Abstract

Water availability is one of the most important environmental controls on vegetation phenology, especially in semi-arid regions, and is often represented in terms of soil moisture in small-scale studies whereas it tends to be represented by precipitation in

- Iarge-scale (e.g. regional) studies. Clearly, soil moisture is the more appropriate indicator for root water uptake and vegetation growth/phenology and therefore its potential advantage and applicability needs to be demonstrated at regional scales. This paper represents a data-based regional study of the effectiveness of alternative indices based on water and energy availability on space-time patterns of spring vegetation green-up
- onset dates estimated from Normalized Difference Vegetation Index (NDVI) datasets in the grasslands of Inner Mongolia, China. The macro-scale hydrological model, VIC, is employed to generate a soil moisture database across the region. In addition to standard index based on temperature, two potential hydrology based indices for prediction of spring onset dates are defined based on the simulated soil moisture data as well as
- on observed precipitation data. Results indicate that the correspondence between the NDVI-derived green-up onset date and the soil moisture derived potential onset date exhibits a significantly better correlation as a function of increasing aridity, compared to that based on precipitation. In this way the soil moisture based index is demonstrated to be superior to the precipitation based index in terms of capturing grassland spring
- ²⁰ phenology. The results also showed that both of the hydrological (water based) indices were superior to the thermal (temperature based) index in determining the patterns of grass green-up in the Inner Mongolia region, indicating water availability to be the dominant control, on average. The understanding about the relative controls on grassland phenology, and the effectiveness of alternative indices to capture these controls,
- ²⁵ are important for future studies and predictions of vegetation phenology change under climate change.

1 Introduction

Changes in vegetation phenology and their impacts on ecosystem functioning and agricultural productivity are becoming serious concerns worldwide, especially in the context of global climate change. Phenology is a general biological term that describes recurring natural events, which may include birds migrating back and forth, flowers blooming, and leaves of trees changing color and falling off in autumn. Specifically, in the case of vegetation, phenology includes bud-burst, green-up, flowering, plant maturing and finally senescence (which are the various phenophases of vegetation dynamics). Vegetation phenology plays a fundamental role in the functioning of many forest or grassland ecosystems, and can also impact the hydrological cycle in significant ways

- grassland ecosystems, and can also impact the hydrological cycle in significant ways by affecting interception and transpiration processes and thus streamflow variability. Their impacts are clearly detectable in seasonal streamflow variability especially when precipitation itself is otherwise seasonally uniform. For example, Czikowsky and Fitzjarrald (2004) studied seasonal runoff variability in North-Eastern USA, and showed
- that the signature of phenology was so strong that the phonological changes could be inferred directly from flow observations. Thompson et al. (2011) and Ye et al. (2012) showed that not accounting for vegetation phenology can lead to poor predictions of both seasonal evaporation and runoff variability in North-East USA, and that a temperature correction that mimics the phenology can help to improve the predictions. More globally. Cause at al. (2001) showed that is arous of the world with significant.
- ²⁰ More globally, Cayan et al. (2001) showed that in areas of the world with significant deciduous forests, changes in transpiration associated with phenology can contribute to significant changes to seasonal runoff.

In the context of climate change, vegetation phenology is influenced by variations in several environmental factors such as temperature, water availability, solar irradiance,

and atmospheric oxygen (Lambers et al., 2008), among which water and temperature (collectively called hydrothermal conditions) are the most important ones and are frequently chosen in phenological studies. Studies show that timings of most phenological events are significantly related to temperature, which means that such events are likely

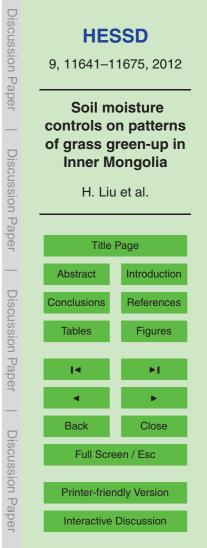

to occur earlier as the climate warms (Sparks, 2000). But in semi-arid and arid regions, the dominant factors that control vegetation phenology may shift according to the changes in thermal condition and/or water condition. Indeed, the water condition may turn out to be the more important factor in drier years (i.e. years with low precipitation).

5

Numerous research efforts have been devoted to quantifying the relationships between phenophases and the controlling or limiting environmental factors. One classic example is the degree-day concept, which is defined as the daily accumulation of air temperature above a certain (base) threshold value during a specific pre-seasonal pe-

- riod (see the review by Wang et al., 1960). This concept attempts to capture the thermal condition needed to be satisfied for vegetation phenological development, which was later extended to include the stress-degree-day concept to include water stress effects (Idso et al., 1978). Considerable work has been conducted in different geographical and climatic regions to understand and quantify the relationships among climate, soil
- ¹⁵ moisture, and phenology for various types of vegetation, such as tomatoes (Weaver et al., 1988), woody vegetation cover (Seghieri et al., 2009), semi-deciduous (Do et al., 2005), and drought deciduous (Jolly and Running, 2004) vegetation types. Most of these studies have been primarily based on ground measurement of phenological features and environmental variables.
- However, such ground measurements cannot be easily extrapolated to characterize large-scale regional vegetation phenology, including regional patterns and broad-scale changes in time. Remote sensing imagery has been widely used over the past two decades for monitoring vegetation dynamics at regional to global scales in view of its synoptic coverage and repeated temporal sampling (Reed et al., 1994; Zhang et al.,
- 25 2003; Julien and Sobrino, 2009; Yang et al., 2012; among many others). This approach also facilitates other kinds of studies that seek to explore the driving factors behind phenology change in the context of climate change (Piao et al., 2006; Wang et al., 2011; Shen et al., 2011). In these studies, hydrothermal conditions tend to be the most investigated factors affecting phenology development and their changes and are almost

always represented, essentially, by the degree-day concept applied to air temperature (for thermal condition) and precipitation (for water condition). In particular, although soil moisture is a more direct and straightforward index that governs vegetation growth and indeed has been frequently used in local studies involving ground measurements, pre-

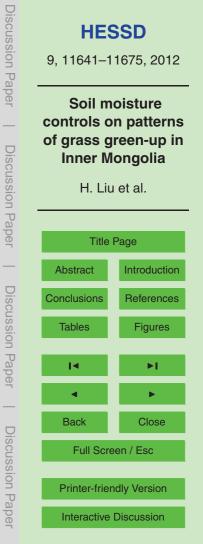

⁵ cipitation replaces it in remote sensing-based studies, possibly because precipitation is more readily available at the larger (e.g. regional) spatial scale.

However, this does not have to remain as a major limitation any more. Recent advances in hydrological modeling capability, especially at large-catchment or regional scales provide a sound basis for estimating or predicting large-scale soil moisture with

- ¹⁰ which to analyze and interpret observed space-time patterns vegetation phenology. A suite of macro-scale hydrological models have now been developed that can incorporate sufficient physics to account for the water and energy balances across the land surface. More importantly, these models can run at spatial and temporal scales much finer than those of climate models and observed meteorological data. The macro-scale
- ¹⁵ hydrological models can already perform reliable simulations of real-time soil moisture and streamflow at daily or sub-daily time steps. Inspired by these recent advanced in modeling capability, one of the goals of this research is to demonstrate the advantage of model-produced soil moisture over observed precipitation for analyzing vegetation phenological change.

In this paper, we are specifically interested in grass phenology. In the case of grasslands, the phenophases include green-up in spring, maturity in summer, senescence in autumn and hibernation in winter. Green-up is the first phonological event, which plays an important role in the whole life cycle of grasses, and can influence the water balance and carbon balance at local, regional and global scales. Here we focus on the

spring grass green-up onset, which is likely to be affected by variations in thermal and moisture supply. The aim is to investigate the soil moisture and temperature controls on grass green-up onset, including the feasibility of using a soil moisture based index for its analysis and its advantages over a precipitation based index. The Inner Mongolia grassland area (IMGA) is selected as the study area. The Advanced Very High

Resolution Radiometer (AVHRR) Normalized Difference Vegetation Index (NDVI) data provided by the Global Inventory Monitoring and Modeling Studies (GIMMS) is used to characterize grass phenology. The distributed Variable Infiltration Capacity (VIC) hydrological model is applied over the IMGA region to generate the distributed soil moisture data used to construct the soil moisture-based index.

This paper is organized as follows. In Sect. 2, we introduce the study area and the data sources, the method used for detection of grass green-up from NDVI data, and provide the basics of the VIC model used for generating soil moisture fields. In this section, we also propose two different indices that are used to characterize water availability based on acid methods.

- ¹⁰ ability, based on soil moisture and precipitation. In Sect. 3, we present the hydrological and meteorological results and additional results that bring out the spatial patterns and temporal trends in the timing of grass green-up in the study area, under an apparent warming trend found in the region. We also use the results of the analysis to demonstrate the superiority of the soil moisture based index over the precipitation based in-¹⁵ dex, and together with these investigate if and how the dominant factors that control
- dex, and together with these investigate if and how the dominant factors that control grass green-up vary in space regionally and in time. This is followed by a brief summary and conclusions in Sect. 4.

2 Methodology

2.1 Study area and data

The IMGA is located in Northern China (Fig. 1). The area has an average altitude of 1100 m above sea level and an area of 3.1 × 10⁵ km². The meteorological data are from the China Meteorological Data Service System (http://cdc.cma.gov.cn/). The study area has 21 stations (see Fig. 1) with records from 1982 to 2006. The mean annual temperature ranges from -3°C to 7°C, which increases from north to south. Annual precipitation ranges from 100 mm to 400 mm, with a mean value of 300 mm, and principally falls between May and September. The mean annual pan evaporation (E20) is

2030 mm. The climate is dry (arid), and the study area belongs to the inland region of China. The dominant vegetation type in the IMGA is grass, as shown in Fig. 1, which is classified according to the MODIS product MOD12C1. The AVHRR NDVI time series data of GIMMS (http://glcf.umiacs.umd.edu/data/gimms/) from 1982 to 2006 are
⁵ used to capture the timing of grass spring green-up onset. The Saodaohezi hydrological station on Luan River (see Fig. 1) close to the study area is chosen to assess the predictions of the VIC hydrological model.

2.2 Macro-scale hydrologic model

25

The VIC model (Liang et al., 1994) was used in this study to simulate the space-time dynamics of soil moisture across the region. VIC is a physically based, semi-distributed macro-scale hydrological model that balances both water and surface energy within a grid cell. The VIC model can also account for sub-grid variability of land surface vegetation classes and soil moisture storage capacity, includes an infiltration algorithm that accounts for the areal extent of soil saturation. Soil layer depths, infiltration, and baseflow parameters have to be tuned during calibration. VIC has been widely used for streamflow simulation and drought monitoring in large river basins globally, and specifically across China as well (e.g. Yuan et al., 2004; Sheffield and Wood, 2007). In this study, the VIC model was implemented across China at a 0.5 degree resolution from 1951 to 2010. The model parameters were calibrated using the method proposed
20 by Xie et al. (2007).

2.3 Green-up Onset Date and the Holdridge Aridity Index

Zhang et al. (2003) defined the Green-up Onset Date (GUD) as the day when the rate of change of the NDVI curvature (RCC) reaches its first local maximum value (see Fig. 2). We adopted this method to capture the grass green-up onset date (GUD) from the satellite images. The NDVI data marked as having good values were averaged within a 3×3 pixel window. A Savitzky-Golay filtering procedure was applied to each

annual time series of NDVI to obtain a smoothed series (Chen et al., 2004; Shen et al., 2011). Afterwards, the smoothed series was fitted by the following four-parameter logistic function (Zhang et al., 2003; Shen et al., 2011):

$$\mathsf{NDVI}(t) = c / \left(1 + e^{a + bt}\right) + d \tag{1}$$

⁵ where, the symbols *a*, *b*, *c* and *d* are best-fit model parameters, with *d* being the initial background NDVI value, and c + d being the maximum NDVI value. An expression for the rate of change of curvature (RCC) was derived from Eq. (1) as follows:

$$\operatorname{RCC} = b^{3}cz \times 3z(1-z)(1+z)^{3} \left[2(1+z)^{3} + b^{2}c^{2}z \right] / \left[(1+z)^{4} + (bcz)^{2} \right]^{2.5} - b^{3}cz \times (1+z)^{2}(1+2z-5z^{2}) / \left[(1+z)^{4} + (bcz)^{2} \right]^{1.5}$$
(2)

10

where, $z = e^{a+bt}$.

It should be noted that for some extreme dry years and/or stations GUD could not be determined at all by the RCC method described above. In fact, the grassland might not even green up in the dry years due to insufficient moisture supply. To investigate the possible connection between grass green-up patterns and aridity, in this paper we characterize the relative aridity of the stations with the use of the Holdridge Aridity Index (HAI), proposed by Holdridge (1947) in a famous paper as part of the definition of the life zone, and has been widely adopted in China (Pan et al., 2003). The HAI index is defined as follows:

HAI =
$$58.93 \times \sum T/365 \times P$$

where, *P* is the annual precipitation (mm); *T* is the daily mean temperature within the range of 0° C to 30° C, which is excluded from the calculation when *T* is less than the lower limit and assigned a value of 30° C when *T* is greater than the upper limit.

(3)

2.4 Proposed environmental indices

The factors influencing vegetation green-up include irradiance, temperature, soil moisture etc., amongst which the thermal and water conditions have been of most concern to large scale vegetation phenology researchers. However, the relationship between

- ⁵ green-up onset and the controlling factors can be complex, and the limiting environmental factor may shift (between places and between years) according to the prevailing hydrothermal conditions. Taking the example of water availability, depending on their biophysical characteristics and physiological features of the vegattion, one can expect that dormant vegetation will not green-up immediately upon seeing the first rainfall,
- a behavior characteristic that can be explained by way of self-protection to avoid water deficit in the subsequent growth stage, in case the rainfall does not persist. This means that water accumulation through precipitation must reach a threshold over some time span before vegetation would green-up. These notions of accumulation, threshold and time span also apply to other environmental factors as well, such as temperature.
- ¹⁵ In the past, to explore the relationships between the environmental factors and vegetation green-up, it has been common to accumulate the indicator variables over a certain, fixed time span, for example the (typical spring) month of May. However, this has the drawback that it is quite possible that vegetation green-up may have already occurred by the middle of May, and therefore the accumulation over the whole month
- ²⁰ of May complicates the relationship, and contributes to poor predictability. Recently, a more flexible and appropriate time span was developed by Shen et al. (2011) for the concept of thermal spring onset date (TSO). The TSO was defined as the date when the green-up can potentially begin, which means the daily temperature accumulated from a certain day to the TSO is above a threshold required for vegetation green-up.
- In the same way, we also need an index to account for the control of water availability on grass green-up. In the past, precipitation has been used as a surrogate for water availability controls on phenological development. In this paper we explore the feasibility of using an index based directly on soil moisture. Therefore, similar (and in addition)

to the definition of TSO, we propose and compare two alternative indices that account for the control of water availability on the potential green-up onset date, i.e. the date by which the water requirement for the onset of green-up is satisfied. First, we define the Soil Moisture Spring green-up Onset date (SMSO) as the date by which the

- accumulated soil moisture storage reaches a threshold that the grass needs to greenup. Secondly, we also adopt an alternative precipitation based index, the Precipitation Spring green-up Onset date (PSO), defined as the date by which the accumulated precipitation reaches a depth threshold that grass needs to green-up. In each case (temperature, soil moisture, precipitation), there are three components to the definition
- of the indices: (1) the end day of the accumulation period; (2) the time span; (3) the threshold. In this study we use the GUD detected from the remote sensing data as the end day of the accumulation period. For any chosen time span, we use the mean of the 25 yr accumulation over that time span as the corresponding threshold value. We then optimize the magnitude of the time span through the use of a maximization procedure
 proposed by Shen et al. (2011). Details of the optimization procedure are described
- below.

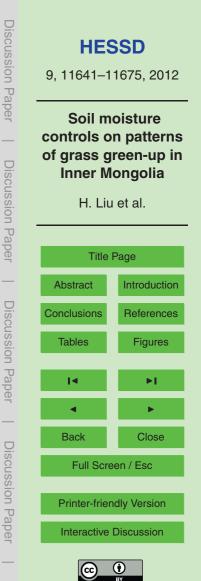

2.4.1 Accumulation threshold

20

If the time span chosen is N_{days} , the corresponding accumulation threshold is defined as the 25-yr (1982 to 2006) average of the N_{days} -accumulated soil moisture (termed as ASM_N):

$$ASM_{N} = 1/25 \sum_{\text{year}=1982}^{2006} \left(\sum_{i=\text{GUD}_{\text{year}}-N}^{\text{GUD}_{\text{year}}-1} SM_{\text{year}}^{i} \right)$$
(4)

where SM_{year}^{i} is the soil moisture for the *i*th DOY in a specific year. Given N_{days} and ASM_N , we then define the SMSO of a certain year (i.e. denoted $SMSO_{1982}^{N_{days}}$ for the year 1982) as the last day of an N_{days} window that fulfills the following 11650

conditions: (a) the accumulated daily soil moisture reaches ASM_N , and (b) it is the earliest time window that fulfills condition (a). As shown in Fig. 3a, if N_{days} is 5, we slide a 5-day moving window starting from the first day of 1982 until the accumulated soil moisture reaches ASM_5 , upon which we record the last day of the current window as $SMSO_{1982}^5$.

2.4.2 Variable time span

After estimating the SMSO for each year between 1982 and 2006, we have an annual time series of SMSO value for a given N_{davs} :

$$SMSO^{N_{days}} = \left\{ SMSO_{1982}^{N_{days}}, SMSO_{1983}^{N_{days}}, ..., SMSO_{2006}^{N_{days}} \right\}$$
(5)

¹⁰ We can repeat this procedure for several values of N_{days} , and in this way obtain several time series of SMSO values. We assume that the potential green-up onset date accounting for water availability should be positively cross-correlated to the GUD time series detected from the remote sensing data. Guided by this thinking, the time span of accumulation (the number of days, N_{days} , preceding the known GUD) was then deter-¹⁵ mined as the value of N_{days} (Note: $1 \le N_{days} \le 90$ in steps of one day) that produces the maximum cross-correlation coefficient between the annual time series of SMSO^{N_{days}} and GUD. The maximization algorithm can be formally presented as follows:

Maximize: cross-correlation
$$(GUD, SMSO^{N_{days}})$$

(6)

(7)

 $_{20}$ GUD = {GUD₁₉₈₂, GUD₁₉₈₃, ..., GUD₂₀₀₆}

The GUD included in Eqs. (6) and (7) is a vector consisting of annual GUD values from 1982 to 2006. Figure 3b presents the maximizing procedure in schematic form, for the case in which $SMSO^5$ is most correlated to the estimated GUD time series, meaning that in this case the optimal accumulation time span is 5 days, and the corresponding accumulation threshold is ASM_5 .

Following this maximization process, the SMSO, $ASM_{N_{SM}}$, and corresponding optimal value of N_{days} (denoted as N_{SM}), and the resulting optimal cross-correlation coefficient between the GUD and SMSO time series are determined for each measurement station. In addition, the same procedure is also followed for the case of precipitation

⁵ and temperature as well, and correspondingly we obtain the values of PSO, AP_{N_P} , N_P , and the optimal cross-correlation coefficient between GUD and PSO time series, likewise the values of TSO, AT_{N_T} , N_T , and the optimal cross-correlation coefficient between GUD and TSO time series. These will be used later for a comparative assessment of the three indices.

10 2.5 Regression of GUD based on a dominant thermal/hydrological index

The estimation procedure described above for the three environmental indices considered water and temperature as alternative controls. In reality, their effects on the GUD must be considered together, not in isolation (i.e. one or the other). If they are to be considered together and regressed together against estimated GUD values, then the question arises as to what accumulation time span to use. We address this problem in this study by alternatively choosing water or temperature as the dominant control, and the remaining one (as the case may be) as a secondary control. In each case (water or temperature being dominant), the chosen time span is that of the dominant control. For example, if soil moisture is assumed as the dominant control, then both soil moisture and air temperature are accumulated over $N_{\rm SM}$ days ahead of the GUD each year, as defined below:

$$SM_{year}^{N_{SM}} = \sum_{i=GUD-1}^{GUD-N_{SM}} SM_{year}^{i}$$
$$T_{year}^{N_{SM}} = \sum_{i=GUD-1}^{GUD-N_{SM}} T_{year}^{i}$$

(8)

(9)

where the year is {1982, 1983, ..., 2006}. In this way we obtain the following vectors and regress the GUD values on both SM^{N_{SM}} and T^{N_{SM}} simultaneously through multiple regression:

$$SM^{N_{SM}} = \left\{ SM^{N_{SM}}_{1982}, SM^{N_{SM}}_{1983}, ..., SM^{N_{SM}}_{2006} \right\}$$
(10)

$${}_{5} \quad \mathsf{T}^{N_{\rm SM}} = \left\{ T^{N_{\rm SM}}_{1982}, T^{N_{\rm SM}}_{1983}, \dots, T^{N_{\rm SM}}_{2006} \right\}$$
(11)

$$GUD_{reg}^{SM} = \beta_1 SM^{N_{SM}} + \beta_2 T^{N_{SM}} + \beta_3$$
(12)

$$r_{SM}^{GUD} = correl(GUD, GUD_{reg}^{SM})$$

(13)

where, β_1 , β_2 , and β_3 are the regression coefficients; and r_{SM}^{GUD} is the correlation between NDVI-derived GUD and the regressed GUD (GUDSM_{reg}). Note that both soil mois-10 ture and precipitation are used as alternative controls to represent water availability. Using a similar procedure (as above), $P^{N_{P}}$, $T^{N_{P}}$, and r_{P}^{GUD} are calculated assuming precipitation as the dominant control (and temperature as secondary control). We then repeat the analysis and estimate SM^{N_T}, T^{N_T}, and r_T^{GUD} by assuming air temperature as the dominant control and soil moisture as the secondary control. In this way, three different regressions are carried out, producing three different correlation coefficients, which are then compared against each other.

Results 3

3.1 Hydrological and meteorological results

The monthly streamflow simulation results at the Saodaohezi station are shown in 20 Fig. 4 (other details of the simulation are left out for reasons of brevity) and the corresponding Nash-Sutcliffe efficiency coefficient (NSCE) is 0.66. This is deemed sufficient for the purposes of this study, and the soil moisture output of the model is used in constructing the soil moisture index as a surrogate for water availability for the vegetation.

Estimation of the aridity index HAI, within the study region indicates that the region is characterized by a dry climate, with HAI values ranging from 1.0 to 5.0 (see Fig. 5 for the location of the gauges as well as the spatial patterns of HAI within the study area). Measurement stations 6 to 9 in the northern middle part of the study area seem to have the highest HAI. These four gauges were therefore excluded from further analysis because it was found that their unusual life cycle could not be detected from remote sensing data using the RCC method.

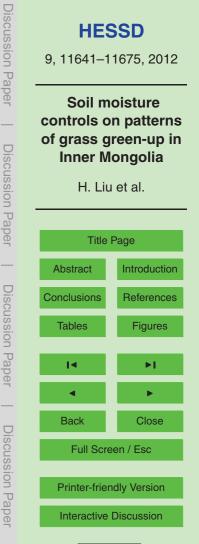

3.2 GUD patterns and the shift of dominant controls in Inner Mongolia

5

We implemented the GUD detection method (Eqs. 1 and 2) to the remaining 17 gauging stations, and estimated their GUD values. For illustration, we have chosen to present the results for three stations that are located at the northern (Station 18), middle (Station 10) and southern (Station 21) parts of the study area, and have different HAI values (their locations being denoted in Fig. 5 by big circles). The resulting annual time series of GUD values for these three stations are presented in Fig. 6 for the years 1982 to

- ¹⁵ 2006. They show that annual GUD values can vary over a wide range, 90 to 160 (day of the year, or DOY), and that there does not appear to be much concurrence between the temporal patterns between the three gauge locations. Whereas Fig. 6 presented illustrative results of GUD variability in time, the GUD values also exhibit considerable spatial (regional) variability. In order to illustrate this, in Fig. 7 we present the spatial pat-
- tern of the 25-yr mean GUD values across the region, with the mean GUD estimated from the NDVI data falling in the range of 116 to 137 (DOY) among the 17 gauging stations. Both of these results show that GUD values in this region exhibit considerable spatial (regional) and temporal (inter-annual) variability.

Based on temperature records between 1982 and 2006 the study region has also experienced a warming of the climate. Figure 8a displays a positive (increasing) trend in the temperature in all meteorological stations. Precipitation, however, shows quite variable trends between the stations. Most meteorological stations exhibit a decreasing (negative) trend in precipitation, whereas a few (6 of the 21) in the south-western part

of the area close to the Qinghai-Tibetan Plateau, show an increasing (positive) trend. The corresponding spatial patterns in temporal changes in the GUD values, presented in Fig. 8b, show prolonged (positive) trends in the middle part of the study region and advanced (negative) trends in the northern as well as southern parts. These patterns

- of temporal GUD trends are also in agreement with results obtained by Yu et al. (2003). From the above results, one can see that although the temperature in the whole area has been rising over the past 25 yr, the spatial and temporal trends in GUD are highly variable, which suggests that grass green-up in this region may be influenced by factors other than the thermal condition, the most important of which is the water condition.
- ¹⁰ We illustrate this using data taken from one station within the study region. Figure 9 presents the time series of (smoothed) NDVI, air temperature, (smoothed) precipitation and also modeled soil moisture for Station 10 for two consecutive years, 1997 and 1998. The estimated GUDs from the NDVI data were 133 and 128 DOY, respectively, and are marked on the figure as vertical lines. In 1997, as can be seen in Fig. 9a, the
- soil moisture was already at a high value since March (perhaps due to carry over from the previous year), but the temperature was too low for green-up until it hit a threshold, so the dominant control in 1997 may have been temperature; in 1998, shown in Fig. 9b, the temperature was uniformly high in April, yet the grass did not green-up until the accumulation of soil moisture due to precipitation rose up and remained high consistently,
- which suggests that the dominant control in 1998 is in fact water (soil moisture). These two examples are excellent illustrations of competing controls on GUD, although this kind of evaluation is very subjective and time consuming. Could there be an alternative way to determine the dominant controls that mimics the same decision-making processes or rules that grasses possibly adopt during their green-up phase? In the next
- section we assess the power of the environmental indices proposed earlier to capture the underlying controls objectively and make prior predictions.

3.3 Soil moisture vs. precipitation as the basis for a water index

The time series of SMSO, PSO and TSO for Station 10 obtained using the estimation procedure described in Sect. 2.4 are presented in Fig. 10 for illustration, along with the corresponding GUD values estimated from the NDVI data. These results indicate,

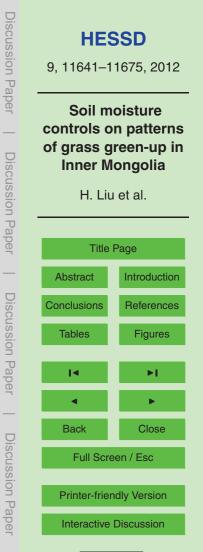

for Station 10, that the PSO values lie mostly above the GUD values (with very little overlap), whereas the SMSO and TSO values seem to fluctuate above and below the GUD values, with considerable overlap. On the basis of these results we speculate that in this case the SMSO and TSO indices are more appropriate indices to explain the inter-annual shifts of GUD, and that the precipitation based index does not have much
 explanatory power to account for the effect of water availability, in relation to the soil moisture based index.

We expect that the correlation between GUD and the soil moisture determined potential green-up onset date (SMSO) would be better correlated in more arid areas, as characterized by the aridity index, HAI. We plotted the correlation coefficients between

- GUD and SMSO obtained at each of the 17 stations as a function of their HAI. In addition, we also plotted the estimated correlation coefficients between GUD and PSO in the same figure so as to assess which of the two indices produces a superior predictive performance. The results are presented in Fig. 11, and show that the correspondence between the GUD and SMSO as a function of HAI is stronger, with a coefficient of de-
- termination of 0.52, whereas the correspondence between GUD and PSO as a function of HAI is rather week, with a coefficient of determination of only 0.02. This result shows that the soil moisture based index (SMSO) is superior to the precipitation based index (PSO) as a measure of water availability for capturing observed GUD variations.

3.4 Regression results based on dominant thermal/hydrological indices

²⁵ The regression results obtained for the 17 stations using the multiple regression procedure described in Sect. 2.5 are shown in Fig. 12. The averaged r_{SM}^{GUD} and r_{P}^{GUD} values over the 17 stations are, respectively, 0.879 and 0.809, which are higher than

the averaged correlation $r_{\rm T}^{\rm GUD}$ (0.791) based on temperature dominance. Figure 12 also indicates persistently higher positions for the hydrological lines (representing $r_{\rm SM}^{\rm GUD}$ and $r_{\rm P}^{\rm GUD}$) than for the thermal line (representing $r_{\rm T}^{\rm GUD}$), implying that the vegetation life cycle in the IMGA may be dominated more by the water condition than by the ther-

- ⁵ mal condition. Furthermore, a slightly larger value of r_{SM}^{GUD} (0.879) than r_{P}^{GUD} (0.809) confirms our earlier result that SMSO is a better index to represent the hydrological condition. Figure 13 presents the spatial pattern of the estimated dominant factors for the 17 stations, based on which of the factors (assumed dominant) produced the best regression on the green-up onset date (GUD) in Inner Mongolia. The result shows that generally the water availability is the dominant control (in none of the stations did the
- generally the water availability is the dominant control (in none of the stations did the temperature found to be dominant) and that the soil moisture based index is superior to the precipitation based index at 12 out of the 17 stations. Even though the water condition is the dominant factor in controlling grass green-up in Inner Mongolia *on average*, in reality it is indeed possible that the dominant factor may shift inter-annually between
- ¹⁵ water and temperature. Can the same environmental indices considered here be used to predict this inter-annual variability of the alternating controls? This is a question that will be addressed in our future work.

4 Discussion and conclusions

Vegetation phenophases, such as spring vegetation green-up, could be influenced by several external factors, of which thermal and water conditions are the two most important ones. The thermal condition is always represented by air temperature, whereas in past remote sensing studies the water condition has been represented by precipitation, not soil moisture, although soil moisture is more directly related to vegetation growth and phenology. To explore the relationships between the environmental factors

²⁵ (e.g. temperature, precipitation) and vegetation green-up, it has been common to accumulate these indicator variables over a given, fixed time span; this is not reasonable

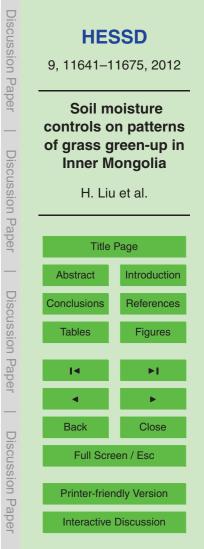

physically and contributes to poor predictability. Although one could pick out the dominant factor subjectively retroactively after the fact, there is a lack of an objective way to determine the dominant factors that controls phenological behavior.

- This paper was motivated by the need to overcoming gaps in predictive understanding the environmental controls underpinning vegetation green-up. Soil moisture at a daily time step was estimated over the study region through regional simulations with the distributed VIC model, which provided the means to explore the role of soil moisture directly. Two spring onset dates, SMSO and PSO, were defined in a way similar to the TSO defined by Shen et al. (2011). For each of these three indices an optimal time span was estimated through a maximizing process, as a way of converting the influence of a hydro/thermal condition to an index that estimates a potential green-up onset date, which makes it possible to determine the dominant factor automatically and
- onset date, which makes it possible to determine the dominant factor automatically and objectively. We found that the correspondence between the GUD and SMSO showed a signifi-
- ¹⁵ cantly better correlation with aridity, as represented by HAI, than that between GUD and PSO. The cross-correlation between NDVI-derived GUD and GUD values obtained by regression with soil moisture was better than the corresponding value obtained using precipitation data. This showed that the soil moisture based index has considerable advantage in predicting grassland spring green-up over the precipitation based index, and
- shows good promise for the assessment of potential change in vegetation phenology under climate change. The study also showed that while the dominant environmental factors that govern grass green-up in Inner Mongolia may shift from year to year, on average the water condition appears to be the dominant control over the whole region. On the basis of the procedures adopted in this study to derive environmental indices,
- ²⁵ we can foresee their potential application for the prediction of Green-up Onset Date under future climate change.

The soil moisture used in this study was the output of a hydrological model, whose reliability to predict soil moisture at a specific location at a scale finer than the model grid is open to question, given the potential for considerable sub-grid heterogeneity.

Clearly, it cannot be a true substitute for local observations. In spite of this, the study showed that the soil moisture based index was superior to the one based on precipitation. A hydrological model operating at finer space scales would therefore be an improvement, and its pursuit is left for further research. Alternatively, recent advances

- in remote sensing suggest that they might provide a new way for regional soil moisture monitoring, e.g. microwave remote sensing. However, the depth of penetration of these remote sensing instruments is a concern. For example, the AMSR-E instrument measures soil moisture over the upper 5 cm of soil (at most) (Rebel et al., 2012), whereas the root zone for grasses over which they extract soil moisture is of the order of 100 mm.
- ¹⁰ These are areas requiring further research.

Besides soil moisture and temperature that were explored in this study, there could be many other factors that could contribute to the variability of the green-up onset date (GUD), such as irradiance, nutrients and oxygen. More detailed investigations at the local level will be needed to explore their roles, relative to the roles of soil moisture and temperature.
