## Abstract

While a large number of non-linear hillslope and catchment rainfall-runoff responses have been attributed to the temporal variability in antecedent moisture conditions (AMCs), two problems emerge: 1) the difficulty of measuring AMCs, and 2) the absence of explicit guidelines for the choice of surrogates or proxies for AMCs. This paper aims at determining whether or not multiple surrogates for AMCs should be used in order not to bias our understanding of a system hydrological behaviour. We worked in a small forested catchment, the Hermine, where soil moisture has been measured at 121 different locations at four depths on 16 occasions. Without making any assumption on active processes, we used various linear and nonlinear regression models to evaluate the point-scale temporal relations between actual soil moisture contents and selected meteorological-based surrogates for AMCs. We then mapped the nature of the “best fit” model to identify 1) spatial clusters of soil moisture monitoring sites whose hydrological behaviour was similar, and 2) potential topographic influences on these behaviours. Two conclusions stood out. Firstly, it was shown that the sole reference to AMCs indices traditionally used in catchment hydrology, namely antecedent rainfall amounts summed over periods of seven or ten days, would have led to an incomplete understanding of the Hermine catchment dynamics. Secondly, the relationships between point-scale soil moisture content and surrogates for AMCs were not spatially homogeneous, thus revealing a mosaic of linear and nonlinear catchment “active” and “contributing” sources whose location was often controlled by surface terrain attributes or the topography of a soil-confining layer interface. These results represent a step forward in developing a hydrological conceptual model for the Hermine catchment as they indicate depth-specific processes and spatially-variable triggering conditions. Further investigations are, however, necessary in order to derive general guidelines for the choice of the best surrogates for AMCs in a catchment.

## 1 Introduction

A large number of non-linear hillslope and catchment rainfall-runoff responses have been documented around the world (e.g., Wipkey and Kirkby, 1978; Sidle et al., 1995; Buttle and Peters, 1997; Buttle et al., 2001; Van Meerveld and McDonnell, 2005; 5 Tromp-Van Meerveld and McDonnell, 2006a; James and Roulet, 2007). Justification for such hydrological responses often lies in the temporal variability in storm size or antecedent moisture conditions (AMCs) (Longobardi et al., 2003; Mishra et al., 2005; James and Roulet, 2009) and the spatial connectivity between source areas. Soil moisture is a major control on catchment response. It is notably used to determine whether 10 a catchment is in a dry and spatially disorganized or in a wet and connected state (Grayson et al., 1997). Catchment AMCs are most often associated with soil moisture contents over a fixed antecedent temporal window that can be defined as:

$$W = (t_0 - x, t_0) \quad (1)$$

Where  $t_0$  is the reference time and  $x$  is the amount of time to be subtracted to account 15 for conditions observed before the reference time. Hence, AMCs are used for various purposes, from computing direct surface runoff via the Soil Conservation Service Curve Number (SCS-CN) methodology (Mishra et al., 2005) to characterizing favourable conditions for hydrologic connectivity to occur (James and Roulet, 2009).

The determination of a catchment AMCs remains difficult given the relative scarcity 20 of spatially-detailed soil moisture data in comparison to rainfall or streamflow data that are more accessible. Owing to these difficulties, several practical approaches have been proposed to define surrogates or proxies for AMCs. Precipitation-based indices have received the largest attention as rainfall data are often available (Longobardi et al., 2003). We here distinguish between antecedent precipitation ( $AP_x$ ) and the antecedent 25 precipitation index ( $API_n$ ).  $AP_x$  is simply the cumulative sum of rainfall recorded over any fixed antecedent temporal window as defined in Eq. (1). The  $API_n$  as put forward by Kohler and Lindsey (1951) is rather a weighted summation of daily precipitation

amounts recorded since the last rainfall as described in Eq. (2):

$$API_n = API_{n-1} + P_{n-1} \cdot \exp(-\alpha \Delta t) \quad (2)$$

Where  $\Delta t = t_n - t_{n-1}$  is the time ( $d$ ) elapsed between the end of the previous rainfall  $P_{n-1}$  and the beginning of the next one  $P_n$ , and  $\alpha$  is a parameter equal to the inverse of the characteristic time of soil moisture depletion ( $d^{-1}$ ). According to Kohler and Lindsey (1951), precipitation-based indices are universally applicable and yield good results provided that they are used in conjunction with season of the year or temperature. Basin evaporation (Longobardi et al., 2003) and the soil moisture index (SMI), which only includes potential evaporation and other climatic factors in its formulation (Mishra et al., 2005), have also been described as potential proxies for AMCs since they relate to soil moisture depletion. Given the findings that pre-event water can play a substantial role in rainfall-runoff response (e.g., Sklash and Farvolden, 1979; Pearce, 1990; Rice and Hornberger, 1998; Kirchner, 2003) and given the wide availability of streamflow data, the antecedent baseflow index (ABFI) (Mishra et al., 2005) and other measures related to discharge recorded just prior the reference time (Kohler and Lindsey, 1951; Longobardi et al., 2003) have been proposed as surrogates for AMCs. Kohler and Lindsey (1951) have advocated that baseflow-derived indices provide reasonably good results in humid and sub-humid regions; however, these indices are strongly dependent upon season of the year and do not necessarily reflect short-term changes in a catchment state. Several authors have emphasized the relative advantage of the ABFI in comparison to antecedent rainfall because it does not force the choice of an antecedent temporal window (Mishra et al., 2005) and it is a better predictor of runoff generation (Longobardi et al., 2003). Nonetheless, the ABFI is not often used in the hydrological literature (Mishra et al., 2005), with the exception of a few studies based on water table heights (e.g., James and Roulet, 2009). The number of days since the last rainfall event is another proxy for AMCs that is seldom used in catchment hydrology (Kohler and Lindsey, 1951)

Interactive Discussion

Several questions arise concerning the selection of a proxy for AMCs for a specific catchment. For instance, with regards to antecedent precipitation, what duration of antecedent temporal window should be used? The term “antecedent” is broadly used in the literature and refers to durations from one hour to 30 days. Antecedent temporal windows of seven days (e.g., Woods and Rowe, 1996; Inamdar and Mitchell, 2007; James and Roulet, 2009) and ten days (e.g., Noguchi et al., 2001; Western et al., 2004) are relatively popular in catchment hydrology. Several studies have relied on the dual use of  $AP_{10}$  and  $AP_{30}$  (e.g., Sidle et al., 1995; Vidon et al., 2009). The curve number (CN) method considers rainfall over a 5-day long antecedent temporal window (SCS, 1956), an approach taken up by some hydrological modeling studies (e.g., Brocca et al., 2008). Silveira et al. (2000), however, compared the single use of 5-day antecedent rainfall with the combined use of 15-day antecedent rainfall and potential evaporation and found no significant differences between the two approaches. While working in a semi-arid environment, Frot and van Wesemael (2009) argued that the use of a 48-h long antecedent temporal window was not appropriate to explain the differences in runoff for events with similar precipitation characteristics and rather chose an antecedent period of 20 days. Within the antecedent window, several scenarios can occur as there may be no rainfall, a single rainfall event, or multiple storms. These events will or will not be accounted for depending on the chosen duration (Salvadori and De Michele, 2006). Thus, Seeger et al. (2004) used a large selection of antecedent windows (i.e. 6 h, 24 h, and 3, 7, 15 and 21 days) in order to discriminate the effects of short-term AMCs from those of long-term AMCs in a small headwater catchment. The wide range of antecedent temporal windows in the literature is unavoidable as there are no explicit guidelines available to specify the relations between soil moisture content and antecedent rainfall during a specific time period (Mishra et al., 2005). Moreover, the effectiveness of surrogate measures for AMCs may be highly dependent upon climate characteristics and scale of observation. However these issues have yet to be addressed if we are to decide between a universal or a regional proxy for AMCs.

One can also ask if it is reasonable to use a sole measure of AMCs for a given catchment. Several authors (e.g., Cappus, 1960; Betson, 1964; Hewlett and Hibbert, 1967; Dunne and Black, 1970; Aryal et al., 2003; Ambroise, 2004) have shown that storm runoff usually originates from consistent parts of a catchment that often represent a small fraction of the whole topographic drainage area. This has been observed in a range of climatic regimes. Soil moisture is a critical hydrological state variable whose spatiotemporal variation indicates the presence of “active” or “contributing” areas or periods (Ambroise, 2004), and this relates to hydrologic connectivity. Dynamic connectivity of catchment source areas is controlled by the time-changing availability of surface/subsurface storm water, not only in terms of magnitude but also in terms frequency, duration, timing and rate (Bracken and Croke, 2007). Disconnected “active” areas involve water fluxes that do not contribute to the global output at a catchment outlet, while “contributing” areas to catchment response are composed of spatially connected “active” areas. Considering that both “active” and “contributing” areas are important in assessing a catchment initial state, do surrogate measures for AMCs reflect these dynamics? From a spatially-distributed point of view, the fact that all catchment areas are not “activated” at the same time may indicate that they are responsive to different hydro-meteorological factors. Similarly, the non-uniform contribution of source areas to streamflow may point towards different triggering hydro-meteorological factors. In that context, should multiple proxies for AMCs be used in order not to bias our understanding of a catchment hydrological behaviour?

This paper investigates that specific question. We examine the hydrological behaviour of a small headwater temperate humid forested system, the Hermine, for which several catchment-wide soil moisture patterns are available. The approach relies on point-scale temporal relations between actual soil moisture content values and selected meteorological-based indices so as to identify the surrogates for AMCs that are best suited to characterize the hydrological behaviour of the system. This simple exercise demonstrates that the sole reference to AMCs measures that are typically used in catchment hydrology would have prevented a full understanding of the Hermine catch-

ment dynamics.

## 2 Methods

### 2.1 Hermine catchment

The Hermine is a 5.1 ha forested catchment located in the Lower Laurentians 80 km north of Montréal, Québec, Canada (Fig. 1a). The total annual precipitation to the region averages 1150 mm ( $\pm 136$  mm) over the last 30 years, of which 30% falls as snow (Biron et al., 1999). The catchment has a relief of 31 m and is drained by an ephemeral stream (Fig. 1b). Soils are 1 to 2 m deep Podzols developed over a bouldery glacial till. The presence of a confining layer at a depth of approximately 75 cm in the soil restricts root penetration, slows water infiltration and thus enhances the probability of rapid lateral shallow subsurface flow. In wet conditions, catchment-scale soil moisture patterns highly depend upon the asymmetric distribution of thick organic horizons; hydrophilic regions are preferentially located on the northern, steeper hillslopes. Near-surface soil moisture is also influenced by the catchment complex surface micro-topography due to fallen tree trunks and boulders at the soil surface. Other particular features of the Hermine include intermittent rills that are activated in very wet conditions (Fig. 1b) and a wet zone located in the upstream part of the valley bottom (Fig. 1b). Forest canopy is dominated by sugar maple and other deciduous tree species. Thus, transpiration is minimal between October and April so that changes in soil moisture and water table in that period are mostly governed by downslope drainage. The interception capacity of the forest canopy, combined with high summer potential evapotranspiration, greatly reduces the likelihood of high runoff except during heavy rainstorms or wet and cool periods. Forest canopy is, however, variable throughout the catchment, with a lower coverage density in upper parts of the southern slope near the catchment divide for example.

## 2.2 Topographic and soil moisture data

A surface digital elevation model (DEM) of the Hermine was obtained by interpolating 640 elevation points collected in the field. Elevation above the catchment outlet was then extracted for 121 sampling locations defined along a 15 by 15 m sampling grid in the catchment (Fig. 1c). The depth to the confining layer was measured at 257 points using a small hand auger that was forced vertically to refusal through the soil profile. For each sampling location, three auger to refusal measurements were made in a 1 m radius and checked for consistency to disregard data that are likely associated with the presence of individual clasts in the soil matrix instead of the targeted confining layer. Data were then interpolated into a subsurface DEM. In order to evaluate topographic influences on the spatial distribution of soil moisture, several secondary terrain attributes were derived from both the surface and the subsurface DEMs: local slope, contributing area and the topographic index (Beven and Kirkby, 1979) were computed using the  $D_{\infty}$  algorithm (Tarboton, 1997), while the multi-resolution valley bottom flatness (MRVBF) index was calculated after Gallant and Dowling (2003). The MRVBF index is derived from an elevation map and identifies flat and low regions at a range of scales. Its largest values flag the broadest and flattest low areas in the catchment. The depth to the confining layer was then extracted for each of the 121 sampling locations (Fig. 1d), together with the values of all secondary terrain attributes.

Soil moisture contents at multiple soil depths were surveyed using a portable 30-inch long rod equipped with a capacitance-based probe (AQUATERR Instruments & Automation) that was pushed into the ground to the desirable depth. On 16 occasions between August 2007 and July 2008, volumetric moisture content in the top 5, 15, 30 and 45 cm of the soil profile was measured on a 0 to 60% scale along the previously defined 15 by 15 m sampling grid, for a total of 121 sampling points. Figure 2 illustrates the contrast between surveys conducted at the Hermine, in terms of measured soil moisture patterns for different AMCs and discharges at the catchment outlet (Table 1).

## 2.3 Surrogates for AMCs and catchment response

For each of the 16 soil moisture survey dates, 12 temperature-based and precipitation-based indices (Table 1) were derived in order to assess their potential to serve as surrogates for antecedent conditions estimated from the soil moisture measurements.

5 Mean daily potential evapotranspiration (PET) was computed after the temperature-based Hargreaves formula (Hargreaves, 1975). A first group of seven precipitation-based indices were used to capture the amount of rainfall added to the system over a given period  $x$  ( $AP_x$ ) prior to the time of interest.  $AP_1$ ,  $AP_2$ ,  $AP_5$ ,  $AP_7$ ,  $AP_{10}$ ,  $AP_{12}$  and  $AP_{14}$  were, respectively calculated as the cumulative rainfall over the 1, 2, 5, 7, 10, 10  
12 and 14 days prior to the survey. A second group of precipitation-based indices were used to reflect the time distribution of the antecedent water inputs. DSP (i.e. days since precipitation) was computed as the number of days elapsed since the last recording at the rain gage, while the  $DSP_{10}$ ,  $DSP_{20}$  and  $DSP_{30}$  indices were computed as the number of days elapsed since the last rainfall intensity exceeding 10, 20 and 30  $\text{mm d}^{-1}$ ,  
15 respectively. The ability of the survey mean soil moisture content (MSMC) to represent the catchment macrostate was also evaluated. Lastly, catchment discharges recorded on survey dates (current-day discharges, hereafter referred as CD\_DISCH) were used to portray the integrated hydrological response at the catchment outlet.

## 2.4 Data analysis

20 Our methodology was twofold (Fig. 3). Firstly, we aimed to determine the nature and the strength of the relationships between point-scale soil moisture (i.e. soil moisture measured at each sampling point) and each of the AMCs and catchment response surrogates previously described. We hypothesized that the identified relationships would illustrate the variety of point-scale hydrologic behaviours that can be encountered within the Hermine catchment. Secondly, we examined the spatial organization of the nature and the strength of these point-scale relationships to link them with possible topographic controls.

studied with regards not only to the nature (e.g. linear versus quadratic, versus cubic, etc.) but also to the strength of the point-scale relationships between actual soil moisture and surrogate measures. Nonparametric Kruskal-Wallis tests were run to assess whether the different types of point-scale relationships were spatially associated with specific topographic properties. Spearman correlation coefficients were also computed between the strength of the point-scale relationships (i.e.  $R$ -square values) and the values of the terrain attributes.

### 3 Results

#### 3.1 Point-scale relationships

Figures 4 and 5 illustrate the spatial heterogeneity in the Hermine when it comes to the relation between point-scale actual soil moisture measurements and any catchment-wide, meteorological-based proxy for AMCs. Figures 4 and 5 also show that the spatial patterns are highly dependent not only upon the chosen surrogate for AMCs but also upon the soil depth considered. For instance, only 20% of the soil moisture sampling sites at a 5 cm depth are significantly ( $p < 0.05$ ) associated with PET (Fig. 5). The best regression model for that relationship is a logarithmic one; however  $R$ -square values do not exceed 0.45. A similar result is obtained at a depth of 15 cm where only 16% of the sampling locations are related to PET, and that proportion drops to zero when depths of 30 or 45 cm are considered.

For precipitation-based indices computed from cumulative rainfall, especially  $AP_1$ ,  $AP_2$  and  $AP_5$ , linear relationships are mostly present at a 5 cm depth while nonlinear relationships tend to dominate from a depth of 15 cm and below (Fig. 4). At all depths, relationships between  $AP_1$  and soil moisture content measurements are statistically significant ( $p < 0.05$ ) but generally weak; unlike relationships between  $AP_2$  and soil moisture content that were mostly fitted with a cubic regression model ( $0.25 \leq R$ -square  $\leq 0.65$ ) at depths of 15, 30 and 45 cm. With  $AP_5$ , linear, quadratic and cubic

Interactive Discussion

regression models are almost equally present at the 5 and 15 cm depths while only cubic and quadratic relationships dominate the patterns at depths of 30 and 45 cm. Significant relations between  $AP_5$  and point-scale soil moisture content measurements are the strongest ( $0.36 \leq R\text{-square} \leq 0.74$ ) and the most widespread over the Hermine catchment area. On the contrary, patterns associated with  $AP_7$ ,  $AP_{10}$  and  $AP_{14}$  show very few, if any, significant relations. Relationships between  $AP_{12}$  and point-scale soil moisture content measurements are of interest not because of their magnitude but rather because they make up a spatial pattern that is a mirror image of the patterns associated with  $AP_1$ ,  $AP_2$  and  $AP_5$  (Fig. 4). With  $AP_{12}$ , significant relationships are confined to a small area on the southern slope; that is opposed to their widespread presence on the northern hillslope and in the catchment upstream area when  $AP_1$ ,  $AP_2$  or  $AP_5$  are used as surrogates for AMCs (Fig. 4).

Spatial patterns of point-scale relationships were also different depending upon the chosen rainfall intensity-based measure of AMCs. Figure 5 shows that for all soil depths, a large proportion of sampling locations are significantly, yet weakly related to DSP, yielding a patchwork of linear, cubic, quadratic and logarithmic negative relationships. When relations with  $DSP_{10}$  and  $DSP_{20}$  are evaluated, less heterogeneous patterns are observed with the predominance of negative logarithmic relationships for  $DSP_{10}$  and of positive inverse relationships for  $DSP_{20}$  (Fig. 5). Significant relationships between  $DSP_{30}$  and point-scale soil moisture content measurements are the most obvious at the 5 cm depth with a mix of strong linear, quadratic and cubic decreasing regression models.

For almost all sampling locations at all depths, significant relationships between soil moisture content measurements and MSMC are found ( $0.25 \leq R\text{-square} \leq 0.81$ ,  $p < 0.05$ ). The vast majority of these relationships are quadratic, cubic or logarithmic (Fig. 5). The proportion of sampling locations sharing nonlinear relationships with MSMC is 44% at a depth of 5 cm and reaches 60% at a depth of 15 cm and even 80% at depths of 30 and 45 cm. As far as the variable CD\_DISCH is concerned, the presence of statistically significant relations is highly dependent upon soil depth (Fig. 6). At

Interactive Discussion

15 cm, only a few sampling locations are characterized by a cubic relationship between point-scale soil moisture content and CD\_DISCH. At 30 and 45 cm, the spatial patterns of significant relationships include linear, quadratic, cubic and logarithmic regression models and resemble the spatial patterns obtained with AP<sub>1</sub>, AP<sub>2</sub> and AP<sub>5</sub>.

### 5 3.2 Topographic influences

Regardless of soil depth, no significant Spearman correlation coefficient was found between the strength (i.e. *R*-square) of the identified point-scale relationships and the values of any surface or subsurface terrain attribute. However, nonparametric Kruskal-Wallis tests showed that the nature of some relations (i.e. the presence of linear, quadratic, cubic, logarithmic or inverse relationships) was associated with topographic variables (Tables 2 and 3).

Elevation above the catchment outlet was the most consistent, statistically significant ( $p < 0.05$ ) control on the spatial patterns of relationships between AMCs proxy variables and soil moisture measurements. Figure 7 shows that at a depth of 5 cm, relationships between AP<sub>1</sub> and point-scale soil moisture content measurements are all polynomial (i.e. linear, quadratic or cubic), however the higher the elevation, the higher order of the relationship. Boxplots also show statistically significant differences in surface elevation depending on the nature of the relationship between point-scale soil moisture measurements and AP<sub>5</sub> at all depths (Fig. 7). As far as DSP<sub>20</sub> is concerned, it is interesting to note that at a depth of 5 cm, no relationship with point-scale soil moisture measurements can be found at elevations below 20 m, yet statistically significant inverse regression models are fitted to the soil moisture and DSP<sub>20</sub> data for sampling sites located above the 20 m elevation level (Fig. 7). At depths of 30 and 45 cm, all five types of relationships between point-scale soil moisture measurements and DSP<sub>20</sub> are present, but mostly at elevations exceeding 10 m above the catchment outlet, with logarithmic relations being preferentially located in upper regions near the catchment divide. At the 5 cm depth, MSMC is linearly related to point-scale soil moisture content mainly for locations whose elevation is below 20 m, otherwise nonlinear relationships

Interactive Discussion

are observed. At depths of 30 and 45 cm, however, nonlinear relationships with MSMC expand across the whole range of elevation values (Fig. 7), thus making it difficult to discern any clear spatial pattern. As for the influence of surface elevation on the relationships between CD\_DISCH and point-scale soil moisture measurements, it is only perceptible at depths of 5 and 15 cm (Fig. 7); however it should be remembered that relationships between CD\_DISCH and point-scale soil moisture at these depths are very weak.

The second, most influential, topographic variable on the patterns of point-scale relationships between AMCs proxy variables and soil moisture was the MRVBF index of the surface and of the impermeable soil layer (Fig. 8). At a depth of 5 cm, we observe that the flatter the soil surface and the more irregular the soil-confining layer interface, the higher order the relationship between point-scale soil moisture measurements and  $AP_1$ . At that same depth of 5 cm, statistically significant inverse relationships were found between point-scale soil moisture content and  $DSP_{20}$  for locations with the most complex subsurface micro-topography (i.e. low values of the MRVBF index for the confining layer). The control exerted by terrain slope is perceptible at a depth of 30 cm (Table 2) as flat areas exhibit quadratic (negative) relationships with  $DSP_{30}$  while steeper areas rather exhibit cubic (negative) relationships with that same surrogate for AMCs. Soil moisture content at the sampling locations with the greatest contributing areas and hence the greatest values of the topographic index also showcase strong, negative, linear relationships with  $DSP_{30}$  at a depth of 30 cm (Fig. 8).

## 4 Discussion

The simple exercise conducted in this paper yielded new insight into the spatial representativity of proxy variables for AMCs or catchment response. While the relationships between actual soil moisture and several surrogate variables do exhibit strong spatial patterns (see examples in Figs. 4–6), some others show rather poor spatial organization, thus casting doubt on the use of a single surrogate to illustrate a catchment

Interactive Discussion

state of wetness. Reaching such a conclusion was only possible through the use of an exhaustive soil moisture dataset that covers nearly the entire set of hydrological conditions of the Hermine catchment (Table 1), except for the winter and early spring seasons. Even though the patterns illustrated in Figs. 4–6 only portray the spatial distribution of statistical relationships between actual soil moisture measurements and surrogate indices, they may reveal critical hydrological information. Hence, we argue that the simple statistical analyses conducted in this paper give lead to a better understanding of the spatial heterogeneity of hydrological patterns and processes in the Hermine catchment.

We hypothesized that maps of the point-scale relationships between soil moisture content measurements and surrogates for AMCs would provide information about variable “active” areas and their “activation” mechanisms. Indeed, locations for which soil moisture is strongly related with AMCs can be labelled as source areas. It is not surprising that the 16–20% of the near-surface catchment area subjected to the influence of PET are located on the upper parts of the southern slope, near the catchment divide and in a few other zones (Fig. 5) where canopy density is lower. A systematic assessment of canopy density needs to be done in the Hermine catchment in order to substantiate that hypothesis. Much of the Hermine, especially near the catchment head and on the northern slope, seems to be “activated” by short-term AMCs as portrayed AP<sub>1</sub>, AP<sub>2</sub> and AP<sub>5</sub> (Fig. 4). Statistically significant, even though weak, relations between soil moisture measurements and AP<sub>12</sub> (Fig. 4) suggest that soil wetness is not persistent in the long-term except for a small portion of the catchment corresponding to a low-elevation wet zone and to thin soils developed over a bedrock outcrop. While 5 and 15 cm soil moisture usually shares linear relationships with AP<sub>1</sub>, AP<sub>2</sub> and AP<sub>5</sub>, nonlinear polynomial relationships (i.e. quadratic and cubic) are observed at depths of 30 and 45 cm (Fig. 4). This may be linked to the fact that the soil storage capacity is a function of the amount and timing of precipitation in addition to evapotranspiration (Ritcey and Wu, 1999), hence the nonlinear relationships.

We also hypothesized that the spatial patterns of point-scale relationships between

soil moisture content and CD\_DISCH is useful to identify catchment areas that might contribute to streamflow discharge. Locations for which soil moisture is strongly related with catchment discharge can be considered as contributing areas. Descriptions of the variable source area concept (e.g., Ambroise, 2004) have been built on the principle that catchment contributing areas are necessarily “active” areas, even though the opposite may not always be true. In that respect, it is worth noting that at depths of 30 and 45 cm, in particular, the spatial patterns of significant relationships between actual soil moisture measurements and CD\_DISCH resemble the spatial patterns of significant relationships between actual soil moisture and AP<sub>1</sub>, AP<sub>2</sub> and AP<sub>5</sub> (Figs. 4 and 6). Our approach makes it possible to distinguish near-surface from deeper potential “contributing” areas. At depths of 5 and 15 cm, locations are either not or nonlinearly related to CD\_DISCH while at depths of 30 and 45 cm, a few sampling locations are involved in linear relationships with the overall catchment response (Fig. 6). From these results, we could argue that the particular locations of linear relationships hint towards sustained subsurface water fluxes leading to the catchment outlet. These locations could be associated with the absence of depressions to fill in the topography of the soil-confining layer interface; hence, they may be set in opposition to the other locations which may be subjected to a soil storage threshold to exceed before any lateral water fluxes can occur, hence the nonlinear relationships (Spence and Woo, 2003; Tromp-Van Meerveld and McDonnell, 2006b; Kusumastuti et al., 2007). Even though plausible, this hypothesis is not confirmed by the Kruskal-Wallis tests results in Tables 2 and 3. In fact, there are no statistically significant differences in subsurface terrain attributes between locations sharing linear relationships with CD\_DISCH and locations sharing nonlinear relationships with CD\_DISCH at depths of 30 and 45 cm. This conclusion highlights the main drawback of the purely statistical approach with regards to hypothesis testing, as the obtained regression models may not necessarily reflect causal relationships.

Concerning the results on MSMC, the important spatial extension of statistically significant relations with point-scale soil moisture content at all four depths indicates that it is a good surrogate for describing the catchment soil moisture macrostate. This is in

accordance with the methodology of several previous studies (e.g., Thierfelder et al., 2003; Grant et al., 2004; James and Roulet, 2009) that relied on the use of the catchment mean shallow soil wetness for process understanding or modeling purposes. We, however, found that the less shallow the soil depth considered, the more locations whose soil moisture measurements were nonlinearly related to MSMC (Fig. 5). Furthermore, even at the 5 cm depth, relations between point-scale soil moisture measurements and MSMC were linear mainly for sampling sites located less than 20 m above the catchment outlet. This result requires further investigation as to how representative the MSMC really is with changing depths and as we move near the Hermine catchment divide.

It must be stressed that the sole reliance on indices often used in catchment hydrology, namely  $AP_7$  and  $AP_{10}$ , would have led us to rely on a surrogate measure that is not related to soil moisture measurements in the Hermine. Even though soil moisture proxies based on antecedent rainfall can give good results (e.g., Kohler and Lindsey, 1951; Longobardi et al., 2003), the choice of the antecedent temporal window is crucial. In our case,  $AP_5$  is the best index to use as a surrogate for AMCs in the Hermine catchment while  $AP_1$ ,  $AP_2$  and  $AP_{12}$  yield fairly good results. Kohler and Lindsey (1951) have argued that indices simply computed from the number of days since the last rain are “obviously insensitive and should not be used if accurate results are required” (p. 2). This statement does not reflect the results obtained for the Hermine catchment, especially when not only the days since the last rain but also the rainfall intensity are considered. Statistically significant relationships were obtained between point-scale soil moisture measurements and DSP,  $DSP_{10}$ ,  $DSP_{20}$  and  $DSP_{30}$ . For  $DSP_{20}$ , a significant topographic control was even identified at the 5 cm depth, as inverse relationships with soil moisture were found for sampling sites located at least 20 m above the catchment outlet while barely any significant relations were obtained below that elevation (Fig. 7). It is also worth mentioning that previous-day discharges were also used as surrogates for AMCs (data not shown) but they were not involved in any significant relationship with point-scale soil moisture measurements; this result is

contradictory to the affirmation of Kohler and Lindsey (1951) who argued that baseflow-derived indices provided reasonably good results in humid and sub-humid regions.

It is interesting to compare results obtained from previous studies in the Hermine catchment with the conclusions of the current paper. For instance, the same soil moisture content dataset was analyzed to identify dominant organizing scales of soil moisture and their topographic controls (Ali et al., 2010). The importance of DSP<sub>30</sub>, in particular, was then revealed: at a depth of 15 cm, the catchment areas subjected to the influence of DSP<sub>30</sub> were present at the broad (>1.4 ha) and the very large (0.85–1.4 ha) characteristic scales whereas at a depth of 45 cm, DSP<sub>30</sub> only influenced soil moisture at scales below 0.85 ha. These conclusions are consistent with the dynamics illustrated in Fig. 5. Furthermore, previous results corroborate the fact that relations between actual soil moisture and AP<sub>7</sub> or AP<sub>14</sub> are very rare and can only be perceived at very fine characteristic scales (<0.1 ha). This comparison sheds light on the scale-dependent spatial representativity of AMCs surrogate measures. Ali et al. (2010), however, did not identify any significant relations between soil moisture and AP<sub>2</sub> at any characteristic scales, while it only captured the influence of AP<sub>5</sub> at the 0.54–0.85 ha scale and the influence of AP<sub>12</sub> at the 0.02–0.1 ha scale. These results are opposite with some of the dynamics illustrated in Fig. 4.

In a paper aiming to identify hydrologically representative connectivity metrics in the Hermine catchment, Ali and Roy (2010) found that the spatial connectedness of locations whose volumetric soil moisture content exceeded 30% was dependent upon AP<sub>7</sub>. The relationship between connectivity and AP<sub>7</sub> then had the form of a step function, which may explain why it was not captured by any of the tested regression models in the current paper. Geochemical data were also used to assess the temporal variability in the nature of catchment sources and their contributions to streamflow (Ali et al., 2001). Multiyear daily stream chemistry data were broken down into several hydrologic scenarios to reflect different conditions with respect to stream discharge and two surrogates for antecedent catchment wetness (i.e. AP<sub>2</sub> and AP<sub>7</sub>). From an end-member mixing analysis (EMMA) applied to each sub-dataset associated with each

Interactive Discussion

assumption on active processes, we computed the point-scale temporal relations between actual soil moisture measurements and commonly used meteorological-based indices so as to identify the surrogates for AMCs that are best suited to the Hermine catchment. Two principal results stood out. Firstly, it was shown that the sole reference to AMCs indices often used in catchment hydrology (i.e.  $AP_7$  or  $AP_{10}$ ) does not provide a complete understanding of the Hermine catchment dynamics; soil moisture was not related to cumulative rainfall amounts over antecedent temporal windows of seven or ten days. Secondly, the relationships between point-scale soil moisture measurements and surrogates for AMCs were not spatially homogeneous, thus revealing a mosaic of linear and nonlinear catchment “active” and “contributing” sources whose location was sometimes controlled by surface terrain attributes or the topography of the soil-confining layer interface. These results represent a step forward in developing a hydrological conceptual model for the Hermine catchment as they indicate depth-specific processes and spatially-variable triggering conditions. Such hydrological behaviour may also exist in other catchments. The analysis also raises several questions on the use of surrogate AMCs measures and on the generalization of results obtained with a single surrogate. Further investigations are, however, necessary to establish robust, causal relationships between soil moisture and meteorological-based proxies for AMCs and then derive guidelines concerning the best surrogate choice.

*Acknowledgements.* We gratefully acknowledge fellowship support awarded by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Fonds québécois de la recherche sur la nature et les technologies (FQRNT) to the first author. The research was also funded by the FQRNT. We thank the staff of the Station de biologie des Laurentides de l'Université de Montréal, Marie-Claude Turmel for her insightful suggestions towards the planning of the soil moisture surveys, and Marius Dulgheru, Gabi Chiaburu, Julie Thérien, Marie Lambois and Claude Gibeault for their occasional help on the field. We heartily thank our field assistants Rachel Thériault and Katherine Sicotte, who were able to take over the organization of the surveys when needed and contributed great effort in data collection. This study is part of the research program of the Canada Research Chair in fluvial dynamics.

**Table 2.** Influence of catchment surface topography (rows) on the nature of the point-scale relationships between soil moisture content and various surrogates (columns). Reported p-values are significant and suggest that at least one relationship type is associated with a median value of the studied topographic variable that is significantly different from the others.

**Table 3.** Influence of the soil confining layer topography (rows) on the nature of the point-scale relationships between soil moisture content and various surrogates (columns). Reported p-values are significant and suggest that at least one relationship type is associated with a median value of the studied topographic variable that is significantly different from the others.

Relationship strength

### Results from STEP 1 for Surrogate measure # 1

← SPEARMAN CORRELATION →  
← KRUSKAL-WALLIS TEST →

#### STEP 1 Examine the spatial variability of hydrological behaviours between point-scale soil moisture and surrogate measures

Methodology:

- a) For each sampling location, identify the statistical relationship type and strength between actual soil moisture and the surrogate
- b) Build database to map relationship type and strength results to assess spatial variability (Fig. 4, 5 and 6)

#### STEP 2 Identify potential topographic influences on the spatial variability of hydrological behaviours

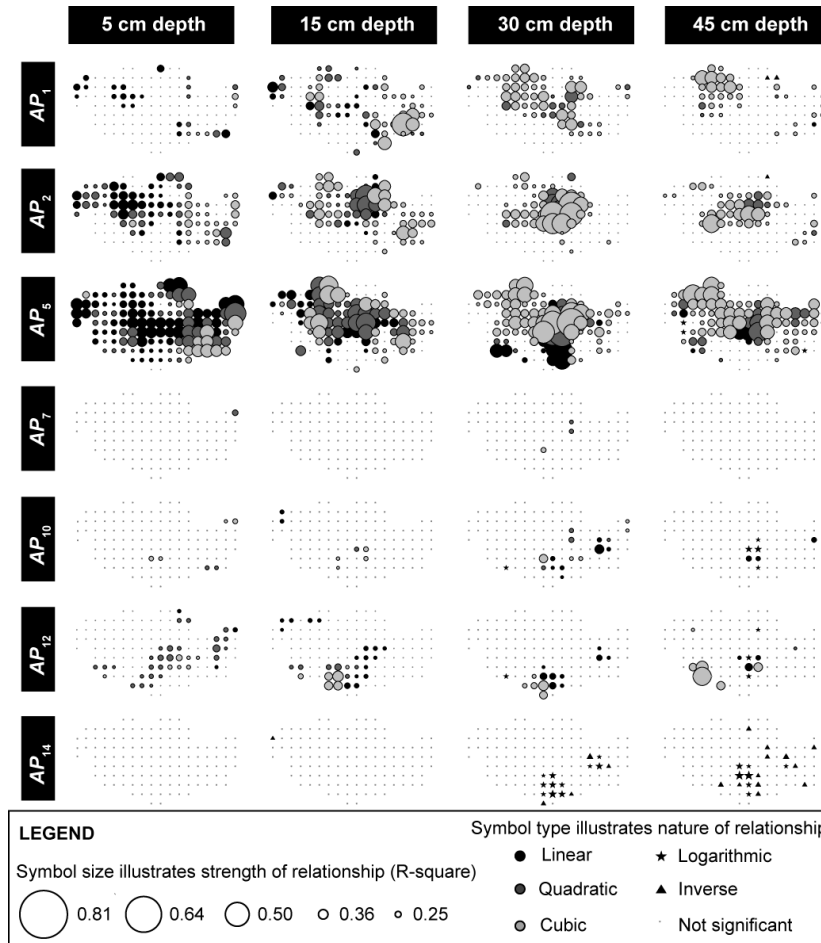

Methodology:

- a) Determine statistical difference in topography of regions with distinct hydrological behaviours (Fig. 7 and 8)
- b) Compute correlation between topography and relationship strength

Fig. 3. Methodological approach used in this paper.

## Appropriate surrogates for antecedent moisture conditions

G. A. Ali and A. G. Roy

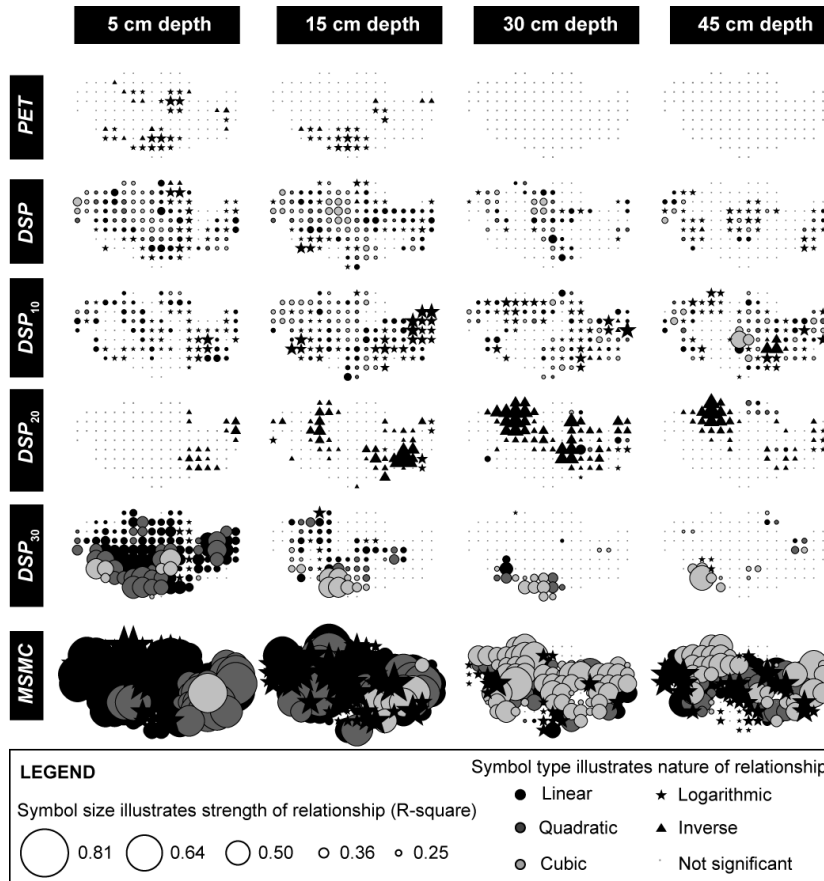

**Fig. 4.** Nature and strength of the relationships between point-scale soil moisture content and  $AP_x$  indices ( $x=1, 2, 5, 7, 10, 12$  or  $14$  days) used as surrogates for AMCs.
