Abstract

Since the Water Framework Directive (WFD) was passed in year 2000, the protection of water bodies in the EU must be understood in a completely different way. Regarding to combined sewer overflows (CSOs) from urban drainage networks, the WFD implies that CSOs cannot be accepted because of their intrinsic features, but must be assessed for their impact on the receiving water bodies in agreement with specific environmental aims. Consequently, both, the urban system and the receiving one must be jointly analysed to evaluate their impact. In this context, a coupled scheme is presented in this paper to assess the CSOs impact in a river system in Torrelavega (Spain). First, an urban model is developed to characterise statistically the CSOs frequency, volume and duration. The main feature of this first model is the fact of being event-based: the system is modelled with some built synthetic storms which cover adequately the probability range of the main rainfall descriptors, i.e., rainfall event volume and peak intensity. Thus, CSOs are characterised in terms of their occurrence probability. Secondly, a continuous and distributed basin model is built to assess the river response at different points in the river network. This model was calibrated initially on a daily scale and downscaled later to the hourly scale. The main objective of this second element of the scheme is to provide the most likely state of the receiving river when a CSO occurs. By combining results of both models, CSO and river flows are homogeneously characterised from a statistical point of view. Finally, results from both models were coupled to estimate the final concentration of some analysed pollutants (the biochemical oxygen demand, BOD, and the total ammonium, NH_4^+), in the river just after the spills.

1 Introduction

Control of waste and storm water generated in urban areas has been an issue since the times of the earliest civilizations. The precursor similar to urban systems known today appeared in the early XX century. The aim of these sewage networks is to send

the largest amount of effluent for treatment. During dry weather, all the waste water is treated, but when it rains and either interception sewers or waste water treatment plant (WWTP) capacities are exceeded, excesses are usually spilled into the receiving water body, generating combined sewer overflows (CSOs). At first it was thought that if these overflows complied with certain dilution restrictions, they would be perfectly acceptable for the receiving water body. However, in about 1960, effluents produced by urban runoff were shown to be one of the main causes of water quality degradation in the receiving water bodies, especially surface continental water bodies, as they are less able to purify themselves. Thereafter the problem was studied and methods were proposed to control and treat CSOs, as well as to introduce environmental criteria in the design of urban drainage and sewage collection systems.

The European Council and Parliament introduced in year 2000 the Water Framework Directive (WFD), passing EC Directive 2000/60/CE, establishing a framework for political action with regard to water quality management in Europe. This directive establishes a radical change in the way to understand water in the environment and how to protect it. The WFD sets that environmental objective is to ensure spoiled water masses regain good ecological and chemical conditions. This implies that CSOs cannot be accepted because of their intrinsic characteristics, but must be evaluated for their impact on the receiving water bodies in agreement with the fixed specific aims. The impact of an overflow or spill is quantified by comparing it to the so-called biological or chemical reference conditions for the water body into which it is spilled.

Storm tanks are certainly one of the most widely used control measures against combined sewer overflows. As far as the reduction of impact in the receiving water body is concerned, a storm tank acts fundamentally in two ways: on one hand, it avoids large quantities of water arriving at the waste water treatment plant during a storm, by regulating it and avoiding a massive overspill into the reception water body, if it overflows or if the downstream collection system does. On the other hand, keeping the water in the tank helps sedimentation and the subsequent elimination of associated pollutants. With a correct tank volume, quite good levels of efficiency can be achieved

Interactive Discussion

in terms of frequency, maximum concentration or spills duration, objectives generally not guaranteed with anti-CSO measures such as floodgates or spillways (Calabro and Viviani, 2006).

For many years, variables such as frequency or total spill volume have been accepted as reasonable indicators to evaluate the impact of pollution in receiving water bodies. Being aware of their limitations, the frequency and/or spills volume can themselves be a good tool for evaluating the system efficiency (Lau et al., 2002), given that in general terms, the more frequent the spills, the lower the impact on the receiving water bodies. Nevertheless, coming back to the Framework Directive, it becomes imperative to characterise the alteration generated by a CSO on the receiving water bodies, i.e., to consider the interaction produced between both elements.

In urban drainage analysis, integrated approaches aim to study quantitative and qualitative aspects of two or more system components together: the sewage network, the WWTP and the receiving water bodies (Rauch et al., 2002; Freni et al., 2009).

This study follows an approach of this type, analysing separately the system components and then coupling the results together. The first component is made up of a simulation of a drainage network of various urban areas; the second corresponds to the hydrological modelling of the river basin, which receives the CSOs from that areas. Lastly, the impact of urban overflows on river water quality has been estimated by coupling the two sets of results.

An important initial question is to decide whether the problem should be approached through continuous simulation or event-based analysis. Continuous simulation has been used widely to evaluate the performance of storm tanks with different storage volumes, devices and operational rules (Calabro and Viviani, 2006). In fact, if continuous simulation is used, all the conditioning factors over the final response of the storage tank and its long-term efficiency can be taken into account. This strategy, however, can be impractical for sizing the system or establishing a proposal for actions with some alternatives, where more general and simpler methodologies could be more appropriate. Of course, the cost of simplification comes down to a loss in representation

of certain factors within the process. In this sense, drainage systems with detention tanks (so called interception-detention systems) analysis with an event-based simulation approach, has shown certain important restrictions especially in case of detention tanks (Calabro, 2004). In fact, it is really difficult to reproduce a single input due to the complex nature of external variables of rainfall process. The methodology presented in this paper, however, demonstrates the great usefulness and potential for diagnosis and characterisation of system efficiencies by combining interception (sewers) and detention (tanks) to reduce spills magnitude and frequency from sewage systems into the receiving water body.

Also, the objective of the river basin hydrological modelling is to generate temporal series of streamflows in urban areas of the lower river basin to consider the CSOs impacts on the river, with special relevance in summertime when streamflow is dramatically reduced. In this component of the coupled model strategy, spatial-temporal variability of streamflow is investigated in various simulation points along the lower river system near to the region's larger settlements and industrially developed areas. In these places, the treatment of waste and storm water will be studied to find out the present situation and its influence on the river water quality. In this case, continuous simulation of the rainfall-runoff process is an essential tool to be able to estimate the initial moisture state and base flow prior to any storm event causing the streamflow to rise. For this reason, hydrologic model is calibrated on a daily scale, which is the temporal resolution of most of the available hydrometeorological information to be downscaled later to an hourly model. Input data for the hourly model include three reconstructed rainfall time-series, by using downscaling techniques. Besides, some changes in calibration strategy were introduced to take into account the lack of hourly streamflow data. Finally, river basin and urban models are coupled to establish the existing relationship between overflows, produced in drainage systems during storm events, and their impact on the receiving river.

2 Case study

The problem analysed herein is the assessment of impacts produced by CSOs of the urban sewer network in the neighbourhoods of Torrelavega city (located in the Northern coast of Spain), on the Saja and Besaya rivers. This involves first an analysis of the present drainage scheme, sewers and storms tanks, which collects both waste and storm water from the urban system along these two rivers; secondly, their relationship with the water transport needs to the WWTP; and finally, the overflow reduction efficiency (reduction of the average number of spills into the receiving river) is analysed in the urban drainage model. On the other hand, it is necessary to determine the temporal evolution of streamflow in several points of the Saja-Besaya receiving river system, when spills from the urban collectors system are produced.

2.1 The urban drainage network

The Saja-Besaya basin is shown in Fig. 1 (left). The sewer system (Fig. 1, right) is composed of a main collector to which are directly drained, or via a secondary sewer, sewage networks coming from nine neighbouring municipalities.

Urban drainage system consists of a general sewer which is 11 km long and follows the Besaya river from Corrales to its junction with the Saja River in Torrelavega and finally until the WWTP in Cueto. A total of 23 secondary sewers run into the main one. At the junctions with the main sewer, there are storm tanks for water storage and peak flows routing with spillways to the river when their capacities are exceeded (Fig. 2).

At present, the system covers an area of 1430 ha, with an average runoff coefficient of 0.65. Population covered by this system is of some 100 000 inhabitants. The urban area is forecast to grow to 3610 ha. Consequently, planned increase is considerable, 2200 ha, representing a 160% growth in the urban area and thus in the impervious surface.

The network has a total of 25 tanks adding up 5530 m³ which imply a net design ratio of 6 m³/ha. This value, as compared with data described in other studies seems

low. However, system diagnosis presented in this paper shows that with the adopted design criteria, acceptable reductions in the CSO can be achieved. The large number of factors involved in the generation of CSO and the high variability of the rainfall regime enable to find design ratios as high as 200 m³/ha (Bachoc et al., 1993) and even 300 m³/ha (Hvitved-Jacobsen et al., 1987). The range in Spain is also wide, with published recommended ratios of up to 120 m³/ha (Temprano et al., 2002).

2.2 Saja and Besaya river basin

The Saja and Besaya river basin is located in the North of Spain forming part of the Atlantic drainage basin. The contributing area is 1050 km² to its mouth into the Bay of Biscay. At the rivers junction, near Torrelavega city, are located most of urban areas producing CSOs that cause problems in the receiving rivers. Average temperatures in the nearby city of Santander range between 9 °C in February and 20 °C in August while the average annual rainfall is over 1100 mm/year with an average of 165 rainy days per year. In general terms, the main drainage network faces perpendicular to the Bay of Biscay coast (S-N). Their fluvial geomorphology is characterised by straight embedded channels with steep slopes in the upper and middle basin, reaching an elevation difference close to 2000 m over a length of only some 50 km.

The river basin is seated on Mesozoic geological formations, in which the limestone rocks at the Jurassic and Cretaceous levels predominate and whose main lithological units are clays and limonites, conglomerates, sandstones, limestones and marls. Deep levels are quite impervious, giving rise to underdeveloped aquifers. According to the FAO classification, main soils in the basin belong to the Cambisol group of Distric, Eutric and Humic types. The hydraulic characteristics associated with these soils were estimated indirectly using pedotransfer functions (Saxton, 1993), from a previous reclassification of soil categories defined by the Soil Conservation Service (in A, B, C and D types).

The land cover at the headwaters and in much of the basin is forest type, characterised by oaks and other hardwood species as eucalyptus and conifers. Scrubland and

grazing land are predominant in the middle and lower basin and some crops are more commons in the valleys. The woodland and scrubland species have been reclassified as homogeneously behaved vegetation categories, with regard to their physiological activity, differentiating between deciduous foliage, evergreen and the in-between type.

5 This classification allows establishing criteria to represent the variability of actual evapotranspiration (ET) rates in the annual cycle for each defined vegetation category.

The erosive processes are not very intensive at the headwaters due to the forest cover, so the streamflow in these areas is of clear water with high concentrations of dissolved oxygen. However, in the lower reaches, where there is a greater urban density
10 with almost 80% of the population concentrated, along with the main industrial activities, rivers flow more slowly across the alluvial planes, water temperature is higher and so environmental aquatic conditions concerning dissolved oxygen are much worse.

3 Urban event-based modelling

Urban scale modelling aim is to characterise statistically CSOs to the receiving water body: flow spilled, their volume and duration. The followed methodology is based on
15 event simulations taken from a model of synthetic hyetographs which cover the range of probability of the two main variables in the problem: the event volume and maximum event intensity. The first variable is actually directly related to the resulting CSO volume and the second one to the maximum flow and overflow that can reach downstream
20 sewers and can, therefore, affect the former indirectly.

As shown previously, the analysis of these systems through event-based simulations suffers from certain restrictions (Calabro, 2004) as it is difficult to represent all the variables implicit in rainfall. However, event-based simulations are chosen rather than continuous simulation for two reasons: firstly, in areas with a humid climate and
25 such continuous and persistent rainfall, the wash-off pattern is quite constant, so the effect of the variable which describes the inter-event time (dry weather), is here of little relevance. It would not be the case, for example, in a semi-arid climate with longer

Interactive Discussion

inter-event times between rainfall episodes. Also, as far as making a diagnosis of the system and a proposal for alternatives and analysis of future scenarios is concerned, event-based simulation is more operative than continuous one.

3.1 Rainfall event series characterization

5 An essential difference between the urban model and the basin model is the temporal discretisation of rainfall inputs. The hourly scale used in the basin model is not appropriate for the urban one for two main reasons: firstly, response times for the urban basin are much faster (about an hour) than those of the river basin. But in contrast, and even more important, the use of large temporal discretisations in the urban model
10 distorts the peak intensity variable of the rainfall inputs, underestimating sewers maximum expected flows. That is why, as explained below, precipitation inputs relating to the urban model require a more precise time step definition.

The used analysis requires high resolution data from rain gauge stations and a relatively large series, in order to characterise correctly the time lag between events (interevent time), event volume v , its duration b and, finally, the peak intensity i_M . Among
15 rainfall gauges provided by the Spanish Meteorological Agency (AEMET), the high resolution 41 year series (1942–1983) from Santander rain gauge, with 5 min time step intensity data, is suitable to proceed with the characterization and fitting of the process variables probability density functions (pdf). The four main steps of rainfall event
20 pattern analysis are: (1) data validation, (2) identification of statistically independent data, (3) analysis of temporal dependence and dependence between variables and finally, (4) the fitting of probability density functions to the selected variables (Andrés-Doménech and Marco, 2008).

Before taking on the statistical analysis, original series of rain gauge records must be
25 separated in statistically independent events (Restrepo-Posada and Eagleson, 1982; Adams et al., 1986; Bonta and Rao, 1988). Results obtained in Santander for the summer period show a critical interevent separation time of 14 h, so that, two rain pulses separated more than this value belong automatically to different precipitation events.

Interactive Discussion

So, for the summer period, (June to September), over the 41 summers analysed there were 1121 events, giving an average of $\theta=27.3$ events per summer. Next, a temporal correlation analysis proves the independence of events from each other. Correlation between the four variables is also not very significant. For these reasons, independence between variables is accepted as valid (Andrés-Doménech and Marco, 2008; Andrés-Doménech et al., 2010).

After the identification of independent storms in the continuous series, the probability density functions fitting of inter-event time (distributed exponentially as it corresponds to a Poisson process), event volume v , duration b and peak intensity i_M is carried out. Local studies in Valencia (Mediterranean coast) and Santander (North Atlantic coast) show that exponential models, widely reported since the problem was first tackled (Di-Toro and Small, 1979) up to the most recent references (Adams and Papa, 2000) are not at all satisfactory for v , b and i_M , so other alternatives should be found (Balistrocchi et al., 2008). High probability density observed close to the origin of nearly all these cases leads to postulate for other candidate pdfs, as Weibull, Gamma-2, Lognormal or Pareto. For climate characteristics in areas such as Santander, Pareto distribution reproduces very closely the characteristics of the studied variables (Andrés-Doménech and Marco, 2008; Andrés-Doménech et al., 2010).

3.2 Synthetic rainfall events

Main problems to be diagnosed in the system are sewer flow capacities and their surcharge and, especially, CSOs from storm tanks into the river. Main rainfall descriptors involved in these concerns are maximum episode intensity and event rainfall volume. The former is in fact directly related to the sewer flow conveyance and possible surcharge states. The latter is also a decisive variable for the CSO analysis. Consequently, synthetic hyetographs defined later combine different levels of non-exceedance probability of these two variables.

Once the duration of the hyetographs has been fixed to 12 h (i.e., the 0.50 percentile), combinations of three maximum intensities and nine event volumes are established, in

Interactive Discussion

order to pay special attention to the characterisation of spill frequency into the river: 27 synthetic hyetographs, result from this method. Intensity discrete values considered correspond to the 25%, 50% and 75% percentiles and in the case of volumes, 10%, 20%,... 80% and 90% percentiles are used.

5 Synthetic storms are defined in the following hyetograph expression

$$i(t) = \begin{cases} C_1 t^N & 0 \leq t \leq kb \\ C_2 (t - b)^N & kb \leq t \leq b \end{cases} \quad (1)$$

Parameters C_1 , C_2 and N are determined assuming event volume and maximum intensity correspond to a bivaried non-exceedance probability, deducted from the marginal distribution functions adjusted previously (Andrés-Doménech and Marco, 2008). So
 10 each synthetic storm has an associated non-exceedance probability

$$P_{\text{event}} = p(V \leq v, I_M \leq i_M) = F_V(v) \cdot F_{I_M}(i_M) \quad (2)$$

Parameters C_1 and C_2 are calculated from the highest intensity instant $t=kb$:

$$\begin{aligned} C_1 &= i_M (kb)^{-N} \\ C_2 &= i_M [(k - 1)b]^{-N} \end{aligned} \quad (3)$$

The event volume is calculated as

$$15 \quad v = \int_{t=0}^{kb} C_1 t^N dt + \int_{t=kb}^b C_2 (t - b)^N dt, \quad (4)$$

so the exponent value results being

$$N = \frac{i_M b}{v} - 1. \quad (5)$$

Depending on the actual values of parameters C_1 , C_2 and N , the shape of the hyetograph will correspond to a long rainfall period with quite regular intensity ($N < 1$) or to a

Interactive Discussion

short shower with a heavy peak intensity ($N > 1$). Notice that if $N = 1$ the hyetograph is triangular (Fig. 3).

The position of the peak intensity in the synthetic events is fixed by the parameter k . To simplify the analysis, the mean representative value from historic series ($k = 0.4$) is adopted. Calabro (2004) deduces that the position of the peak intensity is not the most important factor in evaluating the corresponding CSO impact. He concludes, however, that during long rainfall events, a late peak accentuates generated volumes and maximum flows, while in short events, an early peak favours the pollutants wash-off to the receiving water body.

The reason for simulating the system with this model of synthetic events lies with the advantage of making a simultaneous diagnosis of the conveyance (sewers) and storage (tanks) capacities. Also it will be possible to deduce the system failures frequency law (sewer surcharges and overflows to the receiving water bodies). These synthetic events are, thus, the inputs of the urban model.

3.3 Urban drainage model

The urban drainage model is built using Infoworks CS (Wallingford Software). Infoworks is a hydrologic and hydraulic modelling tool which simulates the whole water-cycle in urban areas. The planning focus of the study and the fact that parameters used in previous works have been respected, allow using a simple runoff production model based on runoff coefficients. Values of 0.90 for densely populated areas, 0.70 for industrial areas and 0.40 for sparsely populated areas are used. Surface runoff has been modelled with simple non-linear reservoirs, whose discharge coefficients are directly related to the basin morphological parameters and land uses. Lastly, routing in the drainage network is solved with the complete Saint-Venant equations and the Preissmann's finite differences scheme.

The model was run with the 27 rainfall events defined above. Each simulation lasted 36 h, (three times the maximum duration of precipitation inputs). The maximum calculation time step was 15 s and results were stored each minute. To consider spills

Interactive Discussion

into the receiving water body from storm tanks, a threshold was established. It was considered to be a spill if flow to the river exceeded $10^{-4} \text{ m}^3/\text{s}$.

Results corresponding to spills are extracted from the 27 simulations (whether or not a spill occurs and, if it does, its volume and duration) and so related to flow volumes and system surcharges in sewers with the aim of diagnose the system.

3.4 Interception sewer diagnosis results

Each of the 27 events defined has an associated probability density in the bivaried space (v, i_M) equal to $p_i q_j$, being p_i the event volume marginal probability ($i=1, \dots, 9$) and q_j the event maximum intensity marginal probability ($j=1, 2, 3$). From the results of each of these simulations, the following data to characterise the system response is obtained. Figure 4 shows the maximum flow associated with the rainfall event probability level that can be expected in main sewer S1 and S7 sections. Each of the three curves corresponds to one of the three maximum intensity percentiles considered. The volume percentiles of rainfall events are represented in the abscissa.

From these results, the drainage system can be characterised in some representative reaches, estimating the average number of surcharges per summer

$$\theta_C = \theta \sum_{i=1}^9 \sum_{j=1}^3 p_i q_j \delta_{i,j} \quad (6)$$

with $\delta_{i,j}=1$ if the event (i, j) simulation produces the sewer section surcharge and $\delta_{i,j}=0$ if not. θ is the number of events per summer characterised previously.

Interactive Discussion

On the other hand, the expected value of the maximum sewer flow can be estimated as

$$E [Q_{\text{MSF}}] = \sum_{i=1}^9 \sum_{j=1}^3 p_i q_j Q_{i,j} \quad (7)$$

where $Q_{i,j}$ is the maximum flow registered during simulation (i, j), in the considered reach.

So, the surcharge characterisation of the sewer system at some key points is illustrated by the expected value of surcharges per summer and the expected value of the maximum flow in Table 1. Besides expected values of flows achieved in each sewer reach, quite moderate, the most relevant result is actually a low level of surcharges per summer. In worst sewer sections, which correspond to those located downstream in the system, 2.1 events per summer (i.e., 7.7%) produce sewer surcharge.

3.5 CSO diagnosis results

Tanks performance characterisation is done in the same way. From the results of each simulation, spilled volumes are obtained in each tank, associated with the rainfall event probability level (Fig. 5).

Notice that for low volume rainfall events, maximum intensity is an important factor in the produced spill, because of surcharges that can happen in sewers and the effect they have on the general system response. However, for events with high rainfall volume, the maximum intensity is no longer decisive in the evolution of spill volumes (the curves tend to be parallel) and it is, clearly, directly proportional to the rainfall volume (for extreme volumes the ratio retained in the tanks is not significant as compared with the rainfall volume).

Interactive Discussion

As in the previous case, the average number of spills per summer in each tank is estimated as

$$\theta_W = \theta \sum_{i=1}^9 \sum_{j=1}^3 p_i q_j \delta_{i,j}. \quad (8)$$

On the other hand, the expected value for the volume spilled per summer in each tank can be estimated as

$$E[W] = \sum_{i=1}^9 \sum_{j=1}^3 p_i q_j W_{i,j} \quad (9)$$

where $W_{i,j}$ is the volume spilled in the simulation (i, j) . So, the average overflow volume will be

$$W_m = E[W] \frac{\theta}{\theta_W}. \quad (10)$$

In a similar way, the expected value of the spill duration per summer in each tank can be estimated as

$$E[D] = \sum_{i=1}^9 \sum_{j=1}^3 p_i q_j D_{i,j} \quad (11)$$

where $D_{i,j}$ is the duration of the spill in the simulation (i, j) . Therefore, the average duration of overflow per event will be

$$D_m = E[D] \frac{\theta}{\theta_W}. \quad (12)$$

Storm tank CSO characterisation is thus quantified by obtaining, for each of them, the expected value of spills per summer and the expected spill volume and duration of the average spill (Table 2). The mean time from the beginning of the storm at which the

Interactive Discussion

spill starts is also obtained for each tank. Note that only 6 from among 16 tanks exceed 6.8 spills per summer (75% of summer events are so, however, detained) and only 2 exceed 11 overflows per summer (so detaining however 60% of summer events). The rest clearly detain more than 75% of summer events. These results highlight a quite good efficiency of the system towards CSO detention. A special concern is also to be reported in tank T7. This tank is the greater of the whole system and provides service to the densest urban area (Torrelavega). Even if it warrants the lower number of spills per summer, note that, when it happens, CSO flow into the river is appreciable. However, for the other tanks, flows spilled into the river are quite moderate. Finally, spill start times from the beginning of the storm ranging 2–4 h are reported. These lags will be used later for coupling these results to river flows achieved with catchment continuous modelling.

In terms of probability, these results characterise the interception-detention system and the CSO produced into the receiving water body from urban basins. The next step is the characterisation of the river basin into which spills take place, with the aim of joining both results together to evaluate the impact these CSOs produce in the river.

4 Catchment continuous modelling

Evaluation of impacts generated by CSOs on the Saja and Besaya rivers requires a characterisation of the streamflow pattern on an event scale basis during the whole year but especially in summer, when the flow recession period occurs. So, from the end of the spring, and during the whole summer the net rainfall is substantially less than the one registered during the rest of the year, which is characterised by a more intense rainfall regime. This strong rainfall seasonality leads to a significant reduction in the rivers base flow in summer, so sporadic storms that occur at this moment of the year are responsible for the greatest CSO impacts.

Streamflow is recorded daily at the Be3 gauge station and, to have an idea of the actual uncertainty, it is based on the measuring method of a regulated scale and the

associated rating curve; most weather stations also take daily measurements so on this time-scale a better representation of the spatial distribution of this variable is obtained. For this reason two versions of the hydrologic model were implemented with different temporal discretisation and different aims: with the first model, $\Delta t=1$ day, the objective is to obtain a good representation of the flow components in the rainfall-runoff process (surface, subsurface and base flow), but especially to estimate streamflow at the 6 simulation points in summer; with the second model with $\Delta t=1$ h, it has been reconstructed all the events in the period with available hourly rainfall data. The different water balance components in the calibration period are controlled when the change from daily to hourly scale is made. This approximation enables to describe the main characteristics of the simulated hydrograph for all individual storms events, such as the response times, the peak flows and the lag times between different simulation points during floods. Simulation points of interest with model outputs (Fig. 1) are located mainly close to urban areas in lower basin reaches, where the CSOs occur.

4.1 Available hydrometeorological information

In the Saja and Besaya basin there is only one gauging station providing reliable information for the whole recorded period, containing simultaneous rainfall data. It is placed on the Besaya River, upstream the confluence with the Saja River in Torrelavega. This station holds hydrologic records from the hydrologic year 1970–1971 to nowadays but they have been affected by a water diversion from the neighbouring Ebro River basin since the hydrologic year 1982–1983 (in Spain, a hydrologic year runs from 1 October to 30 September of next year).

The available rainfall data in the basin is found on a daily scale with precipitation records since 1948 in some stations. Data density is variable in the registration data period, with better records kept between 1970 and 1982. There are also hourly series as a result of a downscaling process in Cabezón de la Sal, Corrales and Torrelavega stations, situated in the mid to low areas of the basin (Fig. 1), over a period of 36 complete years (1948–1983).

Interactive Discussion

The uncertainty sources added to the precipitation downscaling process, the poor representation of the spatial distribution of the hourly precipitation in the basin by the small number of hourly rain gauges and the lack of hourly streamflow data make it impossible to carry out a complete and reliable calibration of all the model's parameters, which will impact in a greater uncertainty in the simulated hourly streamflows with regard to the daily ones.

Finally, potential evapotranspiration (PET) has been calculated in a daily basis at 10 points distributed over the whole basin over the 1950–1951 to 1999–2000 period, using information from diverse sources and temporal scales.

The implementation process of the hydrologic model in daily and hourly scales, as well as the methodology used for the model parameters calibration, the model validation, interpretation and results are described below.

4.2 Description of the hydrological model TETIS

The hydrological simulation model used is TETIS, version 7.2. TETIS is a hydrological model with physically based parameters distributed in space, which allows obtaining results at any point of the basin and incorporating the spatial variability of the water cycle. Even though it is distributed in space, TETIS has a novel effective parameter structure, called split parameter, which allows its automatic calibration (Francés et al., 2007; Vélez et al., 2009) using the optimisation algorithm SCE-UA (Duan et al., 1992). In the split parameter structure implemented in TETIS, the relationship between the a priori estimated parameter maps and the effective maps must be considered as a correction function, or in its simplest form, by way of a correction factor (R) which modifies the first ones globally (Francés et al., 2007). In this way, the spatial variability of parameters in the basin is captured in the initial estimation and the global corrector factor modifies the magnitude of these maps. This methodology reduces drastically the number of variables to be calibrated, to a single factor per hydrologic process represented in the model (Table 3), the initial state of the five model tanks and a coefficient

(β) to incorporate in the rainfall interpolation a linear correction to take into account its variation with altitude (Francés et al., 2007).

4.3 A priori parameter maps

The cell size adopted for the estimation of a priori parameter maps for TETIS implementation in the Saja-Besaya basin is 500 m. This size is in accordance with the spatial resolution of most of the available maps with physical and environmental information. It is of the same order of magnitude of the average hillslope and it is appropriate for the basin size and for the computing time required for the model automatic calibration.

The original digital elevation model, with spatial resolution of 5 m (DEM5) has been upscaled to 500 m (DEM500), maintaining the topological properties of the drainage network. From the DEM500, three additional maps are generated: flow directions, accumulated cells and slopes. The first two are used to define the topological relationship of the drainage network and the last two for the river channel geomorphologic characterisation.

TETIS requires at least four additional maps to be put into the system, containing: land cover indexes; upper static storage capacity (h_u), which includes interception, depression storage and soil capillary storage in root zone; upper soil permeability map (k_s); and lastly, the substrate permeability (k_p).

4.4 TETIS model downscaling calibration and validation

The selected calibration period covers the hydrologic years 1979–1980 to 1981–1982, and is the same for the daily and hourly scales. This fact allows control the different components between the two time scales. The validation period covers the years from 1970–1971 to 1978–1979. Daily streamflows have been corrected to take into account that daily precipitation measurements are taken at 08:00 a.m. and, in the calibration period, the peak flow were reduced by two events whose magnitude was not compatible with the observed rainfall.

Interactive Discussion

The automatic calibration process of the model has been iterative between the daily and hourly scales, using a warming-up period of three months in both cases and checking that the state variables of the model (storage in tanks) hold stationarity condition for the adopted correction factors.

The general procedure in the different iterations of the calibration process between the temporal scales mentioned above is the following:

1. The objective function used in the calibration of the daily model is the root mean square error (RMSE).
2. The initial moisture state of the warming-up period (1 July 1979) was estimated assuming an average storage value in the simulated tanks for the same day in the following three years of the calibration period. The three months warming-up period guarantee the stabilisation of the initial state before the first day of the calibration period (1 October 1979).
3. The direct runoff hillslope velocity correction factor on the hillslope has been fixed at one in the daily model, because at daily scale, this model is low sensible to this process.
4. The R9 correction factor, for the propagation velocity in the river network, was obtained in the hourly time step model by a sensitivity analysis, assuming a concentration time of 5 h for the biggest flood events. The resulting value was adopted in the daily scale and calibrating automatically the remaining correction factors and the β coefficient.
5. The groundwater losses (groundwater flow not connected with the river) are very low, compared to the recharge. So, the R7 was fixed at 0 in both models.
6. The β spatial interpolation coefficient for precipitation was adjusted in the hourly time step model, to obtain the same total volume of precipitation than in the daily

Interactive Discussion

scale, given that the observed streamflow is daily and the spatial distribution of rainfall is not very well represented as mentioned above.

7. The R2 correction factor for evapotranspiration in the hourly time step model has been adjusted using the same criteria as for the precipitation. Thus, the same volume of ET and rainfall excess on both scales is guaranteed.
8. In the hourly time step model the same initial state conditions are assumed and the corrective factors for base flow and subsurface flow were maintained as for the daily scale, being automatically calibrated the corresponding factors for infiltration, percolation and static storage processes.
9. For calibration of the hourly time step model, a modification has been made to the objective function to be optimised (RMSE). In this case the average value of the function is evaluated at 24 h intervals to compare with the daily observed value (broken down into 24 equal hourly values), in an attempt to reproduce the infra-daily variability.

In Table 3 the final correction factors values are shown for the daily and hourly calibrations, after various iterations following the above described sequence.

Figure 6 shows the daily scale calibration, giving an efficiency index (Nash and Sutcliffe, 1970) of 0.81 and a balance error of -4.60% . For the validation period, at this time scale the efficiency index is 0.65 and the balance error is 9.87% . These results are satisfactory taking into account all the sources of uncertainty in the initial information.

Considering the hourly time step model, it is not shown any statistic because the streamflows are observed at daily basis (Fig. 7). Regarding the balance, there is a tendency to slightly overestimate the baseflows. Therefore, the simulated streamflows by the daily model were adopted at the beginning of flood events and also to correct the successive simulated hourly flows.

4.5 Hydrological modelling results in the basin

The period from 1951–1952 (beginning of the PET series) to 1991–1992 (end of daily precipitations) has been simulated continuously on a daily scale basis. From the hydrological basin regime point of view, it can be said that there are three different periods within the annual cycle:

1. A marked summer period of very low water levels from July to September, with streamflows clearly inferior to the rest of the year. This is due to the small relative size of the aquifers, which produce a base flow representing only 12% of the total simulated streamflow at simulation point Be3 (similar results at other points).
2. In contrast, between November and May, streamflows are much greater due to heavier precipitations and higher moisture of the upper soil layer.
3. Finally, in June and October there is a transition between the two previously described states.

For this reason, to simulate floods during the low flow periods, only the months from July to September were taken into account.

The period from 1951–1952 to 1982–1983 (end of hourly precipitation data) has been simulated continuously with the hourly time step model. Figure 7 shows the results obtained for several months of the validation period, including summer of 1979. The observed streamflow does not present a smooth behaviour due to the daily resolution. In contrast, the simulated streamflow looks continuous. Some events not properly simulated by the hourly model can be explained considering the worsening of the areal precipitation description going from the daily scale to the hourly one, since the latter counts just with 3 rain-gauges.

4.6 Separation and characterisation of flood events

From this continuous calculated series, all the flood events taking place in the summer period were separated from those of the rest of the year and statistically analysed at each simulation point. To separate them, the event was considered to begin when the streamflow starts to rise and to end after 14 consecutive hours without rainfall, according to the critical interevent separation time adopted in the urban model for the summer period and being 20 hours the minimum flood duration to take into account the concentration time. At each simulation point, the daily streamflow simulated the day before to the flood beginning (Q_0), hourly streamflows after 5, 10, 15 and 20 h ($Q_5, Q_{10}, Q_{15}, Q_{20}$) and the peak flow (Q_p) were analysed. The magnitude associated to each individual flood event i was defined in terms of non-exceedance probability of the associated storm event total rainfall depth (V) as

$$p(V \leq v_i) = \frac{i}{n + 1} \quad (13)$$

Where i is the ranking position of v_i for the storm rainfall depth series ranked in ascending order.

To summarize the results of all the previously identified events in the simulation period, exponential functions were fitted to the empirical relations between each of the aforementioned variables and the associated storm non-exceedance probability.

Streamflow variability of Q_0 , Q_5 , Q_{10} , Q_{15} and Q_{20} is high with respect to the storm probability at all simulation points, and therefore average values were adopted. Namely, Fig. 8 shows at Be3 and Sa-Be simulation points the calculated average streamflow for summer events, corresponding to non-exceedance probability levels which are able to generate significant CSO in the urban area ranging from 0.50 to 0.99.

On the other hand, it can be observed that during summer period the preceding streamflow ($t=0$ in Fig. 8) is independent of the probability level, being less than $3 \text{ m}^3/\text{s}$ in the Besaya River (Be3), $3.5 \text{ m}^3/\text{s}$ in the Saja River and $6.4 \text{ m}^3/\text{s}$ downstream

Interactive Discussion

their junction (Sa-Be). Likewise, as the storm magnitude increases, the streamflow increases as well, but not excessively. For instance, at Be3 simulation point for a rainstorm with an associated probability of 0.75, the streamflow expected value is 2.91 m³/s, whereas after 20 h from the flood beginning it increases up to 4.8 m³/s (Fig. 8).

The previous analysis was also made for the set of events corresponding to the rest of the year (October to June). In contrast to summer events, during the rest of the year there is a slight increase in the preceding streamflow with the storm probability, due to the greater correlation between rainstorm episodes in wet months. This highlights that the preceding average streamflow for the whole range of probabilities is approximately four times greater than those in the summer period. For example, at point Be3, the preceding streamflow for an associated storm probability of 0.50 in summer is 2.82 m³/s, while for the rest of the year it increases to 11.96 m³/s; at point Sa2, the corresponding values are 3.50 and 13.30 m³/s; and downstream the rivers junction these values are 6.38 and 25.7 m³/s, respectively.

These results allow relating the river streamflows with the rainfall magnitude through its probability. In this way, from a probabilistic point of view, it can be established the existing streamflow conditions in any point of the river network when the associated CSO occurs.

5 Coupled results

5.1 Environmental objectives

The River Basin Management Plan for the water district to which the basin belongs, establishes water quality objectives for the rivers to be met. In this case, for the Saja and Besaya rivers, quality criteria are established for two uses: urban water supply and river suitability for fish-life.

Interactive Discussion

CSOs impact analysis into the river has been done exclusively using two parameters: the biochemical oxygen demand (BOD) and the total ammonium (NH_4^+). Maximum admitted concentrations of these pollutants for each of the contemplated uses are imposed by both Spanish and European current legislation. European legislation for potable water is the 75/440/CEE Directive and the corresponding aptitude for fish-life is the 2006/44/CE Directive. Nevertheless, in this case, the Spanish legislation has to be considered because of being more restrictive. For the urban water supply, the Spanish legislation (order 927/1988) classifies surface water destined to becoming drinking water in three groups (A1, A2 and A3), according to the degree of treatment they must undergo, and establishes limit values for each pollutant. The basin plan establishes that A2 quality must be reached for the Saja and Besaya rivers. As far as aptitude for fish life is concerned, it is classified as apt for salmon or apt for cyprinidae, depending on the river reach sensitivity. The River Basin Management Plan demands salmon quality for the Saja and Besaya rivers. In the following table, objectives for each of the two considered pollutants can be seen.

Table 4 shows values to be more restrictive when they correspond to fresh water fish production, so these will be the values that should not be exceeded in the river to comply simultaneously with both quality objectives.

5.2 Coupled scheme and results

With the coupled simulation scheme described above, each representative synthetic event generated in the urban model could be associated with a description of the most probable state of the receiving rivers using their response times and the temporal evolution of streamflow in the river during the following 20 h from the beginning of the hydrograph. From Fig. 8, as explained in previous section, expected streamflow in the river at the spill point of interest for a non-exceedance level of probability P , Q_0^P are obtained.

Interactive Discussion

In parallel, the magnitude of the spills from the urban catchments are characterised from the probabilistic approach (Fig. 5) and volume and duration values for the same non-exceedance level P , W_U^P and D_U^P respectively, can be deduced.

In addition, as a result of sampling, values are adopted for the average concentrations of pollutants analysed in CSO and in the receiving river upstream the urban areas where spills occur. $C_{U,i}$ is the average concentration of the pollutant i in CSO and $C_{0,i}$ is the average concentration of the same pollutant in the river upstream the urban areas. The evaluation of impact is made for the BOD and total ammonia parameters. Average values during the summer period of base concentrations in the river for both pollutants are $C_{0,BOD}=2.9$ mg/l and $C_{0,NH4}=0.4$ mg/l, according to sampling data provided by the water district. Besides, concentrations of these pollutants in CSO are adopted from previous studies undertaken in each urban catchment by the water district and are contrasted with reference values from the literature (Ellis, 1989; MMA, 2002). Thus, the average BOD concentration per overflow is established at $C_{U,BOD}=150$ mg/l and for the ammonium at $C_{U,NH4}=2$ mg/l. These values are in the lower range of intervals usually reported by literature; nevertheless, they are appropriate to dominating sparse urban areas in the study.

Evaluation of the immediate impact of CSO in the receiving rivers is estimated with Eq. (14), for the non-exceedance probability level (P), being $C_{F,i}^P$ the final concentration of pollutant i in the river straight after the spill.

$$C_{F,i}^P = \frac{C_{U,i}Q_U^P + C_{0,i}Q_{0,i}^P}{Q_U^P + Q_{0,i}^P} = \frac{C_{U,i} \frac{W_U^P}{D_U^P} + C_{0,i}Q_{0,i}^P}{\frac{W_U^P}{D_U^P} + Q_{0,i}^P} \quad (14)$$

To fix the probability level P for which results are evaluated, as reported before, 25% of the $\theta=27.3$ events occurring in average per summer produce significant CSO (Table 2). So, the adopted probability of non-exceedance is $P=0.75$. The values W_U^P , D_U^P y Q_0^P correspond to a non-exceedance probability of 0.75 and are deduced from the urban drainage model and the basin one respectively. In Table 5, average flow volumes of

Interactive Discussion

the CSO affecting each simulation point in the river are shown, deduced from values in Table 2. It also shows the instant the overflow occurs from the beginning of the storm.

Results in Table 6 shows, from the moment the spill starts, the expected streamflow in the river Q_0^P for each analysed point, at the moment when the CSO happens and for a non-exceedance probability of 0.75. These values are deduced from results summarized in Fig. 8. Finally, with Eq. (14) the instantaneous BOD and NH_4^+ concentrations in the river after the spills are calculated. Table 6 shows the results obtained in four of the simulation points considered in the river system. Base river concentration for BOD of 2.9 mg/l is the limit for reaching the threshold level for salmon-bearing rivers (Table 4). Consequences are therefore clear. When a spill from an urban runoff occurs, the river BOD rises to values around 10 mg/l, which do not agree with the quality values required. The same effect is not seen, however, with ammonium, where spills produce increases in river concentration which are not significant (Table 6). Results obtained with regard to the BOD highlight the importance of minimising overflows from urban environments into river systems especially during low flow periods. However, notice that concentrations obtained in the river after the CSO correspond to intermittent and transitory occurrences and so must be evaluated as such. In any case, the recurrence level with which significant discharges are produced, (1 of each 4 events per summer) and with resulting pollution parameters in the river after they happen (Table 6) allow to conclude that the analysed system although not strictly in agreement with legal imperatives does provide an acceptable service level.

5.3 Sensitivity analysis

The results obtained are analysed with two sensitivity tests. First sensitivity of results on a fixed probability level is analysed, and secondly with regard to the time lag from the beginning of the storm in the river basin and the actual overflow.

To evaluate the incidence of the event magnitude on river concentrations after spills, a sensitivity analysis of the BOD results regarding the non-exceedance probability was done, following the above described methodology and varying the threshold probability

Interactive Discussion

level P . As can be seen in Fig. 9, as the non-exceedance probability level increases the spilled flow increases too leading to higher BOD concentrations in the river after the CSO. However, for high non-exceedance probabilities, increase in volume spilled by the tanks moderates and is compensated by a greater streamflow in the river which leads to a stabilisation of the river BOD after the overflow. This fact occurs for a lower probability at Be1 simulation point which is the one located upstream in the system and which is only affected by the spill from two tanks (T2 and T3).

Lastly, Fig. 10 shows the sensitivity analysis results for the BOD river concentration depending on the time lag between the spill and the start of the storm in the river basin which conditions the expected streamflow in the river Q_0^P when the CSO happens.

The analysis of these latest results shows that as the spill slows as compared to the flood start, the resulting BOD concentrations reduce as the streamflow increases significantly in the river (Fig. 8), while, of course, the river peak flow time is not exceeded.

6 Conclusions

Indicators such as frequency or spill volume reduction are good tools for assessing storm tanks behaviour for the CSO reduction into receiving water bodies. Nevertheless, according to the EU Water Framework Directive, it is at present necessary to analyse specifically the impact these CSO generate into the environment. The study presented herein follows an approach with this aim, analysing separately an urban drainage network and the river basin into which CSO occur. Finally, results from these two parallel studies are coupled to assess the CSO impact into the river. The case study developed corresponds to the urban drainage network of Torrelavega (Spain) and its neighbouring municipalities which spill runoff overflows into the Saja and Besaya rivers.

The urban scale modelling aim is to characterise statistically CSO to the river with spilled flows, their volume and duration. Prior, a rainfall analysis is achieved in order to build synthetic storms which cover the full range of probability of the main rainfall descriptors for this issue: rainfall event volume and maximum intensity. Thus, each

Interactive Discussion

synthetic storm has an associated non-exceedance probability and provides the input for the simulations performed with Infoworks. With those results, CSO characterisation is quantified by obtaining for each tank the expected value of the spill frequency, volume and duration. Besides, the average instant from the beginning of the storm at which the spill starts is also obtained in order to accomplish the temporal coupling between both models successfully.

Evaluation of the CSO impacts into the receiving water bodies requires the analysis of the streamflow pattern in the river on an event scale basis. Thus, a continuous hydrological basin model is performed with TETIS to provide the event response in the basin attached to a storm non-exceedance probability. To reach this objective, two versions of the model are implemented. First, the model is calibrated in a daily scale to assess a good representation of all the flow components. Then, with an hourly discretization, the event analysis is achieved. Simulation points are located where CSO from urban areas occur. In each of them, average streamflows are obtained, associated to a non-exceedance probability level and related to the time elapsed since the beginning of the storm. A key feature regarding summer periods is that when events start, streamflow increases over time with higher rates in the first 10 h and the magnitude depends strongly on the storm event probability. After 10 h, streamflow keeps rising, though at lower rate. Another relevant feature is that as time goes the differences between the average streamflows related to the abovementioned storm probability values increase.

With this simulation scheme, each synthetic event and CSO generated with the urban model could be associated with a description of the most probable state of the receiving river, coupling both response times: the river basin and the urban catchment. Final evaluation of the CSO impact into the river is assessed by averaging pollutant concentrations from CSO and the river base flow, and estimating, thus, the final concentration in the river immediately after the overflow. The main interest of this approach is that all the results, even the coupled ones, are always related to the same non-exceedance probability level as a result of the coupled scheme.

Table 3. Calibrated values of the correction factors and β coefficient with the automatic optimization algorithm for hourly and daily models.

Correction Factor	TETIS parameters decomposition	Daily Value	Hourly Value
R_1 – Static storage capacity	$h_u^* = R_1 \cdot h_u$	1.428	1.590
R_2 – Index of monthly land cover density ($i=1,2,\dots,12$) for ET	$\lambda_i^* = R_2 \cdot \lambda_i$	1.364	1.470
R_3 – Infiltration capacity	$k_s^* = R_3 \cdot k_s$	0.027	0.882
R_4 – Direct runoff hillslope velocity (linear reservoir)	$u_{OF}^* = R_4 \cdot u_{OF}$	1.0	1.0
R_5 – Percolation capacity	$k_p^* = R_5 \cdot k_p$	0.0029	0.0041
R_6 – Subsurface flow rate (linear reservoir)	$k_{ff}^* = R_6 \cdot k_s$	120.1	120.1
R_7 – Groundwater loss capacity	$k_{gp}^* = R_7 \cdot k_p$	0.0	0.0
R_8 – Base flow rate (linear reservoir)	$k_{bf}^* = R_8 \cdot k_p$	8.21	8.21
R_9 – Stream flow velocity	$u_{CF}^* = R_9 \cdot u_{CF}$	0.60	0.60
β – Rainfall interpolation coefficient	$X_i = \sum_{j=1}^n w_{oj} [X_j + \beta(z_i - z_j)]$	0.00431 [mm/(m d)]	0.00142 [mm/(m h)]
