Abstract

New samples were collected in the three major Saharan aquifers namely, the “Continental Intercalaire” (CI), the “Complexe Terminal” (CT) and the Phreatic aquifer (Phr) and completed with unpublished more ancient chemical and isotopic data. Instead of classical Debye-Hückel extended law, Specific Interaction Theory (SIT) model, recently incorporated in Phreeqc 3.0 was used. Inverse modeling of hydrochemical data constrained by isotopic data was used here to quantitatively assess the influence of geochemical processes: at depth, the dissolution of salts from the geological formations during upward leakage *without evaporation* explains the transitions from CI to CT and to a first pole of Phr (pole I); near the surface, the dissolution of salts from sebkhas by rainwater explains another pole of Phr (pole II). In every case, secondary precipitation of calcite occurs during dissolution. All Phr waters result from the mixing of these two poles together with calcite precipitation and ion exchange processes. These processes are quantitatively assessed by Phreeqc model. Globally, gypsum dissolution and calcite precipitation were found to act as a carbon sink.

Keywords: hydrochemistry, stable isotopes, Sahara, Algeria

1. INTRODUCTION

A scientific study published in 2008 showed that 85% of the world population lives in the driest half of the Earth. More than 1 billion people residing in arid and semi-arid areas of the world have only access to little or no renewable water resources (OECD, 2008). In many arid regions such as Sahara, groundwater is the only source of water supply for domestic, agricultural or industrial purposes, causing most of the time overuse and / or degradation of water quality.

The groundwater resources of Ouargla basin (Lower-Sahara, Algerian) (Fig. 1) are contained in three main reservoirs (UNESCO, 1972; Eckstein and Eckstein, 2003; OSS, 2003, 2008):

- at the top, the phreatic aquifer (Phr), located in sandy gypsum permeable formations of Quaternary, is almost unexploited (only north of Ouargla) due to its salinity (50 g/L);

Email address: slm_rabia@yahoo.fr (R. Slimani)

- 34 • in the middle, the “Complexe Terminal” (CT) aquifer, (Cornet and Gouscov, 1952; UN-
35 ESCO, 1972) which is the most exploited, and includes several aquifers in different geo-
36 logical formations. It circulates in one or two lithostratigraphic formations of the Eocene
37 and Senonian carbonates or Miopliocene sands;
- 38 • at the bottom, the “Continental Intercalaire” (CI) aquifer, where water is contained in the
39 lower Cretaceous continental formations (Barremian and Albian), mainly composed of
40 sandstones, sands and clays. It is only partially exploited because of its significant depth.

41 After use, waters are discharged in a closed system (endorheic basin) and constitute a poten-
42 tial hazard to the environment, to public health and may jeopardize the sustainability of agricul-
43 ture (rising of the phreatic aquifer watertable, extension of soil salinization and so on) (Hamdi-
44 Aïssa et al., 2004; Slimani, 2006). Several previous studies (Guendouz, 1985; Fontes et al., 1986;
45 Guendouz and Moulla, 1996; Edmunds et al., 2003; Guendouz et al., 2003; Hamdi-Aïssa et al.,
46 2004; Foster et al., 2006; OSS, 2008; Al-Gamal, 2011) tried, starting from chemical and isotopic
47 information (^2H , ^{18}O , ^{234}U , ^{238}U , ^{36}Cl) to best characterize the relationships between aquifers.
48 They were more specifically tackling the issue of the Continental Intercalaire recharge. These
49 investigations dealt particularly with water chemical facies, mapped isocontents of various pa-
50 rameters, and reported typical geochemical ratios ($[\text{SO}_4^{2-}]/[\text{Cl}^-]$, $[\text{Mg}^{2+}]/[\text{Ca}^{2+}]$) as well as other
51 correlations. Minerals / solutions equilibria were checked by computing saturation indices with
52 respect to calcite, gypsum, anhydrite and halite, but processes were only qualitatively assessed.

53 In the present study, new data were collected in order to characterize the hydrochemical and
54 the isotopic composition of the major aquifers in Ouargla’s region. They also aimed at identify-
55 ing the origin of the mineralization and water-rock interactions that occur along the flow. New
56 possibilities offered by progress in geochemical simulations were used. More specifically, the
57 inverse modeling of chemical reactions allows us to select the best conceptual model for the in-
58 terpretation of the geochemical evolution of the Ouargla aquifer. The stepwise inversion strategy
59 involves designing a list of the scenarios that includes the most plausible combinations of geo-
60 chemical processes, solving scenarios in a stepwise manner, and selecting the scenario that pro-
61 vides the best conceptual geochemical model (Dai et al., 2006). Inverse modeling with Phreeqc
62 3.0 was used to quantitatively assess the influence of the processes that explain the acquisition
63 of solutes for the different aquifers: dissolution, precipitation, mixing and ion exchange. This
64 results in constraints on mass balances as well as on the exchange of matter between aquifers.

65 2. METHODOLOGY

66 2.1. Presentation of the study area

67 The study area is located in the northeastern desert of Algeria “Lower-Sahara” (Le Houérou,
68 2009) near the city of Ouargla (Fig. 1), $31^\circ 54'$ to $32^\circ 1'$ N and $5^\circ 15'$ to $5^\circ 27'$ E, with a mean eleva-
69 tion of 134 (masl). It is located in the quaternary fossil valley of Oued Mya basin. Present climate
70 belongs to the arid Mediterranean-type (Dubief, 1963; Le Houérou, 2009; ONM, 1975/2013).
71 This climate is characterized by a mean annual temperature of 22.5°C , a yearly rainfall of
72 43.6 mm/yr and a very high evaporation rate of $2,138\text{ mm/yr}$.

73
74 Ouargla’s region and the entire Lower Sahara has experienced during its long geological
75 history alternating marine and continental sedimentation phases. During Secondary era, vertical

76 movements affected the Precambrian basement and Primary causing particularly progressive col-
77 lapse of its central part, along an axis passing substantially through the Oued Righ valley and the
78 upper portion of the valley oued Mya. According to (Furon, 1960), a epicontinental sea spread
79 to the Lower Eocene of northern Sahara. After the Oligocene, the sea gradually withdrew. It is
80 estimated at present that this sea did not reach Ouargla and transgression stopped at the edge of
81 the bowl (Lelièvre, 1969). The basin is carved into Miopliocene (MP) deposits, which alternate
82 with red sands, clays and sometimes marls; gypsum is not abundant and dated from Pontian (MP)
83 (Cornet and Gouscov, 1952; Dubief, 1953; Ould Baba Sy and Besbes, 2006). The continental
84 Pliocene consists of a local limestone crust with puddingstone or lacustrine limestone (Fig. 2),
85 shaped by eolian erosion into flat areas (regs). The Quaternary formations are lithologically com-
86 posed of alternating layers of permeable sand and relatively impermeable marl (Aumassip et al.,
87 1972; Chellat et al., 2014).

88 The exploitation of Miopliocene aquifer is ancient and at the origin of the creation of the
89 oasis (Lelièvre, 1969; Moulias, 1927). The piezometric level was higher (145 m a.s.l.) but over-
90 exploitation at the end of the XIXth century led to a catastrophic decrease of the resource, with
91 presently more than 900 boreholes (ANRH, 2011).

92 The exploitation of Senonian aquifer dates back to 1953 at a depth 140 m to 200 m depth,
93 with a small initial rate *ca.* 540 L mn⁻¹; two boreholes have been exploited since 1965 and 1969,
94 with a total flowrate *ca.* 2,500 L mn⁻¹, for drinking water and irrigation.

95 The exploitation of Albian aquifer dates back to 1956, with a piezometric level 405 m and a
96 pressure 22 kg cm⁻². Presently, two boreholes are exploited:

- 97 • El Hedeb I, 1,335 m depth, with a flowrate 141 L s⁻¹;
- 98 • El Hedeb II, 1,400 m depth, with a flowrate 68 L s⁻¹.

99 2.2. *Sampling and analytical methods*

100 The sampling scheme complies with the flow directions of the two formations (Phr and CT
101 aquifers); for the CI aquifer only five points are available, so it is impossible to choose a transect
102 (Fig. 3). Groundwater samples ($n = 107$) were collected during a field campaign in 2013, along
103 the main flow line of Oued Mya, 67 piezometers tap the phreatic aquifer, 32 wells tap the CT
104 aquifer and 8 boreholes tap the CI aquifer (Fig. 3). Analyses of Na⁺, K⁺, Ca²⁺, Mg²⁺, Cl⁻,
105 SO₄²⁻ and HCO₃⁻ were performed by ion chromatography at Algiers Nuclear Research Center
106 (CRNA). Previous and yet unpublished data (Guendouz and Moulla, 1996) sampled in 1996 are
107 used here too: 59 samples for Phr aquifer, 15 samples for CT aquifer and 3 samples for the CI
108 aquifer for chemical analyses, data ¹⁸O and ³H (Guendouz and Moulla, 1996).

109 2.3. *Geochemical method*

110 Phreeqc (Parkhurst and Appelo, 2013) was used to check minerals / solution equilibria us-
111 ing the specific interaction theory (SIT), *i.e.* the extension of Debye-Hückel law by Scatchard
112 and Guggenheim incorporated recently in Phreeqc 3.0. Inverse modeling was used to calculate
113 the number of minerals and gases' moles that must respectively dissolve or precipitate/degas to
114 account for the difference in composition between initial and final water end members (Plum-
115 mer and Back, 1980; Kenoyer and Bowser, 1992; Deutsch, 1997; Plummer and Sprinkle, 2001;
116 Güler and Thyne, 2004; Parkhurst and Appelo, 2013). This mass balance technique has been
117 used to quantify reactions controlling water chemistry along flow paths (Thomas et al., 1989).
118 It is also used to quantify the mixing proportions of end-member components in a flow system

119 (Kuells et al., 2000; Belkhiri et al., 2010, 2012). The Inverse modeling involves designing a list
120 of the scenarios that includes the most plausible combinations of geochemical processes. For
121 example, the way to identify whether calcite dissolution/precipitation is relevant or not consists
122 of solving the inverse problem under two alternate scenarios: (1) considering a geochemical sys-
123 tem in which calcite is present, and (2) considering a geochemical system without calcite. After
124 solving the two scenarios, it is usually possible to select the better result as the solution of the
125 inverse problems and conclude whether calcite dissolution/precipitation is relevant or not. This
126 stepwise strategy allows us to identify the relevance of a given chemical process by solving the
127 inverse problem under alternative scenarios in which the process is either occurring or not.

128 3. RESULTS AND DISCUSSION

129 Tables 1 to 5 illustrate the results of the chemical and the isotopic analyses. Samples are
130 ordered according to an increasing salt content that was estimated from their specific electric
131 conductivity (EC). In both phreatic and CT aquifers, temperature is close to 25 °C, while for
132 CI aquifer, temperature is close to 50 °C. The results presented in those tables are raw ana-
133 lytical data that were corrected for defects of charge balance before computing activities with
134 Phreeqc. As analytical errors could not be ascribed to a specific analyte, the correction was
135 made proportionally. The corrections do not affect the anions to anions mole ratios such as for
136 $[\text{HCO}_3^-]/([\text{Cl}^-] + 2[\text{SO}_4^{2-}])$ or $[\text{SO}_4^{2-}]/[\text{Cl}^-]$, whereas they affect the cation to anion ratio such
137 as for $[\text{Na}^+]/[\text{Cl}^-]$.

138 3.1. Characterization of chemical facies of the groundwater

139 Piper diagrams drawn for the studied groundwaters (Fig. 4) broadly show a scatter plot
140 dominated by a Chloride-Sodium facies. However, when going into small details, the widespread
141 chemical facies of the Phr aquifer is closer to the NaCl pole than those of CI and CT aquifers. The
142 facies of the Phreatic aquifer most concentrated samples are in the following order: Ca-sulfate <
143 Na-sulfate = Mg-sulfate < Na-chloride. This sequential order of solutes is comparable to that of
144 other groundwater occurring in North Africa, and especially in the neighboring area of the chotts
145 (depressions where salts concentrate by evaporation) Merouane and Melrhir (Vallès et al., 1997;
146 Hamdi-Aïssa et al., 2004).

147 3.2. Spatial distribution of the mineralization

148 The salinity of the phreatic aquifer varies considerably depending on the location (near wells
149 or drains) and time (influence of irrigation) (Fig. 5a).

150 Its salinity is low around irrigated and fairly well-drained areas, such as the palm groves of
151 Hassi Miloud, just north of Ouargla (Fig. 3) that benefit from freshwater and are drained to the
152 sebkha Oum el Raneb. However, the three lowest salinity values are observed in the wells of
153 Ouargla palm-grove itself, where the Phr aquifer watertable is deeper than 2 m.

154 Conversely, the highest salinity waters are found in wells drilled in the chotts and sebkhas (a
155 sebkha is the central part of a chott where salinity is the largest) (Safioune and Oum er Raneb)
156 where the aquifer is often shallower than 50 cm.

157 The salinity of the Complexe Terminal (Miopliocene) aquifer (Fig. 5b) is much lower than
158 that of the Phr aquifer, and ranges from 1 to 2 g/L; however, its hardness is larger and it contains
159 more sulfate, chloride and sodium than the waters of the Senonian formations and those of the

160 CI aquifer. The salinity of the Senonian aquifer ranges from 1.1 to 1.7 g/L , while the average
161 salinity of the Continental Intercalaire is 0.7 g/L (Fig. 5c).

162 A likely contamination of the Miopliocene aquifer by phreatic groundwaters through casing
163 leakage in an area where water is heavily loaded with salt and therefore particularly aggressive
164 cannot be excluded.

165 3.3. Saturation Indices

166 The calculated saturation indices reveal that waters from CI at 50 °C are close to equilibrium
167 with respect to calcite, except for 3 samples that are slightly oversaturated. They are however all
168 undersaturated with respect to gypsum (Fig. 6).

169 Moreover, they are oversaturated with respect to dolomite and undersaturated with respect to
170 anhydrite and halite (Fig. 7).

171 Waters from CT and phreatic aquifers show the same pattern, but some of them are more
172 largely oversaturated with respect to calcite, at 25 °C.

173 However, several phreatic waters (P031, P566, PLX4, PL18, P002, P023, P116, P066, P162
174 and P036) that are located in the sebkhas of Sefioune, Oum-er-Raneb, Bamendil and Ain el
175 Beida's chott are saturated with gypsum and anhydrite. This is in accordance with high evapora-
176 tive environments found elsewhere (UNESCO, 1972; Hamdi-Aïssa et al., 2004; Slimani, 2006).

177 No significant saturation indices' evolution from the south to the north upstream and down-
178 stream of Oued Mya (Fig. 7) is observed. This suggests that the acquisition of mineralization
179 is due to geochemical processes that have already reached equilibrium or steady state in the
180 upstream areas of Ouargla.

181 3.4. Change of facies from the carbonated pole to the evaporites' pole

182 The facies shifts progressively from the carbonated (CI and CT aquifers) to the evaporites'
183 one (Phr aquifer) with an increase in sulfates and chlorides at the expense of carbonates (SI
184 of gypsum, anhydrite and halite). This is illustrated by a decrease of the following two ratios:
185 $[\text{HCO}_3^-]/([\text{Cl}^-] + 2[\text{SO}_4^{2-}])$ (Fig. 8) from 0.2 to 0 and of the ratio $[\text{SO}_4^{2-}]/[\text{Cl}^-]$ from 0.8 to
186 values ranging from 0.3 and 0 (Fig. 9) while salinity increases. Carbonate concentrations tend
187 towards very small values, while it is not the case for sulfates. This is due to both gypsum
188 dissolution and calcite precipitation.

189 Chlorides in groundwater may come from three different sources: (i) ancient sea water en-
190 trapped in sediments; (ii) dissolution of halite and related minerals that are present in evaporite
191 deposits and (iii) dissolution of dry fallout from the atmosphere, particularly in these arid regions
192 (Matiatos et al., 2014; Hadj-Ammar et al., 2014).

193 For most of the sampled points the $[\text{Na}^+]/[\text{Cl}^-]$ ratio remains close to 1, but significant ranges
194 are observed: from 0.85 to 1.26 for CI aquifer, from 0.40 to 1.02 for the CT aquifer and from 0.13
195 to 2.15 for the Phr aquifer. All the measured points from the three considered aquifers are more
196 or less linearly scattered around the unity slope straight line that stands for halite dissolution
197 (Fig. 10). The latter appears as the most dominant reaction occurring in the medium. However,
198 at very high salinity, Na^+ seems to swerve from the straight line, towards smaller values.

199 A further scrutiny of (Fig. 10) shows that CI waters are very close to the 1:1 line. CT
200 waters are enriched in both Na^+ and Cl^- but slightly lower than the 1:1 line while phreatic waters
201 are largely enriched and much more scattered. CT waters are closer to the seawater mole ratio
202 (0.858), but some lower values imply a contribution from another source of chloride than halite
203 or from entrapped seawater. Conversely, a $[\text{Na}^+]/[\text{Cl}^-]$ ratio larger than 1 is observed for phreatic

204 waters, which implies the contribution of another source of sodium, most likely sodium sulfate,
205 that is present as mirabilite or thenardite in the chotts and the sebkhas areas.

206 $[\text{Br}^-]/[\text{Cl}^-]$ ratio ranges from 2×10^{-3} to 3×10^{-3} . The value of this molar ratio for halite is
207 around 2.5×10^{-3} , which matches the aforementioned range and confirms that halite dissolution
208 is the most dominant reaction taking place in the studied medium.

209 In these aquifers, calcium originates both from carbonate and sulfate (Fig. 11 and 12). Three
210 samples from CI aquifer are close to the $[\text{Ca}^{2+}]/[\text{HCO}_3^-]$ 1:2 line, while calcium sulfate disso-
211 lution explains the excess of calcium. However, a small but significant number of samples (9)
212 from phreatic aquifer are depleted in calcium, and plot under the $[\text{Ca}^{2+}]/[\text{HCO}_3^-]$ 1:2 line. This
213 cannot be explained by precipitation of calcite, as some are undersaturated with respect to that
214 mineral, while others are oversaturated.

215 In this case, a cation exchange process seems to occur leading to a preferential adsorption
216 of divalent cations, with a release of Na^+ . This is confirmed by the inverse modeling that is
217 developed below and which implies Mg^{2+} fixation and Na^+ and K^+ releases.

218 Larger sulfate values observed in the phreatic aquifer (Fig. 12) with $[\text{Ca}^{2+}]/[\text{SO}_4^{2-}] < 1$ can
219 be attributed to a sodium-magnesium sulfate dissolution from a mineral bearing such elements.
220 This is for instance the case of bloedite.

221

222 3.5. Isotope geochemistry

223 CT and CI aquifer exhibit depleted and homogeneous ^{18}O contents, ranging from -8.32‰
224 to -7.85‰ . This was already previously reported by many authors (Edmunds et al., 2003;
225 Guendouz et al., 2003; Moulla et al., 2012). On the other hand, ^{18}O values for the phreatic
226 aquifer are widely dispersed and vary between -8.84‰ to 3.42‰ (Table 6).

227 Waters located north of the Hassi Miloud to Sebkhet Safioune axis are more enriched in
228 heavy isotopes and therefore more evaporated. In that area, water table is close to the surface
229 and mixing of both CI and CT groundwaters with phreatic ones through irrigation is nonexistent.
230 Conversely, waters located south of Hassi Miloud up to Ouargla city show depleted values. This
231 is the clear fingerprint of a contribution to the Phr waters from the underlying CI and CT aquifers
232 (Gonfiantini et al., 1975; Guendouz, 1985; Fontes et al., 1986; Guendouz and Moulla, 1996).

233 Phreatic waters result from a mixing of two end-members. An evidence for this is given
234 by considering the ($[\text{Cl}^-]$, ^{18}O) relationship (Fig. 13). The two poles are: i) a first pole of ^{18}O
235 depleted groundwater (Fig. 14), and ii) another pole of ^{18}O enriched groundwater with positive
236 values and a high salinity. The latter is composed of phreatic waters occurring in the northern
237 part of the study region.

238 Pole I represents the waters from CI and CT whose isotopic composition is depleted in ^{18}O
239 (average value around -8.2‰) (Fig. 13). They correspond to an old water recharge (palæorecharge);
240 whose age estimated by means of ^{14}C , exceeds 15.000 years BP (Guendouz, 1985; Guendouz and
241 Michelot, 2006). So, it is not a water body that is recharged by recent precipitation. It consists of
242 CI and CT groundwaters and partly of phreatic waters, and can be ascribed to an upward leakage
243 favored by the extension of faults near Amguid El-Biod dorsal.

244 Pole II, observed in Sebkhet Safioune, can be ascribed to the direct dissolution of surficial
245 evaporitic deposits conveyed by evaporated rainwater.

246 Evaporation alone cannot explain the distribution of data that is observed (Fig. 13). An
247 evidence for this is given in a semi-logarithmic plot (Fig. 14), as classically obtained according
248 to the simple approximation of Rayleigh equation (cf. Appendix):

$$\delta^{18}\text{O} \approx 1000 \times (1 - \alpha) \log[\text{Cl}^-] + cte, \quad (1)$$

$$\approx -\epsilon \log[\text{Cl}^-] + cte, \quad (2)$$

249 where α is the fractionation factor during evaporation, and $\epsilon \equiv -1000 \times (1 - \alpha)$ is the enrich-
250 ment factor (Ma et al., 2010; Chkir et al., 2009).

251 CI and CT waters are better separated in the semi-logarithmic plot because they are differen-
252 tiated by their chloride content. According to equation (1), simple evaporation gives a straight
253 line (solid line in Fig. 14). The value of ϵ used is the value at 25 °C, which is equal to -73.5 .
254 There is only one sample (P115) on the evaporation straight line, which could be considered as
255 an outlier in Fig. 13 ($[\text{Cl}^-] \approx 0$). All other samples fit on the logarithmic curve derived from the
256 mixing line illustrated by Fig. 13.

257 The phreatic waters that are close to pole I (Fig. 13) correspond to groundwaters occurring in
258 the edges of the basin (Hassi Miloud, piezometer P433) (Fig. 14). They are low-mineralized and
259 acquire their salinity via two processes namely: dissolution of evaporites along their underground
260 transit up to Sebket Safioune and dilution through upward leakage by the less-mineralized wa-
261 ters of CI and CT aquifers (for example Hedeb I for CI and D7F4 for CT) (Fig. 14) (Guendouz,
262 1985; Guendouz and Moulla, 1996).

263 The rates of the mixing that are due to upward leakage from CI to CT towards the phreatic
264 aquifer can be calculated by means of a mass balance equation. It only requires knowing the δ
265 values of each fraction that is involved in the mixing process.

266 The δ value of the mixture is given by:
$$\delta_{\text{mix}} = f_1 \times \delta_1 + f_2 \times \delta_2 \quad (3)$$

267 where f_1 is the fraction of CI aquifer, f_2 the fraction of the CT and δ_1 , δ_2 are the respective
268 isotope contents.

269 Average values of mixing fractions from each aquifer to the phreatic waters computed by
270 means of equation (3) gave the rates of 65 % for CI aquifer and 35% for CT aquifer.

271 A mixture of a phreatic water component that is close to pole I (*i.e.* P433) with another one
272 which is rather close to pole II (*i.e.* P039) (Fig. 13 and 14), for an intermediate water with a $\delta^{18}\text{O}$
273 signature ranging from -5‰ to -2‰ gives mixture fraction values of 52 % for pole I and 48 %
274 for pole II. Isotope results will be used to independently cross-check the validity of the mixing
275 fractions derived from an inverse modeling involving chemical data (*cf. infra*).

276 Turonian evaporites are found to lie in between CI deep aquifer, and the Senonian and
277 Miocene formations bearing CT aquifer. CT waters can thus simply originate from ascend-
278 ing CI waters that dissolve Turonian evaporites, a process which does involve any change in ^{18}O
279 content. Conversely, phreatic waters result to a minor degree from evaporation, and mostly from
280 dissolution of sebkhas evaporites by ^{18}O enriched rainwater and mixing with CI-CT waters.

281 3.5.1. Tritium content of water

282 Tritium contents of Phr aquifer are relatively small (Table 6), they vary between 0 and 8 TU.
283 Piezometers PZ12, P036 and P068 show values close to 8 TU, piezometers P018, P019, P416,
284 P034, P042 and P093 exhibit values ranging between 5 and 6 TU, and the rest of the samples'
285 concentrations are lower than 2 TU.

286 This values are dated back to November 1992 so they are old values. This is the main reason
287 why they are considered high comparatively to what is expected to be found nowadays. In fact,

288 at present times, tritium figures have fallen lower than 5 TU in precipitation measured in the
289 northern part of the country.

290 The comparison of these results with that of precipitation which was 16 TU in 1992 was
291 collected from the National Agency for Water Resources station from Ouargla).

292 This value seems to be high but we can note that we are in an arid area (desert) where precip-
293 itation is very scarce and irregular. Precipitation takes place in the form of sudden thunderstorms
294 in an unsaturated atmosphere and a great part of this precipitation evaporates back into the mois-
295 ture unsaturated atmosphere sometimes during many cycles. Consequently, an enrichment in
296 tritium happens because when water evaporates back, the lightest fractions (isotopes) are the
297 ones that evaporate first causing an enrichment in Tritium in the remaining fraction. The 16 TU
298 value would thus correspond then to a rainy event that had happened during the same sampling
299 period (Nov. 1992). It's the only available value and it is not a weighted mean for a long period
300 of time. It is the most representative value for that region and for that time. Unfortunately, all the
301 other stations (Algiers, Ankara, and Tenerife) (Martinelli et al., 2014) are subject to a completely
302 different climatic regime and besides the fact that they have more recent values, can absolutely
303 not be used for our case. Therefore all the assumptions based on recent tritium rain values do not
304 apply to this study.

305 Depleted contents in ^{18}O and low tritium concentrations for phreatic waters fit well the mix-
306 ing scheme and confirm the contribution from the older and deeper CI/CT groundwaters. The
307 affected areas were clearly identified in the field and correspond to locations that are subject to
308 a recycling and a return of irrigation waters whose origin are CI/CT boreholes. Moreover, the
309 mixing that is clearly brought to light by the Cl^- vs. ^{18}O diagrams (Fig. 13 and 14) could partly
310 derive from an ascending drainage from the deep and confined CI aquifer (exhibiting depleted ho-
311 mogenous ^{18}O contents and very low tritium), a vertical leakage that is favoured by the Amguid
312 El-biod highly faulted area (Guendouz and Moulla, 1996; Edmunds et al., 2003; Guendouz et al.,
313 2003; Moulla et al., 2012).

314 3.6. Inverse modeling

315 We assume that the relationship between ^{18}O and Cl^- data obtained in 1996 is stable with
316 time, which is a logical assumption as times of transfer from CI to both CT and Phr are very long.
317 Considering both ^{18}O and Cl^- data, CI, CT and Phr data populations can be categorized. The CI
318 and CT do not show appreciable ^{18}O variations, and can be considered as a single population.
319 The Phr samples consist however of different populations: Pole I, with $\delta^{18}\text{O}$ values close to -8,
320 and small Cl^- concentrations, more specifically less than 35 mmol L^{-1} ; Pole II, with $\delta^{18}\text{O}$ values
321 larger than 3, and very large Cl^- concentrations, more specifically larger than $4,000 \text{ mmol L}^{-1}$
322 (Table 7); intermediate Phr samples result from mixing between poles I and II (mixing line in
323 Fig. 13, mixing curve in Fig. 14) and from evaporation of pole I (evaporation line in Fig. 14).

324 The mass-balance modeling has shown that relatively few phases are required to derive ob-
325 served changes in water chemistry and to account for the hydrochemical evolution in Ouargla's
326 region. The mineral phases' selection is based upon geological descriptions and analysis of rocks
327 and sediments from the area (OSS, 2003; Hamdi-Aïssa et al., 2004).

328 The inverse model was constrained so that mineral phases from evaporites including gypsum,
329 halite, mirabilite, glauberite, sylvite and bloedite were set to dissolve until they reach saturation,
330 and calcite, dolomite were set to precipitate once they reached saturation. Cation exchange reac-
331 tions of Ca^{2+} , Mg^{2+} , K^+ and Na^+ on exchange sites were included in the model to check which
332 cations are adsorbed or desorbed during the process. Dissolution and desorption contribute as

333 positive terms in the mass balance, as elements are released in solution. On the other hand,
334 precipitation and adsorption contribute as negative terms, while elements removed from the so-
335 lution. $\text{CO}_{2(g)}$ dissolution is considered by Phreeqc as a dissolution of a mineral, whereas $\text{CO}_{2(g)}$
336 degassing is dealt with as if it were a mineral precipitation.

337 Inverse modelling leads to a quantitative assessment of the different solutes' acquisition pro-
338 cesses and a mass balance for the salts that are dissolved or precipitated from CI, CT and Phr
339 groundwaters (Fig. 14, Table 8), as follows:

- 340 • transition from CI to CT involves gypsum, halite and sylvite dissolution, and some ion
341 exchange namely calcium and potassium fixation on exchange sites against magnesium
342 release, with a very small and quite negligible amount of $\text{CO}_{2(g)}$ degassing. The maximum
343 elemental concentration fractional error equals 1%. The model consists of a minimum
344 number of phases (*i.e.* 6 solid phases and $\text{CO}_{2(g)}$); Another model implies as well dolomite
345 precipitation with the same fractional error;
- 346 • transition from CT to an average water component of pole I involves dissolution of halite,
347 sylvite, and bloedite from Turonian evaporites, with a very tiny calcite precipitation. The
348 maximum fractional error in elemental concentration is 4%. Another model implies $\text{CO}_{2(g)}$
349 escape from the solution, with the same fractional error. Large amounts of Mg^{2+} and SO_4^{2-}
350 are released within the solution (Sharif et al., 2008; Li et al., 2010; Carucci et al., 2012);
- 351 • the formation of Phr pole II can be modeled as being a direct dissolution of salts from the
352 sebkha by rainwater with positive $\delta^{18}\text{O}$; the most concentrated water (P036 from Sebkhet
353 Safioune) is taken here for pole II, and pure water as rainwater. In a decreasing order
354 of amounts respectively involved in that process, halite, sylvite, gypsum and huntite dis-
355 solve, and little calcite precipitates while some Mg^{2+} are released versus K^+ fixation on
356 exchange sites. The maximum elemental fractional error in the concentration is equal to
357 0.004%. Another model implies dolomite precipitation with some more huntite dissolv-
358 ing, instead of calcite precipitation, but salt dissolution and ion exchange are the same.
359 Huntite, dolomite and calcite stoichiometries are linearly related, so both models can fit
360 field data, but calcite precipitation is preferred compared to dolomite precipitation at low
361 temperature;
- 362 • the origin of all phreatic waters can be explained by a mixing in variable proportions of
363 pole I and pole II. For instance, waters from pole I and pole II can easily be separated by
364 their $\delta^{18}\text{O}$ respectively close to -8‰ and 3.5‰ (Fig. 13 and 14). Mixing the two poles
365 is of course not an inert reaction, but rather results in the dissolution and the precipitation
366 of minerals. Inverse modeling is then used to compute both mixing rates and the extent
367 of matter exchange between soil and solution. For example, a phreatic water (piezometer
368 P068) with intermediate values ($\delta^{18}\text{O} = -3$ and $[\text{Cl}^-] \approx 2\text{ M}$) is explained by the mixing
369 of 58% water from pole I and 42% from pole II. In addition, calcite precipitates, Mg^{2+}
370 fixes on exchange sites, against Na^+ and K^+ , gypsum dissolves as well as a minor amount
371 of huntite (Table 8). The maximum elemental concentration fractional error is 2.5% and
372 the mixing fractions' weighted the $\delta^{18}\text{O}$ is -3.17‰ , which is very close to the measured
373 value (-3.04‰). All the other models, making use of a minimum number of phases, and
374 not taking into consideration ion exchange reactions are not found compatible with isotope
375 data. Mixing rates obtained with such models are for example 98% of pole I and 0.9% of

376 pole II, which leads to a $\delta^{18}O = (-7.80\text{‰})$ which is quite far for the real measured value
377 (-3.04‰) .

378 The main types of groundwaters occurring in Ouargla basin are thus explained and could
379 quantitatively be reconstructed. An exception is however sample P115, which is located exactly
380 on the evaporation line of Phr pole I. Despite numerous attempts, it could not be quantitatively
381 rebuilt. Its 3H value (6.8) indicates that it is derived from a more or less recent water component
382 with very small salt content, most possibly affected by rainwater and some preferential flow
383 within the piezometer. As this is the only sample on this evaporation line, there remains a doubt
384 on its significance.

385 Globally, the summary of mass transfer reactions occurring in the studied system (Table 8)
386 shows that gypsum dissolution results in calcite precipitation and $CO_{2(g)}$ dissolution, thus acting
387 as an inorganic carbon sink.

388 4. CONCLUSIONS

389 Groundwater hydrochemistry is a good record indicator for the water-rock interactions that
390 occur along the groundwater flowpath. The mineral load reflects well the complex processes
391 taking place while water circulates underground since its point of infiltration.

392 The hydrochemical study of the aquifer system occurring in Ouargla's basin allowed us to
393 identify the origin of its mineralization. Waters exhibit two different facies: sodium chloride and
394 sodium sulfate for the phreatic aquifer (Phr), sodium sulfate for the Complexe Terminal (CT)
395 aquifer and sodium chloride for the Continental Intercalaire (CI) aquifer. Calcium carbonate pre-
396 cipitation and evaporite dissolution explain the facies change from carbonate to sodium chloride
397 or sodium sulfate. However reactions imply many minerals with common ions, deep reactions
398 without evaporation as well as shallow processes affected by both evaporation and mixing. Those
399 processes are separated by considering both chemical and isotopic data, and quantitatively ex-
400 plained making use of an inverse geochemical modeling. The main result is that Phr waters do
401 not originate simply from infiltration of rainwater and dissolution of salts from the sebkhas. Con-
402 versely, Phr waters are largely influenced by the upwardly mobile deep CT and CI groundwaters,
403 fractions of the latter interacting with evaporites from Turonian formations. Phreatic waters oc-
404 currence is explained as a mixing of two end-member components: pole I, which is very close to
405 CI and CT, and pole II, which is highly mineralized and results from the dissolution by rainwater
406 of salts from the sebkhas.

407 At depth, CI leaks upwardly and dissolves gypsum, halite and sylvite, with some ion ex-
408 change, to give waters of CT aquifer composition.

409 CT transformation into Phr pole I waters involves the dissolution of Turonian evaporites
410 (halite, sylvite and bloedite) with minor calcite precipitation.

411 At the surface, direct dissolution by rainwater of salts from sebkhas (halite, sylvite, gypsum
412 and some huntite) with precipitation of calcite and Mg^{2+}/K^+ ion exchange results in pole II Phr
413 composition.

414 All phreatic groundwaters result from a mixing of pole I and pole II water that is accompanied
415 by calcite precipitation, fixation of Mg^{2+} on ion exchange sites against the release of K^+ and Na^+ .

416 Moreover, some $CO_{2(g)}$ escapes from the solution at depth, but dissolves much more at the
417 surface. The most complex phenomena occur during the dissolution of Turonian evaporites while
418 CI leaks upwardly towards CT, and from Phr I to Phr II, while the transition from CT to Phr I

419 implies a very limited number of phases. Globally, gypsum dissolution and calcite precipitation
 420 processes both act as an inorganic carbon sink.

421 **ACKNOWLEDGEMENTS**

422 The authors wish to thank the staff members of the National Agency for Water Resources in
 423 Ouargla (ANRH) and the Laboratory of Algerian waters (ADE) for the support provided to the
 424 Technical Cooperation within which this work was carried out. Analyses of ^{18}O were funded by
 425 the project CDTN / DDHI (Guendouz and Moulla, 1996). The supports of University of Ouargla
 426 and of INRA for travel grants of R. Slimani and G. Bourrié are gratefully acknowledged too.

427 **APPENDIX**

428 According to a simple Rayleigh equation, the evolution of the heavy isotope ratio in the
 429 remaining liquid R_l is given by:

$$R_l \approx R_{l,0} \times f_l^{\alpha-1}, \quad (4)$$

430 where f_l is the fraction remaining liquid and α the fractionation factor.

431 The fraction remaining liquid is derived from chloride concentration, as chloride can be con-
 432 sidered as conservative during evaporation: all phreatic waters are undersaturated with respect to
 433 halite, that precipitates only in the last stage. Hence, the following equation holds:

$$f_l \equiv \frac{n_{w,1}}{n_{w,0}} = \frac{[\text{Cl}^-]_0}{[\text{Cl}^-]_1}. \quad (5)$$

434 By taking natural logarithms, one obtains:

$$\ln R_l \approx (1 - \alpha) \times \ln[\text{Cl}^-] + cte, \quad (6)$$

435 As, by definition,

$$R_l \equiv R_{std.} \times \left(1 + \frac{\delta^{18}\text{O}}{1000}\right), \quad (7)$$

436 one has:

$$\ln R_l \equiv \ln R_{std.} + \ln\left(1 + \frac{\delta^{18}\text{O}}{1000}\right), \quad (8)$$

$$\approx \ln R_{std.} + \frac{\delta^{18}\text{O}}{1000}, \quad (9)$$

437 hence, with base 10 logarithms:

$$\delta^{18}\text{O} \approx 1000(1 - \alpha) \log[\text{Cl}^-] + cte, \quad (10)$$

$$\approx -\epsilon \log[\text{Cl}^-] + cte, \quad (11)$$

438 where as classically defined $\epsilon = 100(\alpha - 1)$ is the enrichment factor.

Table 8: Summary of mass transfer for geochemical inverse modeling. Phases and thermodynamic database are from Phreeqc 3.0 (Parkhurst and Appelo, 2013).

Phases	Stoichiometry	CI/CT	CT/Phr I	Rainwater/P036	PhrI/PhrII 60%/40%
Calcite	CaCO ₃	—	-6.62×10^{-6}	-1.88×10^{-1}	-2.26×10^{-1}
CO ₂ (g)	CO ₂	-6.88×10^{-5}	—	8.42×10^{-4}	5.77×10^{-4}
Gypsum	CaSO ₄ · 2 H ₂ O	4.33×10^{-3}	—	1.55×10^{-1}	1.67×10^{-1}
Halite	NaCl	7.05×10^{-3}	3.76×10^{-3}	6.72	1.28
Sylvite	KCl	2.18×10^{-3}	1.08×10^{-3}	4.02×10^{-1}	—
Bloedite	Na ₂ Mg(SO ₄) ₂ · 4 H ₂ O	—	1.44×10^{-3}	—	—
Huntite	CaMg ₃ (CO ₃) ₄	—	—	4.74×10^{-2}	5.65×10^{-2}
Ca ion exchange	CaX ₂	-1.11×10^{-3}	—	—	—
Mg ion exchange	MgX ₂	1.96×10^{-3}	—	1.75×10^{-1}	-2.02×10^{-1}
Na ion exchange	NaX	—	—	—	3.92×10^{-1}
K ion exchange	KX	-1.69×10^{-3}	—	-3.49×10^{-1}	1.20×10^{-2}

Values are in mol/kg (H₂O). Positive (mass entering solution) and negative (mass leaving solution) phase mole transfers indicate dissolution and precipitation, respectively; — indicates no mass transfer.

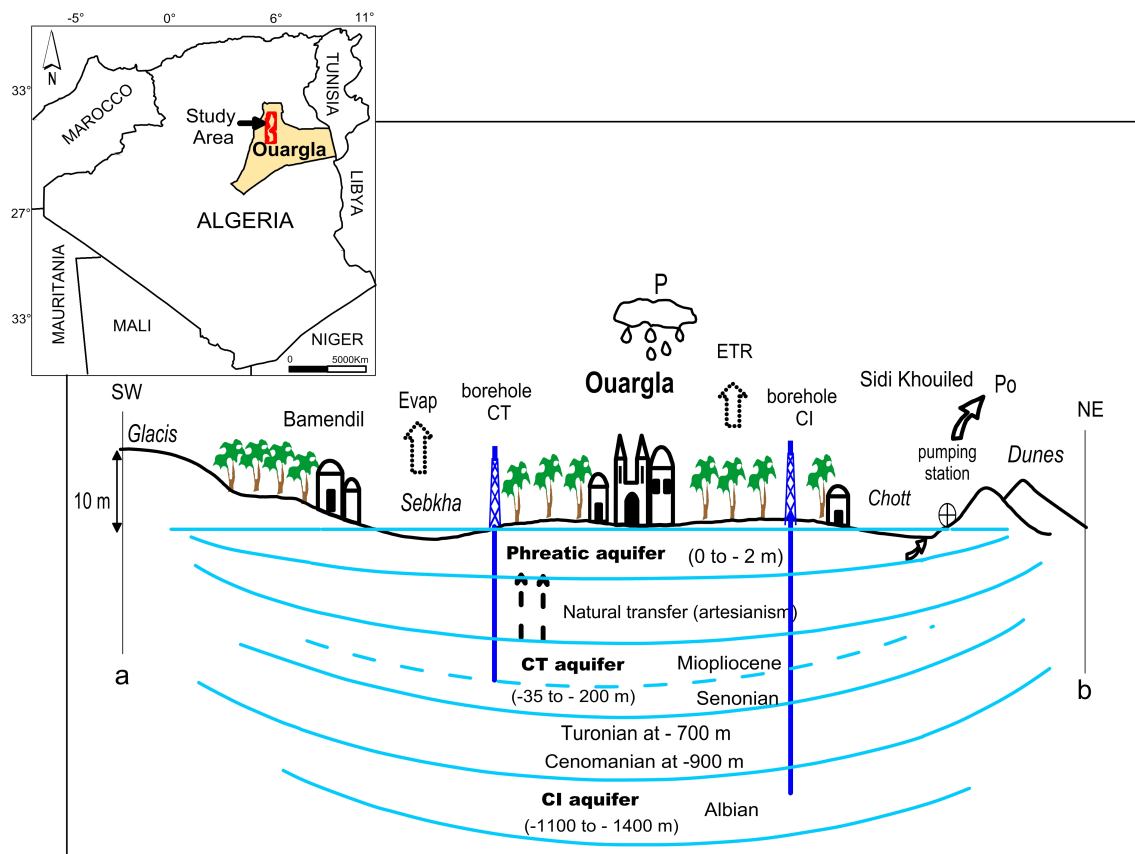

Figure 1: Localisation and schematic relations of aquifers in Ouargla. *Blue lines represent limits between aquifers, and the names of aquifers are given in bold letters; as the limit between Senonian and Miopliocene aquifers is not well defined, a dashed blue line is used. Names of villages and cities are given in roman (Bamendil, Ouargla, Sidi Khouiled), while geological/geomorphological features are in italic (Glacis, Sebkh, Chott, Dunes). Depths are relative to the ground surface. Letters a and b refer to the cross section (fig. 2) and to the localisation map (fig. 3).*

Figure 2: Geologic cross section in the region of Ouargla.
The blue pattern used for Chott and Sebkha correspond to the limit of the saturated zone.

Figure 3: Localisation map of sampling point

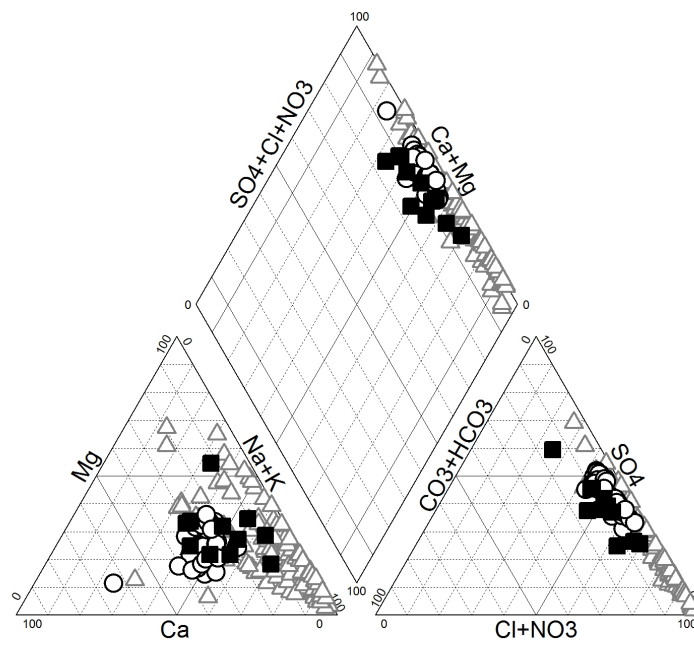

Figure 4: Piper diagram for Continental Intercalaire (filled squares), Complexe Terminal (open circles) and Phreatic aquifer (open triangles).

5

Figure 5: Contour maps of the salinity (expressed as global mineralization) in the aquifer system, (a) Phreatic aquifer; (b) and (c) Complexe Terminal [(b) Miopliocene and (c) Senonian]; figures are isovalues of global mineralization (values in g/L).

Figure 6: Equilibrium diagrams of calcite (top) and gypsum (bottom) for Continental Intercalaire (filled squares), Complexe Terminal (open circles) and Phreatic aquifer (open triangles). Equilibrium lines are defined as: $\log[\text{Ca}^{2+}] + \log[\text{CO}_3^{2-}] = \log K_{sp}$ for calcite, and $\log[\text{Ca}^{2+}] + 2 \log[\text{H}_2\text{O}] + \log[\text{SO}_4^{2-}] = \log K_{sp}$ for gypsum.

Figure 7: Variation of saturation indices with distance from south to north in the region of Ouargla.

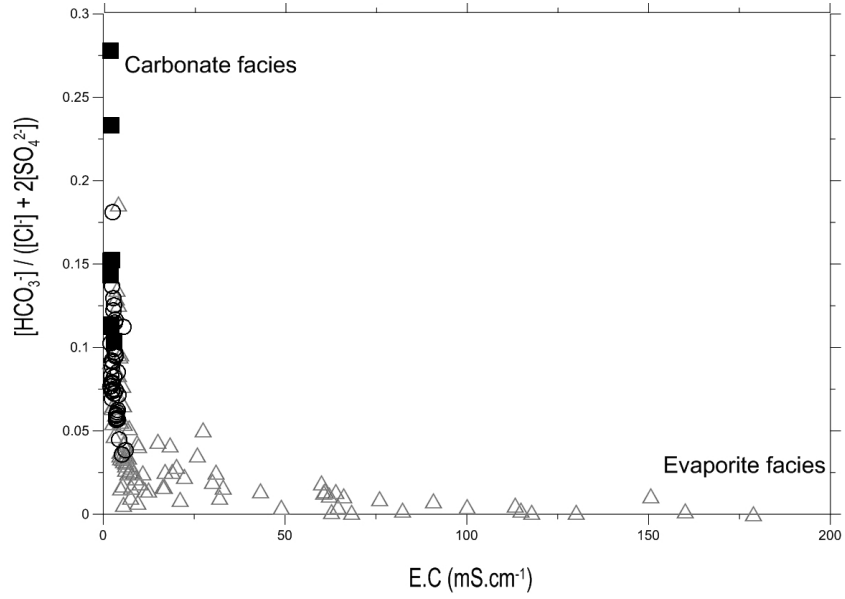

Figure 8: Change from carbonate facies to evaporite from Continental Intercalaire (filled squares), Complexe Terminal (open circles) and Phreatic aquifer (open triangles).

Figure 9: Change from sulfate facies to chloride from Continental Intercalaire (filled squares), Complexe Terminal (open circles) and Phreatic aquifer (open triangles).

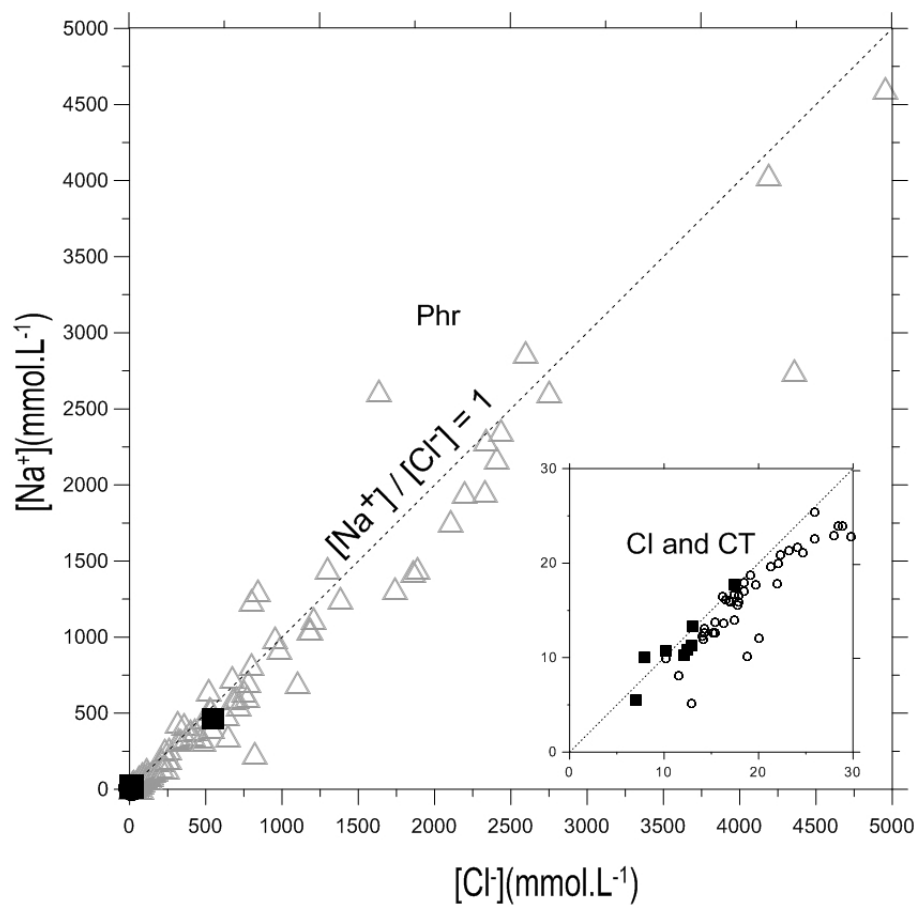

Figure 10: Correlation between Na^+ and Cl^- concentrations in Continental Intercalaire (filled squares), Complex Terminal (open circles) and Phreatic aquifer (open triangles). Seawater composition (star) is $[\text{Na}^+] = 459.3 \text{ mmol L}^{-1}$ and $[\text{Cl}^-] = 535.3 \text{ mmol L}^{-1}$ (Stumm and Morgan, 1999, p.899).

Figure 11: Calcium vs. HCO_3^- diagram in Continental Intercalaire (filled squares), Complexe Terminal (open circles), Phreatic aquifer (open triangles) and Seawater composition (star) is $[Ca^{2+}] = 10.2 \text{ mmol.L}^{-1}$ and $[HCO_3^-] = 2.38 \text{ mmol.L}^{-1}$ (Stumm and Morgan, 1999, p.899).

Figure 12: Calcium vs. SO_4^{2-} diagram in Continental Intercalaire (filled squares), Complexe Terminal (open circles), Phreatic aquifer (open triangles) and Seawater composition (star) is $[\text{Ca}^{2+}] = 10.2 \text{ mmol L}^{-1}$ and $[\text{SO}_4^{2-}] = 28.2 \text{ mmol L}^{-1}$ (Stumm and Morgan, 1999, p.899).

Figure 13: Chloride concentration versus $\delta^{18}\text{O}$ in Continental Intercalaire (filled squares), Complexe Terminal (open circles) and Phreatic aquifer (open triangles) from Ouargla.

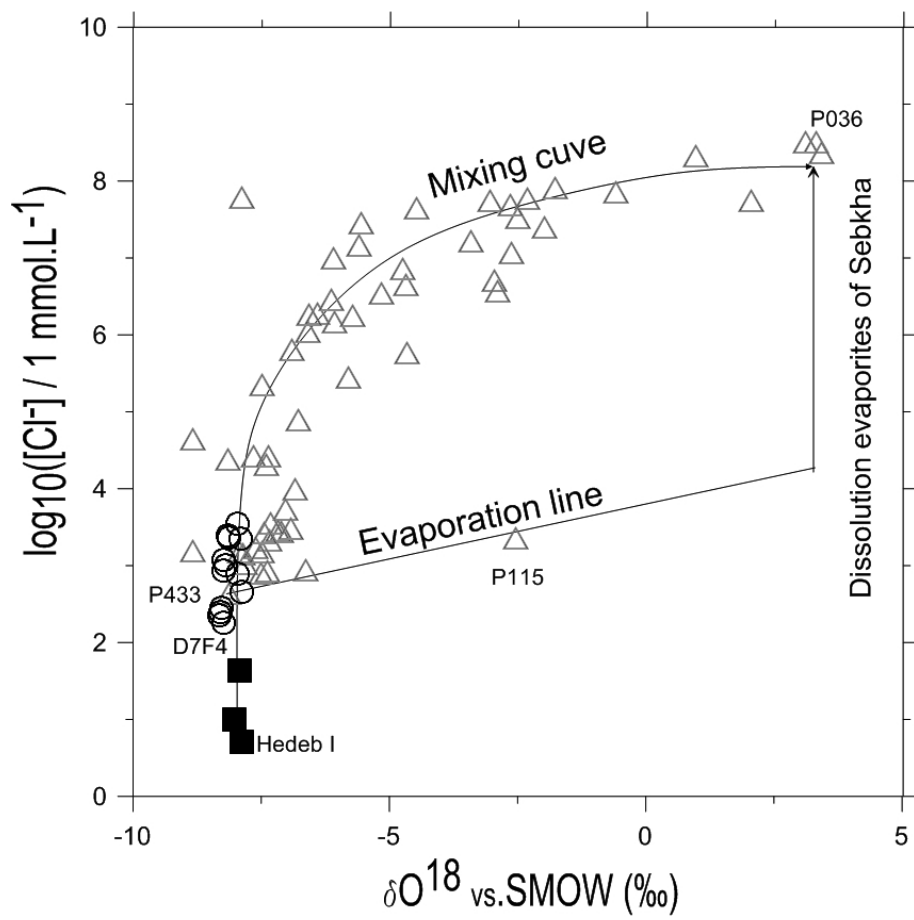

Figure 14: Log $[\text{Cl}^-]$ concentration versus $\delta^{18}\text{O}$ in Continental Intercalaire (filled squares), Complexe Terminal (open circles) and Phreatic aquifer (open triangles) from Ouargla.
