm is presented the index would produce a value of 0, suggesting no hysteresis.
194 Using the HI value in conjunction with loop area will however provide clarification as a storm which has
195 an HI of 0 but a positive loop area has to be a complex loop shape. The advantage with our new
196 technique is that the user can choose to interrogate other output metrics within these results, such
197 as the quantified loop area and the distribution of HI values calculated for each section of the loop in
198 addition to the averaged HI value. By looking at the distribution of values it is simple to identify
199 complex loop shapes such as figure-of-eight (due to both positive and negative values calculated for
200 the various loop sections) and ensures correct interpretation of the HI values. Although we do not
201 explore the advantage of these further analyses here, we suggest they potentially provide a richer
202 analysis of hysteresis dynamics that we aim to explore in future papers.

203 We suggest the new index provides a consistent approach to the core loop characteristics and
204 therefore is more easily interpretable by the user when comparing behaviour between storms or field
205 sites. Figure 2a-f(IV) show the resulting distributions of HI_{new} generated using varying increments of
206 discharge. The analysis shows that the distribution of calculated values was generally more stable
207 compared with the HI_{LA} method and, in many cases, fewer increments of discharge were necessary to
208 produce a statistically stable representation of the storm loop shape (Table 1). The results
209 demonstrate that increasing the increments to every 10% of discharge allowed 95% of storms and
210 using 5% increments allows 100% of storms to be robustly characterised in terms of their loop shape,
211 meaning that the addition of more sections did not significantly alter the distribution of HI results.

212 *4. Conclusions and recommendations*

213 The concept of using an index to aid the quantification of storm hysteresis has been established for
214 over two decades. However few papers have chosen to use them, perhaps due to the limitations
215 associated with the most common methods. This technical note was designed to test systematically,
216 for the first time, the way that the HI is calculated and to quantify the impact of the chosen method
217 on the results. This technique is useful when the user's interest is in the relative characteristics of the
218 loop geometries. The analysis has led to a number of recommendations concerning how the HI should

219 be calculated in order to produce results which are both statistically robust and comparable between
220 storms and field sites:

- 221 1. Storms should be normalised before analysis so that multiple storms can be robustly
222 compared.
- 223 2. A difference method, such as the new index (HI_{new}) proposed here, should be used in
224 preference to a ratio method as it produces results which are easier to interpret, allowing
225 quantification of the extent of the hysteresis effect that can be directly compared between
226 contrasting catchments even when the magnitude of the storms varies greatly.
- 227 3. Multiple sections of each loop should be analysed so that the extent and direction of the
228 hysteresis can be accounted for throughout the flow range. Sections should be calculated at
229 least every 10% of the discharge range, although every 5% is recommended as it is likely,
230 based on our analysis, to produce robust results for almost all storm sizes and shapes.
- 231 4. The distribution of HI values calculated across the sections should be examined in addition to
232 the averaged value, as this aids robust classification of complex loop shapes, including figure-
233 of-eight loops.

234 Undertaking the analysis of hysteresis loops using these guidelines improves the clarity of the
235 hysteresis index as a diagnostic tool for the analysis of storms and how discharge-concentration
236 patterns vary. The new index (HI_{new}) is able to describe robustly the shape and direction of a hysteretic
237 pattern in storms of any size, and can be used to compare storms from multiple catchments. This
238 means that the index becomes more useful as it has the potential to become a standardised analytical
239 technique that can be utilised by the water quality research community. Lloyd et al. (2016a) illustrates
240 the use of the new hysteresis index to investigate storm behaviours across different water quality
241 parameters and between contrasting catchments. The cited study exemplifies the power of having
242 such a summary statistic, as different parameters and field sites can be rapidly and robustly compared.
243 The information provided by the HI_{new} can be used in conjunction with other common metrics such as
244 storm maximum concentration to produce a useful and robust quantitative representation of storm
245 hydrochemical behaviour. This is timely given the marked increase in the number of catchment scale
246 water quality monitoring initiatives, which are now employing high temporal resolution monitoring to
247 improve understanding of pollution sources and delivery pathways. Our ongoing research is exploring
248 the use of this new index in understanding differences in catchment dynamics associated with storm
249 behaviours.

349

350

351

352 Figure 1: Plots showing a) impact of storm initial concentration, b) storm initial discharge on the
 353 value of the calculated HI when the mid-point in discharge and raw data is used and c) an idealised
 354 and normalised storm illustrating the impact of measuring different quantiles of flow on the HI
 355 calculated. Where HI_L and HI_{LA} are the original and adapted Lawler et al. (2006) methods,
 356 respectively and HI_{new} , the proposed new method. Colours represent different discharge intervals
 357 measured.

358

359 Figure 2: Plots showing six storms with varying loop shapes and sizes (a-f), where (I) is the hysteresis
 360 loop using the raw data, (II) is the distribution of HI values using the original and adapted Lawler et
 361 al. (2006) methods (HI_L/HI_{LA}) using varying percentiles of flow, (III) is the hysteresis loop plotted using
 362 normalised data, and (IV) is the distribution of HI values using the new method (HI_{new}) using varying
 363 percentiles of flow. The grey areas show the distributions which are not statistically different from
 364 each other. In panels I and III, the black line represents the median and the boxes represent the 5th-
 365 95th percentiles of the uncertainty range.

366

367 Figure 3: diagram showing examples of how the sampling intervals for the calculation of the HI_{LA} and
 368 HI_{new} are determined. The coloured arrows and dashed lines illustrate the position of sections used
 369 for the calculation of the HI, where 50%, 25% or 10% intervals are used. The coloured dots show the
 370 positions on the rising and falling limbs used to calculate the HI.

371

372

373 Figure 4: showing a) the original storm, where the black line represents the median and the boxes
 374 the 5th-95th percentiles of the uncertainty around the line, and b) illustrates the HI_{new} of the
 375 normalised storm.
