## 10 **Abstract**

11 Observations of climate are often available on very different spatial scales from observations  
12 of the natural environments and resources that are affected by climate change. In order to help  
13 bridge the gap between these scales using modelling, a new dataset of daily meteorological  
14 variables was created at 1 km resolution over Great Britain for the years 1961-2012, by  
15 interpolating coarser resolution climate data and including the effect of local topography. These  
16 variables were used to calculate atmospheric evaporative demand (AED) at the same spatial  
17 and temporal resolution. Two functions that represent AED were chosen: one is a standard form  
18 of Potential Evapotranspiration (PET) and the other is a derivative of it used by hydrologists  
19 that includes the effect of water intercepted by the canopy (PETI). Temporal trends in these  
20 functions were calculated, with PET found to be increasing in all regions, and at an overall rate  
21 of  $0.021 \pm 0.021 \text{ mm d}^{-1} \text{ decade}^{-1}$  in Great Britain, while PETI was found to be increasing at a  
22 rate  $0.023 \pm 0.023 \text{ mm d}^{-1} \text{ decade}^{-1}$  in England ( $0.028 \pm 0.025 \text{ mm d}^{-1} \text{ decade}^{-1}$  in the English  
23 Lowlands), but not increasing at a statistically significant rate in Scotland or Wales. The trends  
24 were found to vary by season, with spring PET increasing by  $0.043 \pm 0.019 \text{ mm d}^{-1} \text{ decade}^{-1}$   
25 ( $0.038 \pm 0.018 \text{ mm d}^{-1} \text{ decade}^{-1}$  when the interception correction is included) in Great Britain,  
26 while there is no statistically significant trend in other seasons. The trends were attributed  
27 analytically to trends in the climate variables; the overall positive trend was predominantly  
28 driven by rising air temperature, although rising specific humidity had a negative effect on the  
29 trend. Increasing downward short- and longwave radiation made an overall positive  
30 contribution to the PET trend, while the 10 m wind speed had a negative effect. The trend in  
31 spring PET was particularly strong due to a strong increase in spring downward shortwave  
32 radiation.  
33

## 34 **1 Introduction**

35 There are many studies showing the ways in which our living environment is changing over  
36 time: changing global temperatures (IPCC, 2013), radiation (Wild, 2009) and wind speeds  
37 (McVicar et al., 2012) can have significant impacts on ecosystems and human life (IPCC,  
38 2014a). While there are overall global trends, the impacts can vary between regions (IPCC,  
39 2014b). In the UK, wildlife surveys of both flora (Wood et al., 2015; Evans et al., 2008) and  
40 fauna (Pocock et al., 2015) show a shift in patterns and timing (Thackeray et al., 2010). In  
41 addition, the UK natural resources of freshwater (Watts et al., 2015), soils (Reynolds et al.,  
42 2013; Bellamy et al., 2005) and vegetation (Berry et al., 2002; Hickling et al., 2006; Norton et  
43 al., 2012) are changing. The UK is experiencing new environmental stresses on the land and  
44 water systems through changes in temperature and river flows (Crooks and Kay, 2015; Watts  
45 et al., 2015; Hannaford, 2015), which is part of a widespread global pattern of temperature  
46 increase and circulation changes (Watts et al., 2015).

47 To explain these changes in terms of climate drivers, there are several gridded meteorological  
48 datasets available at global and regional scales. Global datasets can be based on observations –  
49 for example the 0.5° resolution Climate Research Unit time series 3.21 (CRU TS 3.21) data  
50 (Jones and Harris, 2013; Harris et al., 2014) – while some are based on global meteorological  
51 reanalyses bias-corrected to observations – for example the WATCH Forcing Data (WFD, 0.5°;  
52 Weedon et al. (2011)), the WATCH Forcing Data methodology applied to ERA-Interim  
53 reanalysis product (WFDEI, 0.5°; Weedon et al. (2014)) and the Princeton Global  
54 Meteorological Forcing Dataset (1°; Sheffield et al. (2006)). At the regional scale in Great  
55 Britain (GB), there are datasets that are derived directly from observations – for example the  
56 Met Office Rainfall and Evaporation Calculation System (MORECS) dataset at 40 km  
57 resolution (Thompson et al., 1981; Hough and Jones, 1997) and the UKCP09 observed climate  
58 data at 5 km resolution (Jenkins et al., 2008).

59 However, while regional observations of carbon, methane and water emissions from the land  
60 (Baldocchi et al., 1996), the vegetation cover (Morton et al., 2011) and soil properties  
61 (FAO/IIASA/ISRIC/ISS-CAS/JRC, 2012) are typically made at the finer landscape scale of  
62 100 m to 1000 m, most of these long-term gridded meteorological datasets are only available  
63 at a relatively coarse resolution of a few tens of km. These spatial scales may not be  
64 representative of the climate experienced by the flora and fauna being studied, and it has also  
65 been shown that input resolution can have a strong effect on the performance of hydrological

66 models (Kay et al., 2015). In addition, the coarse temporal resolution of some datasets, for  
67 example the monthly CRU TS 3.21 data (Harris et al., 2014; Jones and Harris, 2013), can miss  
68 important sub-monthly extremes.

69 Regional studies are important to identify drivers and impacts of changing meteorology that  
70 may or may not be reflected in trends in global means. For example, in Canada (Vincent et al.,  
71 2015) and Europe (Fleig et al., 2015), high resolution meteorological data have been used to  
72 identify the impacts of changing circulation patterns, while in Australia wind speed data have  
73 been used to quantify the effects of global stilling in the region (McVicar et al., 2008). While  
74 there are datasets available at finer spatial and temporal resolutions for the UK (such as  
75 UKCP09 (Jenkins et al., 2008)), these often do not provide all the variables needed to identify  
76 the impacts of changing climate.

77 To address this, we have created a meteorological dataset for Great Britain at 1 km resolution  
78 (Robinson et al., 2015a). It is derived from the observation-based MORECS dataset (Thompson  
79 et al., 1981; Hough and Jones, 1997), and then downscaled using information about topography.  
80 This is augmented by an independent precipitation dataset – Gridded Estimates of daily and  
81 monthly Areal Rainfall for the United Kingdom (CEH-GEAR; Tanguy et al. (2014); Keller et  
82 al. (2015)) – along with variables from two global datasets – WFD and CRU TS 3.21 – to  
83 produce a comprehensive, observation-based, daily meteorological dataset at 1 km × 1 km  
84 spatial resolution.

85 In order to understand the effect of meteorology on the water cycle, a key variable in  
86 hydrological modelling is the atmospheric evaporative demand (AED), which is determined by  
87 meteorological variables (Kay et al., 2013). It has been shown that water-resource and  
88 hydrological model results are largely driven by how this property is defined and used  
89 (Haddeland et al., 2011). The AED can be expressed in several ways, for instance the  
90 evaporation from a wet surface, from a well-watered but dry uniform vegetated cover, or from  
91 a hypothetical well-watered but dry version of the actual vegetation. Metrics such as the Palmer  
92 Drought Severity Index (PDSI; Palmer (1965)) use potential evapotranspiration (PET) as an  
93 input while many hydrological models such as Climate and Land use Scenario Simulation in  
94 Catchments (CLASSIC; Crooks and Naden (2007)) or Grid-to-Grid (G2G; Bell et al. (2009)),  
95 use as input a distinct form of the PET which includes the intercepted water from rainfall (this  
96 is described later in the text) which we hereby name PETI. While hydrological models can  
97 make use of high resolution topographic information and precipitation datasets, they are often

98 driven with PET calculated at a coarser resolution (Bell et al., 2011; Bell et al., 2012; Kay et  
99 al., 2015). Therefore, we have also created a dataset consisting of estimates of PET and PETI,  
100 which can be used to run high-resolution hydrological models (Robinson et al., 2015b).

101 Other regional studies have created gridded estimates of AED in Austria (Haslinger and  
102 Bartsch, 2016) and Australia (Donohue et al., 2010). Regional studies of trends in AED have  
103 seen varied results, with increasing AED seen in Romania (Paltineanu et al., 2012), Serbia  
104 (Gocic and Trajkovic, 2013), Spain (Vicente-Serrano et al., 2014), some regions of China (Li  
105 and Zhou, 2014) and Iran (Azizzadeh and Javan, 2015; Hosseinzadeh Talaei et al., 2013; Tabari  
106 et al., 2012), decreasing AED in north east India (Jhajharia et al., 2012) and regions in China  
107 (Yin et al., 2009; Song, 2010; Shan et al., 2015; Zhao et al., 2015; Zhang et al., 2015; Lu et al.,  
108 2016) and regional variability in Australia (Donohue et al., 2010) and China (Li et al., 2015).  
109 In order to understand this variability, it is important to quantify the relative contributions of  
110 the changing meteorological variables to trends in AED and regional studies often find different  
111 drivers of changing AED (see McVicar et al. (2012) for a review). Relative humidity has been  
112 shown to drive AED in the Canary Islands (Vicente-Serrano et al., 2016), wind speed and air  
113 temperature were shown to have nearly equal but opposite effects in Australia (Donohue et al.,  
114 2010), while in China sunshine hours (Li et al., 2015), wind speed (Yin et al., 2009) or a  
115 combination of the two (Lu et al., 2016) have been shown to drive trends. Rudd and Kay (2015)  
116 investigated projected changes in PET using a regional climate model, but little has been done  
117 to investigate historical trends of AED in the UK.

118 The objectives of this paper are (i) to evaluate the trends in key meteorological variables in  
119 Great Britain over the years 1961-2012; (ii) to evaluate the AED in Great Britain over the same  
120 time period; (iii) to investigate the effect of including interception in the formulation of PET  
121 called PETI; (iv) to evaluate trends in PET over the time period of interest; and (v) to attribute  
122 the trends in PET to trends in meteorological variables. To address these objectives, the paper  
123 is structured as follows. Section 2 presents the calculation of the meteorological variables.  
124 Section 3 presents the calculation of PET and PETI from the meteorological variables and  
125 assesses the difference between PET and PETI. In Section 4 the trends in annual means of the  
126 meteorological variables and AED are calculated and the trends in PET are attributed to trends  
127 in meteorological variables. In Section 5 the results are discussed and conclusions are presented  
128 in Section 6.

## 129 **2 Calculation of meteorological variables**

130 The meteorological variables included in this new dataset (Robinson et al., 2015a) are daily  
131 mean values of air temperature, specific humidity, wind speed, downward longwave (LW) and  
132 shortwave (SW) radiation, precipitation and air pressure, plus daily temperature range (Table  
133 1). These variables are important drivers of near-surface conditions, and, for instance, are the  
134 full set of variables required to drive the JULES land surface model (LSM) (Best et al., 2011;  
135 Clark et al., 2011), as well as other LSMs.

136 The data were derived primarily from MORECS, which is a long-term gridded dataset starting  
137 in 1961 and updated to the present (Thompson et al., 1981; Hough and Jones, 1997). It  
138 interpolates five variables from synoptic stations (daily mean values of air temperature, vapour  
139 pressure and wind speed, daily hours of bright sunshine and daily total precipitation) to a 40  
140 km × 40 km resolution grid aligned with the Ordnance Survey National Grid. There are  
141 currently 270 stations reporting in real time, while a further 170 report the daily readings on a  
142 monthly basis, but numbers have varied throughout the run. The algorithm interpolates a  
143 varying number of stations (up to nine) for each square, depending on data availability (Hough  
144 and Jones, 1997). The interpolation is such that the value in each grid square is the effective  
145 measurement of a station positioned at the centre of the square and at the grid square mean  
146 elevation, averaged from 00:00 GMT to 00:00 GMT the next day. MORECS is a consistent,  
147 quality-controlled time series, which accounts for changing station coverage. The MORECS  
148 variables were used to derive the air temperature, specific humidity, wind speed, downward  
149 LW and SW radiation and air pressure in the new dataset. The WFD and CRU TS 3.21 datasets  
150 were used for surface air pressure and daily temperature range respectively, as they could not  
151 be calculated from MORECS. Additionally precipitation was obtained from the CEH-GEAR  
152 data, which is a product directly interpolated to 1 km from the station data (Keller et al., 2015).

153 The spatial coverage of the dataset was determined by the spatial coverage of MORECS, which  
154 covers the majority of Great Britain, but excludes some coastal regions and islands at the 1 km  
155 scale. For most of these points, the interpolation was extended from the nearest MORECS  
156 squares, but some outlying islands (in particular Shetland and the Scilly Isles) were excluded  
157 when the entire island was further than 40 km from the nearest MORECS square.

## 158 **2.1 Air temperature**

159 Air temperature,  $T_a$  (K), was derived from the MORECS air temperature. The MORECS air  
160 temperature was reduced to mean sea level, using a lapse rate of  $-0.006 \text{ K m}^{-1}$  (Hough and  
161 Jones, 1997). A bicubic spline was used to interpolate from 40 km resolution to 1 km resolution,  
162 then the temperatures were adjusted to the elevation of each 1 km square using the same lapse  
163 rate. The 1 km resolution elevation data used were aggregated from the Integrated Hydrological  
164 Digital Terrain Model (IHDTM) – a 50 m resolution digital terrain model (Morris and Flavin,  
165 1990).

## 166 **2.2 Specific humidity**

167 Specific humidity,  $q_a$  ( $\text{kg kg}^{-1}$ ), was derived from the MORECS vapour pressure, which was  
168 first reduced to mean sea level, using a lapse rate of  $-0.025 \% \text{ m}^{-1}$  (Thompson et al., 1981). The  
169 actual lapse rate of humidity will, in general, vary according to atmospheric conditions.  
170 However, calculating this would require more detailed information than is available in the input  
171 data used. Any method of calculating the variation of specific humidity with height will involve  
172 several assumptions, but the method used here is well-established and is used by the Met Office  
173 in calculating MORECS (Thompson et al., 1981). The value of the vapour pressure lapse rate  
174 is chosen to keep relative humidity constant with altitude, rather than assuming that the specific  
175 humidity itself is constant.

176 A bicubic spline was used to interpolate vapour pressure to 1 km resolution then the values  
177 were adjusted to the 1 km resolution elevation using the IHDTM elevations. Finally the specific  
178 humidity was calculated, using

$$179 \quad q_a = \frac{\epsilon e}{p_* - (1 - \epsilon)e}, \quad (1)$$

180 where  $e$  is the vapour pressure (Pa) and  $\epsilon = 0.622$  is the mass ratio of water to dry air (Gill,  
181 1982). The air pressure,  $p_*$ , in this calculation was assumed to have a constant value of 100000  
182 Pa because this was prescribed in the computer code. It would be better to use a varying air  
183 pressure, as calculated in Section 2.8, but this makes a negligible difference (of a few percent)  
184 to the calculated specific humidity and a constant  $p_*$  was retained.

### 185 **2.3 Downward shortwave radiation**

186 Downward SW radiation,  $S_d$  ( $\text{W m}^{-2}$ ), was derived from the MORECS hours of bright sunshine  
187 (defined as the total number of hours in a day for which solar irradiation exceeds  $120 \text{ W m}^{-2}$   
188 (WMO, 2013)). The value calculated is the mean SW radiation over 24 hours. The sunshine  
189 hours were used to calculate the cloud cover factor,  $C_f = n/N$ , where  $n$  is the number of hours  
190 of bright sunshine in a day, and  $N$  is the total number of hours between sunrise and sunset  
191 (Marthews et al., 2011). The cloud cover factor was interpolated to 1 km resolution using a  
192 bicubic spline. The downward SW solar radiation for a horizontal plane at the Earth's surface  
193 was then calculated using the solar angle equations of Iqbal (1983) and a form of the Angstrom-  
194 Prescott equation which relates hours of bright sunshine to solar irradiance (Ångström, 1918;  
195 Prescott, 1940), with empirical coefficients calculated by Cowley (1978). They vary spatially  
196 and seasonally and effectively account for reduction of irradiance with increasing solar zenith  
197 angle, as well as implicitly accounting for spatially- and seasonally-varying aerosol effects.  
198 However, they do not vary interannually and thus do not explicitly include long-term trends in  
199 aerosol concentration.

200 The downward SW radiation was then corrected for the average inclination and aspect of the  
201 surface, assuming that only the direct beam radiation is a function of the inclination and that  
202 the diffuse radiation is homogeneous. It was also assumed that the cloud cover is the dominant  
203 factor in determining the diffuse fraction (Muneer and Munawwar, 2006). The aspect and  
204 inclination were calculated using the IHDTM elevation at 50 m resolution, following the  
205 method of Horn (1981), and were then aggregated to 1 km resolution. The top of atmosphere  
206 flux for horizontal and inclined surfaces was calculated following Allen et al. (2006) and the  
207 ratio used to scale the direct beam radiation.

### 208 **2.4 Downward longwave radiation**

209 Downward LW radiation,  $L_d$  ( $\text{W m}^{-2}$ ), was derived from the 1 km resolution air temperature  
210 (Sect. 2.1), vapour pressure (Sect. 2.2) and cloud cover factor (Sect. 2.3). The downward LW  
211 radiation for clear sky conditions was calculated as a function of air temperature and  
212 precipitable water using the method of Dilley and O'Brien (1998), with precipitable water  
213 calculated from air temperature and humidity following Prata (1996). The additional  
214 component due to cloud cover was calculated using the equations of Kimball et al. (1982),  
215 assuming a constant cloud base height of 1000 m.

## 216 **2.5 Wind speed**

217 The wind speed at a height of 10 m,  $u_{10}$  ( $\text{m s}^{-1}$ ), was derived from the MORECS 10 m wind  
218 speed, which were interpolated to 1 km resolution using a bicubic spline and adjusted for  
219 topography using a 1 km resolution dataset of mean wind speeds produced by the UK Energy  
220 Technology Support Unit (ETSU) (Newton and Burch, 1985; Burch and Ravenscroft, 1992).  
221 This used Numerical Objective Analysis Boundary Layer (NOABL) methodology and station  
222 wind measurements over the period 1975-84 to produce a map of mean wind speed over the  
223 UK. To calculate the topographic correction, the ETSU wind speed was aggregated to 40 km  
224 resolution, then the difference between each 1 km value and the corresponding 40 km mean  
225 found. This difference was added to the interpolated daily wind speed. In cases where this  
226 would result in a negative wind speed, the wind speed was set to zero.

## 227 **2.6 Precipitation**

228 Precipitation rate,  $P$  ( $\text{kg m}^{-2} \text{s}^{-1}$ ), is taken from the daily CEH-GEAR dataset (Tanguy et al.,  
229 2014; Keller et al., 2015), scaled to the appropriate units. The CEH-GEAR methodology uses  
230 natural neighbour interpolation (Gold, 1989) to interpolate synoptic station data to a 1 km  
231 resolution gridded daily dataset of the estimated precipitation in 24 hours between 09:00 GMT  
232 and 09:00 GMT the next day.

## 233 **2.7 Daily temperature range**

234 Daily temperature range (DTR),  $D_T$  (K), was obtained from the CRU TS 3.21 monthly mean  
235 daily temperature range estimates on a  $0.5^\circ$  latitude  $\times$   $0.5^\circ$  longitude grid, which is interpolated  
236 from monthly climate observations (Harris et al., 2014; Jones and Harris, 2013). There is no  
237 standard way to correct DTR for elevation, so these data were reprojected to the 1 km grid with  
238 no interpolation and the monthly mean used to populate the daily values in each month.  
239 Although DTR is not required in the calculation of AED, it is a required input of the JULES  
240 LSM, in order to run at sub-daily timestep.

## 241 **2.8 Surface air pressure**

242 Surface air pressure,  $p^*$  (Pa), was derived from the WFD, an observation-corrected reanalysis  
243 product, which provides 3 hourly meteorological data for 1958-2001 on a  $0.5^\circ$  latitude  $\times$   $0.5^\circ$   
244 longitude resolution grid (Weedon et al., 2011). Mean monthly values of WFD surface air

245 pressure and air temperature were calculated for each 0.5° grid box over the years 1961-2001.  
246 These were reprojected to the 1 km grid with no interpolation, then the lapse rate of air  
247 temperature (Sect. 2.1) used to calculate the integral of the hypsometric equation, in order to  
248 obtain the air pressure at the elevation of each 1 km grid (Shuttleworth, 2012). The mean  
249 monthly values were used to populate the daily values in the full dataset, thus the surface air  
250 pressure in the new dataset does not vary interannually, but does vary seasonally. This is  
251 reasonable as the trend in surface air pressure in the WFD is negligible (Weedon et al., 2011).

## 252 **2.9 Spatial and seasonal patterns of meteorological variables**

253 Long-term mean values of the meteorological variables were calculated for each 1 km square  
254 over the whole dataset (1961-2012) (Fig. 1). Four sub-regions of interest were defined (Fig. 2);  
255 three of these regions correspond to nations (England, Wales and Scotland), while the fourth is  
256 the ‘English lowlands’, a subset of England, covering south-central and south-east England,  
257 East Anglia and the East Midlands (Folland et al., 2015). Mean-monthly climatologies (Fig. 3)  
258 were calculated over the whole of Great Britain (GB), and over these four regions of interest.

259 The maps clearly show the effect of topography on the variables (Fig. 1), with an inverse  
260 correlation between elevation and temperature, specific humidity, downward LW radiation and  
261 surface air pressure and a positive correlation with wind speed. The precipitation has an east-  
262 west gradient due to prevailing weather systems and orography. The fine-scale structure of the  
263 downward SW radiation is due to the aspect and elevation of each grid cell, with more spatial  
264 variability in areas with more varying terrain. As no topographic correction has been applied to  
265 DTR, it varies only on a larger spatial scale. Although specific humidity is inversely  
266 proportional to elevation, relative humidity is not, as the saturated specific humidity will also  
267 be inversely proportional to elevation due to the decrease in temperature with height.

268 The mean-monthly climatologies (Fig. 3) demonstrate the differences between the regions, with  
269 Scotland generally having lower temperatures and more precipitation than the average, and  
270 England (particularly the English lowlands) being warmer and drier.

## 271 **2.10 Validation of meteorology**

272 The precipitation dataset, CEH-GEAR, has previously been validated against observations  
273 (Keller et al., 2015). Other studies discuss the uncertainties in the CRU TS 3.21 daily  
274 temperature range data (Harris et al., 2014) and WFDEI air pressure data (Weedon et al., 2014).

275 For the other variables, the MORECS data set is ultimately derived from the synoptic stations  
276 around the UK which represent most of the available observed meteorological data. The only  
277 way to validate the gridded meteorology presented here is to compare it to independently  
278 observed data, which are available at a few sites where meteorological measurement stations  
279 are located. Here we carry out a validation exercise with data from four sites from the UK,  
280 which have meteorological measurements available for between 5 and 10 years. Details of the  
281 sites and data are in Appendix A. Fig. 4 shows the comparison of data set air temperature with  
282 the observed air temperature at each of the four sites. This shows a strong correlation ( $r^2$   
283 between 0.94 and 0.97) between the data set and the observations. Fig. 5 shows the mean-  
284 monthly climatology calculated from both the data set and from the observations (only for times  
285 for which observations were available) and demonstrates that the data set successfully captures  
286 the seasonal cycle. This has been repeated for downward SW radiation and for an estimate of  
287 the mixing ratio of water vapour, 10 m wind speed and surface air pressure (Appendix A). The  
288 air temperature, downward SW radiation and mixing ratio all have high correlations and  
289 represent the seasonal cycle well. The wind speed is overestimated by the derived data set at  
290 two sites, which is likely to be due to land cover effects. The modelling which produced the  
291 ETSU dataset uses topography but not land cover (Burch and Ravenscroft, 1992; Newton and  
292 Burch, 1985), so at sites with tall vegetation the wind speed is likely to be less than the modelled  
293 value. The air pressure has a low correlation because the data set contains a mean-monthly  
294 climatological value. However, the mean bias is low and the RMSE is small, confirming that it  
295 is reasonable to use a climatological value in place of daily data.

### 296 **3 Calculation of potential evapotranspiration (PET)**

297 There are several ways to assess the evaporative demand of the atmosphere. Pan evaporation  
298 can be modelled using the Pen-Pan model, or open-water evaporation can be modelled with the  
299 Penman equation. However, neither of these account for the fact that in general the evaporation  
300 is occurring from a vegetated surface. A widely used model is the Penman-Monteith PET,  $E_P$   
301 ( $\text{mm d}^{-1}$ , equivalent to  $\text{kg m}^{-2} \text{d}^{-1}$ ), which is a physically-based formulation of the AED of the  
302 atmosphere (Monteith, 1965). It provides an estimate of AED dependent on the atmospheric  
303 conditions but allowing for the fact that the water is evaporating through the surface of  
304 leaves and thus the resistance is higher. It is calculated from the daily meteorological variables  
305 using the equation

$$E_p = \frac{t_d}{\lambda} \frac{\Delta A + \frac{c_p \rho_a}{r_a} (q_s - q_a)}{\Delta + \gamma \left(1 + \frac{r_s}{r_a}\right)}, \quad (2)$$

where  $t_d = 86400 \text{ s d}^{-1}$  is the length of a day,  $\lambda = 2.5 \times 10^6 \text{ J kg}^{-1}$  is the latent heat of evaporation,  $q_s$  is saturated specific humidity ( $\text{kg kg}^{-1}$ ),  $\Delta$  is the gradient of saturated specific humidity with respect to temperature ( $\text{kg kg}^{-1} \text{ K}^{-1}$ ),  $A$  is the available energy ( $\text{W m}^{-2}$ ),  $c_p = 1010 \text{ J kg}^{-1} \text{ K}^{-1}$  is the specific heat capacity of air,  $\rho_a$  is the density of air ( $\text{kg m}^{-3}$ ),  $q_a$  is specific humidity ( $\text{kg kg}^{-1}$ ),  $\gamma = 0.004 \text{ K}^{-1}$  is the psychrometric constant,  $r_s$  is stomatal resistance ( $\text{s m}^{-1}$ ) and  $r_a$  is aerodynamic resistance ( $\text{s m}^{-1}$ ) (Stewart, 1989).

The saturated specific humidity,  $q_s$  ( $\text{kg kg}^{-1}$ ), is calculated from saturated vapour pressure,  $e_s$  (Pa), using Eq. (1). The saturated vapour pressure is calculated using an empirical fit to air temperature

$$e_s = p_s \exp\left(\sum_{i=1}^4 a_i \left(1 - \frac{T_s}{T_a}\right)^i\right), \quad (3)$$

where  $p_s = 101325 \text{ Pa}$  is the steam point pressure,  $T_s = 373.15 \text{ K}$  is the steam point temperature and  $a = (13.3185, -1.9760, -0.6445, -0.1299)$  are empirical coefficients (Richards, 1971).

The derivative of the saturated specific humidity with respect to temperature,  $\Delta$  ( $\text{kg kg}^{-1} \text{ K}^{-1}$ ), is therefore

$$\Delta = \frac{T_s}{T_a^2} \frac{p_s q_s}{p_* - (1 - \epsilon) e_s} \sum_{i=1}^4 i a_i \left(1 - \frac{T_s}{T_a}\right)^{i-1}. \quad (4)$$

The available energy,  $A$  ( $\text{W m}^{-2}$ ), is the energy balance of the surface,

$$A = R_n - G, \quad (5)$$

where  $R_n$  is the net radiation ( $\text{W m}^{-2}$ ) and  $G$  is the soil heat flux ( $\text{W m}^{-2}$ ). The net soil heat flux is negligible at the daily timescale (Allen et al., 1998), so the available energy is equal to the net radiation, such that

$$A = (1 - \alpha) S_d + \varepsilon (L_d - \sigma T_*^4), \quad (6)$$

where  $\sigma$  is the Stefan-Boltzmann constant,  $\alpha$  is the albedo and  $\varepsilon$  the emissivity of the surface and  $T_*$  is the surface temperature (Shuttleworth, 2012). For this study the surface temperature is approximated by using the air temperature,  $T_a$ .

The air density,  $\rho_a$  ( $\text{kg m}^{-3}$ ), is a function of air pressure and temperature,

$$332 \quad \rho_a = \frac{p_*}{rT_a}, \quad (7)$$

333 where  $r = 287.05 \text{ J kg}^{-1} \text{ K}^{-1}$  is the gas constant of air.

334 The stomatal and aerodynamic resistances are strongly dependent on land cover due to  
 335 differences in roughness length and physiological constraints on transpiration of different  
 336 vegetation types. In addition, the albedo and emissivity are also dependent on the land cover.  
 337 In order to investigate the effect of meteorology on AED, as distinct from land use effects, the  
 338 PET was calculated for a single land cover type over the whole of the domain. If necessary, this  
 339 can be adjusted to give an estimate of PET specific to the local land cover, for example using  
 340 regression relationships (Crooks and Naden, 2007). As a standard, the Food and Agriculture  
 341 Organization of the United Nations (FAO) calculate reference crop evaporation for a  
 342 hypothetical reference crop, which corresponds to a well-watered grass (Allen et al., 1998).  
 343 Following this, the PET in the current study was calculated for a reference crop of 0.12 m  
 344 height, with constant stomatal resistance,  $r_s = 70.0 \text{ s m}^{-1}$ , an albedo of 0.23 and emissivity of  
 345 0.92 over the whole of Great Britain. This study therefore neglects the effect of land-use on  
 346 evaporation, which could be investigated in future by calculating PET for different land surface  
 347 types, with different coverage for each year of the dataset.

348 Following Allen et al. (1998), the aerodynamic resistance,  $r_a \text{ (s m}^{-1}\text{)}$ , is a function of the 10 m  
 349 wind speed

$$350 \quad r_a = \frac{278}{u_{10}}. \quad (8)$$

351 Thus the PET is a function of six of the meteorological variables: air temperature, specific  
 352 humidity, downward LW and SW radiation, wind speed and surface air pressure.

353 To explore the role of the different meteorological variables in the AED, it is helpful to split  
 354 the radiative component (the first part of the numerator in Equation 2) from the wind component  
 355 (the second part). Formally, this is defined as follows (Doorenbos, 1977):

356 The radiative component,  $E_{PR}$ ,

$$357 \quad E_{PR} = \frac{t_d}{\lambda} \frac{\Delta A}{\Delta + \gamma \left(1 + \frac{r_s}{r_a}\right)}, \quad (9)$$

358 and the aerodynamic component,  $E_{PA}$ ,

$$359 \quad E_{PA} = \frac{t_d}{\lambda} \frac{c_p \rho_a}{\Delta + \gamma \left(1 + \frac{r_s}{r_a}\right)} (q_s - q_a), \quad (10)$$

360 such that  $E_P = E_{PR} + E_{PA}$ .

### 361 **3.1 Potential evapotranspiration with interception (PETI)**

362 When rain falls, water is intercepted by the canopy. The evaporation of this water is not  
363 constrained by stomatal resistance but is subject to the same aerodynamic resistance as  
364 transpiration (Shuttleworth, 2012). At the same time, transpiration is inhibited in a wet canopy.  
365 Suppression of transpiration is well observed both by comparing eddy-covariance fluxes and  
366 observations of sap flow (Kume et al., 2006; Moors, 2012), and by observing stomatal and  
367 photosynthesis response to wetting (Ishibashi and Terashima, 1995). For plants which have at  
368 least some of their stomata on the upper surface of the leaves, this can be due to water directly  
369 blocking the stomata. However, in GB most plants have stomata only on the underside of the  
370 leaves, so the transpiration is inhibited by other mechanisms.

371 Physically, the suppression may simply be due to the fact that energy is used in evaporating the  
372 intercepted water, so less is available for transpiration (Bosveld and Bouten, 2003) or that the  
373 increased humidity of the air, due to evaporation of intercepted water, causes the stomata to  
374 close (Lange et al., 1971). It may also be due to the presence of water causing stomatal closure  
375 through physiological reactions, which can be observed even when the stomata are on the  
376 underside of a leaf and the water is lying on the upper side (Ishibashi and Terashima, 1995).

377 In the short term after a rain event, potential water losses due to evaporation may be  
378 underestimated if only potential transpiration is calculated, and therefore overall rates  
379 underestimated. As transpiration is inhibited over the wet fraction of the canopy (Ward and  
380 Robinson, 2000) , the PET over a grid box will be a linear combination of the potential  
381 interception and potential transpiration, each weighted by the fraction of the canopy that is wet  
382 or dry. This can be accounted for by introducing an interception term to the calculation of PET,  
383 giving PETI. This is modelled as an interception store, which is (partially) filled by rainfall,  
384 proportionally inhibiting the transpiration. As the interception store dries, the relative  
385 contribution of interception is decreased and the transpiration increases. This correction is  
386 applied on days with precipitation, while on days without precipitation, the potential is equal to  
387 the PET defined in Eq. 2. Although an unconventional definition of PET, a similar interception  
388 correction is applied to the PET provided at 40 km resolution by MORECS (Thompson et al.,  
389 1981) which is used widely by hydrologists.

390 This method implicitly assumes that the water is liquid, however snow lying on the canopy will  
 391 also inhibit transpiration, and will be depleted by melting as well as by sublimation. The rates  
 392 may be slower, and the snow may stay on the canopy for longer than one day. However, the  
 393 difference of accounting for canopy snow as distinct from canopy water will have a small effect  
 394 on large-scale averages, as the number of lying snow days in GB is relatively low, and they  
 395 occur during winter when the PET is very small.

396 The PETI is a weighted sum of the PET,  $E_P$ , (as calculated in Eq 2.) and potential interception,  
 397  $E_I$ , which is calculated by substituting zero stomatal resistance,  $r_s=0 \text{ s m}^{-1}$ , into Eq. 2. To  
 398 calculate the relative proportions of interception and transpiration, it is assumed that the wet  
 399 fraction of the canopy is proportional to the amount of water in the interception store. The  
 400 interception store,  $S_I$  ( $\text{kg m}^{-2}$ ), decreases through the day according to an exponential dry down  
 401 (Rutter et al., 1971), such that

$$402 \quad S_I(t) = S_o e^{-\frac{E_I}{S_{tot}} t}, \quad (11)$$

403 where  $E_I$  is the potential interception,  $S_{tot}$  is the total capacity of the interception store ( $\text{kg m}^{-2}$ ),  
 404  $S_o$  is the precipitation that is intercepted by the canopy ( $\text{kg m}^{-2}$ ) and  $t$  is the time (in days) since  
 405 a rain event. The total capacity of the interception store is calculated following Best et al.  
 406 (2011), such that

$$407 \quad S_{tot} = 0.5 + 0.05\Lambda, \quad (12)$$

408 where  $\Lambda$  is the leaf area index (LAI); for the FAO standard grass land cover the LAI is 2.88  
 409 (Allen et al., 1998). The fraction of precipitation intercepted by the canopy is found also  
 410 following Best et al. (2011), assuming that precipitation lasts for an average of 3 hours.

411 The wet fraction of the canopy,  $C_{wet}$ , is proportional to the store size, such that

$$412 \quad C_{wet}(t) = \frac{S(t)}{S_{tot}}. \quad (13)$$

413 The total PETI is the sum of the interception from the wet canopy and the transpiration from  
 414 the dry canopy,

$$415 \quad E_{PI}(t) = E_I C_{wet}(t) + E_P (1 - C_{wet}(t)). \quad (14)$$

416 This is integrated over one day to find the total PETI,  $E_{PI}$  ( $\text{mm d}^{-1}$ ), to be

$$E_{PI} = S_0 \left( 1 - e^{-\frac{E_I}{S_{tot}}} \right) + E_P \left( 1 - \frac{S_0}{E_I} \left( 1 - e^{-\frac{E_I}{S_{tot}}} \right) \right).$$

(15)

The PETI is a function of the same six meteorological variables as the PET, plus the precipitation.

### 3.2 Spatial and seasonal patterns of PET and PETI

Both PET and PETI have a distinct gradient from low in the north-west to high in the south-east, and they are both inversely proportional to the elevation (Fig. 6), reflecting the spatial patterns of the meteorological variables. The PETI is 8 % higher than the PET overall but this difference is larger in the north and west, where precipitation rates, and therefore interception, are higher (Fig. 6). In Scotland, the higher interception and lower AED mean that this increase is a larger proportion of the total, with the mean PETI being 11 % larger than the PET (in some areas the difference is more than 25%). In the English lowlands the difference is smaller, at 6 %, but this is a more water limited region where hydrological modelling can be sensitive to even relatively small adjustments to PET (Kay et al., 2013).

The seasonal climatology of both PET and PETI follow the meteorology (Fig. 7), with high values in the summer and low in the winter. Although the relative difference peaks in winter, the absolute difference between PET and PETI is bimodal, with a peak in March and a smaller peak in October (September in Scotland) (Fig. 7), because in winter the overall AED is low, while in summer the amount of precipitation is low, so the interception correction is small. The seasonal cycle of PET is driven predominantly by the radiative component, which has a much stronger seasonality than the aerodynamic component (Fig. 8).

On a monthly or annual timescale, the ratio of PET to precipitation is an indicator of the wet- or dryness of a region (Oldekop, 1911; Andréassian et al., 2016). Low values of PET relative to precipitation indicate wet regions, where evaporation is demand-limited, while high values indicate dry, water-limited regions. In the wetter regions (Scotland, Wales) mean-monthly PET and PETI (Fig. 7) are on average lower than the mean-monthly precipitation (Fig. 3) throughout the year, while in drier regions (England, English lowlands) the mean PET and PETI are higher than the precipitation for much of the summer, highlighting the regions' susceptibility to hydrological drought (Folland et al., 2015).

## 446 **4 Decadal trends**

### 447 **4.1 Meteorological Variables**

448 Annual means of the meteorological variables (Fig. 9) and the PET and PETI (Fig. 10) were  
449 calculated for each region. The trends in these annual means were calculated using linear  
450 regression; the significance ( $P$  value) and 95% confidence intervals (CI) of the slope are  
451 calculated specifically allowing for the non-zero lag-1 autocorrelation, to account for possible  
452 correlations between adjacent data points (Zwiers and von Storch, 1995; von Storch and Zwiers,  
453 1999). In addition, seasonal means were calculated, with the four seasons defined to be Winter  
454 (December-February), Spring (March-May), Summer (June-August) and Autumn (September-  
455 November), and trends in these means were also found. The trends can be seen in Table 2.

456 The trends in the annual and seasonal means for all regions are plotted in Fig. 11; trends that  
457 are statistically significant at the 5% level are plotted with solid error bars, those that are not  
458 significant are plotted with dashed lines. The analysis was repeated for each pixel in the 1 km  
459 resolution dataset; maps of these rates of change can be seen in Appendix B.

460 There was a statistically significant trend in air temperature in all regions (except in winter),  
461 which agrees with recent trends in the Hadley Centre Central England Temperature (HadCET)  
462 dataset (Parker and Horton, 2005) and in temperature records for Scotland (Jenkins et al., 2008)  
463 as well as in the CRUTEM4 dataset (Jones et al., 2012). An increase in winter precipitation in  
464 Scotland is seen in the current dataset, which leads to a statistically significant increase in the  
465 annual mean precipitation of GB. However, all other regions and seasons have no statistically  
466 significant trends in precipitation. Long term observations show that there has been little trend  
467 in annual precipitation, but a change in seasonality with wetting winters and drying summers  
468 since records began, although with little change over the past 50 years (Jenkins et al., 2008).  
469 The statistically significant decline in wind speed in all regions is consistent with the results of  
470 McVicar et al. (2012) and Vautard et al. (2010), who report decreasing wind speeds in the  
471 northern hemisphere over the late 20<sup>th</sup> century.

### 472 **4.2 Potential Evapotranspiration**

473 The trends of the meteorological variables are interesting in their own right. But for hydrology,  
474 it is the impact that the trends have on evaporation that matters and that depends on their  
475 combination, which can be expressed through PET.

476 The regional trends of annual mean PET and PETI can be seen in Table 2, and the trends in the  
477 annual and seasonal means of PET, PETI, and the radiative and aerodynamic components of  
478 PET are plotted in Fig. 12 for all regions. Maps of the trends can be seen in Appendix B. The  
479 trend in the radiative component of PET is positive over the whole of GB. However, the trend  
480 in the aerodynamic component varies; for much of Wales, Scotland and northern England, it is  
481 not significant, or is slightly negative, while in south-east England and north-west Scotland it  
482 is positive. This leads to a positive trend in PET over much of GB, but no significant trend in  
483 southern Scotland and northern England. There is a statistically significant increase in annual  
484 PET in all regions except Wales; the GB trend ( $0.021 \pm 0.021 \text{ mm d}^{-1} \text{ decade}^{-1}$ ) is equivalent to  
485 an increase of  $0.11 \pm 0.11 \text{ mm d}^{-1}$  ( $8.3 \pm 8.1 \%$  of the long term mean) over the whole dataset.  
486 Increases in PETI are only statistically significant in England ( $0.023 \pm 0.023 \text{ mm d}^{-1} \text{ decade}^{-1}$ )  
487 and English lowlands ( $0.028 \pm 0.025 \text{ mm d}^{-1} \text{ decade}^{-1}$ ), where the increases over the whole  
488 dataset are  $0.12 \pm 0.12 \text{ mm d}^{-1}$  ( $8.0 \pm 8.0 \%$  of the long term mean) and  $0.15 \pm 0.13 \text{ mm d}^{-1}$  ( $9.7 \pm 8.8$   
489  $\%$  of the long term mean) respectively. There is a difference in trend between different seasons.  
490 In winter, summer and autumn there are no statistically significant trends in PET or PETI, other  
491 than the English lowlands in autumn, but the spring is markedly different, with very significant  
492 trends ( $P < 0.0005$ ) in all regions. The GB spring trends in PET ( $0.043 \pm 0.019 \text{ mm d}^{-1} \text{ decade}^{-1}$ )  
493 and PETI ( $0.038 \pm 0.018 \text{ mm d}^{-1} \text{ decade}^{-1}$ ) are equivalent to an increase of  $0.22 \pm 0.10 \text{ mm d}^{-1}$   
494 ( $13.8 \pm 6.2 \%$  of the long-term spring mean) and  $0.20 \pm 0.09 \text{ mm d}^{-1}$  ( $11.2 \pm 5.3 \%$  of the long-term  
495 spring mean) over the length of the dataset respectively. The radiative component of PET has  
496 similarly significant trends in spring, while the aerodynamic component has no significant  
497 trends in any season (Fig. 12), indicating that the trend in PET is due to the increasing radiative  
498 component.

499 There are few studies of long-term trends in AED in the UK. MORECS provides an estimate  
500 of Penman-Monteith PET with interception correction calculated directly from the 40 km  
501 resolution meteorological data (Hough and Jones, 1997; Thompson et al., 1981), and increases  
502 can be seen over the dataset (Rodda and Marsh, 2011). But as the PET and PETI in the current  
503 dataset are ultimately calculated using the same meteorological data (albeit by different  
504 methods), it is not unexpected that similar trends should be seen. Site-based studies suggest an  
505 increase over recent decades (Burt and Shahgedanova, 1998; Crane and Hudson, 1997), but it  
506 is difficult to separate climate-driven trends from local land-use trends. A global review paper  
507 (McVicar et al., 2012) identified a trend of decreasing AED in the northern hemisphere, driven  
508 by decreasing wind speeds, however they also reported significant local variations on trends in

509 pan evaporation, including the increasing trend observed by Stanhill and Möller (2008) at a site  
 510 in England after 1968. Matsoukas et al. (2011) identified a statistically significant increase in  
 511 PET in several regions of the globe, including southern England, between 1983 and 2008,  
 512 attributing it predominantly to an increase in the radiative component of PET, due to global  
 513 brightening. However, these results were obtained using reanalysis data, which is limited in its  
 514 ability to capture trends in wind speed. This limitation has been documented in both northern  
 515 (Pryor et al., 2009) and southern (McVicar et al., 2008) hemispheres.

516 Regional changes in actual evaporative losses can be estimated indirectly using regional  
 517 precipitation and runoff or river flow. Using a combination of observations and modelling,  
 518 Marsh and Dixon (2012) identified an increase in evaporative losses in Great Britain from 1961-  
 519 2011. Hannaford and Buys (2012) note seasonal and regional differences in trends in observed  
 520 river flow, suggesting that decreasing spring flows in the English lowlands are indicative of  
 521 increasing AED. However, changing evaporative losses can also be due to changing supply  
 522 through precipitation, so it is important to formally attribute the trends in PET to changing  
 523 climate, in order to understand changing evapotranspiration.

### 524 **4.3 Attribution of trends in potential evapotranspiration**

525 In order to attribute changes in PET to changes in climate, the rate of change of PET,  $dE_p/dt$   
 526 ( $\text{mm d}^{-1} \text{ decade}^{-1}$ ), can be calculated as a function of the rate of change of each variable  
 527 (Roderick et al., 2007),

$$528 \quad \frac{dE_p}{dt} = \frac{dE_p}{dT_a} \frac{dT_a}{dt} + \frac{dE_p}{dq_a} \frac{dq_a}{dt} + \frac{dE_p}{du_{10}} \frac{du_{10}}{dt} + \frac{dE_p}{dL_d} \frac{dL_d}{dt} + \frac{dE_p}{dS_d} \frac{dS_d}{dt} . \quad (16)$$

529 Note that we exclude the surface air pressure, because this dataset uses a mean-monthly  
 530 climatology as the interannual variability of air pressure is negligible. The derivative of the PET  
 531 with respect to each of the meteorological variables can be found analytically (Appendix C).  
 532 The derivatives are calculated from the daily meteorological data at 1 km resolution.  
 533 Substituting the slopes of the linear regressions of the gridded annual means (Appendix B) for  
 534 the rate of change of each variable with time, and the overall time-average of the derivatives of  
 535 PET with respect to the meteorological variables, the contribution of each variable to the rate  
 536 of change of PET can be calculated at 1 km resolution. These are then averaged over the regions  
 537 of interest. The same can also be applied to the radiative and aerodynamic components  
 538 independently.

539 Note that this can also be applied to the regional means of the derivatives of PET and the trends  
540 in the meteorological variables. The results are compared in Table 3 and the two approaches  
541 are consistent. For the regional analysis, we also quote the 95% CI. However, for the gridded  
542 values, there is such high spatial coherence that combining the 95% CI over the region results  
543 in unreasonably constrained results. We therefore use the more conservative CI obtained from  
544 the regional analysis. Also note that this method assumes that the rate of change of the variables  
545 with respect to time is constant over the whole dataset (and thus the product of the means is  
546 equal to the mean of the products), and indeed this is how it is often applied (Donohue et al.,  
547 2010; Lu et al., 2016). The effect of this assumption was investigated by repeating the analysis  
548 with seasonal trends and means, but this makes negligible difference to the results.

549 Fig. 13 shows the contribution of each meteorological variable to the rate of change of the  
550 annual mean PET and to the radiative and aerodynamic components and compares the total  
551 attributed trend to that obtained by linear regression. The percentage contribution is in Table 4,  
552 calculated as a fraction of the fitted trend. The final columns shows the total attributed trend as  
553 a percentage of the fitted trend, to demonstrate the success of the attribution at recovering the  
554 fitted trends. For the PET trend and for the trend in the radiative component, these values  
555 generally sum to the linear regression to within a few percent. However, for the aerodynamic  
556 component, the fitted trend is very small (an order of magnitude smaller than the PET and  
557 radiative component trends), and much smaller than the statistical uncertainty. This means that  
558 there can be a large and/or negative percentage difference between the attributed and fitted  
559 trends, even when the absolute difference is negligible.

560 The largest overall contribution to the rate of change of PET comes from increasing air  
561 temperature, which has the effect of increasing the aerodynamic component (as it makes the air  
562 more able to hold water), but it decreases the radiative component (due to increasing outgoing  
563 LW radiation). However, the decrease due to increasing specific humidity largely cancels this  
564 increase in the aerodynamic component. Overall the next largest increases are caused by  
565 increasing downward SW radiation, particularly in the English regions in the spring, as it  
566 increases the radiative component of PET. However, in Scotland and Wales, the increasing  
567 downward LW radiation is also important. Finally, the decreasing wind speed has the effect of  
568 increasing the radiative component, but decreasing the aerodynamic component, so overall it  
569 tends to cause a decrease in PET.

570 Since the increasing air temperature and downward LW and SW radiation have the effect of  
571 increasing PET, but the increasing specific humidity and decreasing wind speed tend to  
572 decrease it, then the overall trend is positive, but smaller than the trend due to air temperature  
573 alone.

## 574 **5 Discussion**

575 These high resolution datasets provide insight into the effect of the changing climate of Great  
576 Britain on AED over the past five decades. There have been significant climatic trends in the  
577 UK since 1961; in particular rising air temperature and specific humidity, decreasing wind  
578 speed and decreasing cloudiness. Although some are positive and some negative, these  
579 meteorological trends combine to give statistically significant trends in PET.

580 Wind speeds have decreased more significantly in the west than the east, and show a consistent  
581 decrease across seasons. Contrary to Donohue et al. (2010) and McVicar et al. (2012), this study  
582 finds that the change in wind speed of the late 20<sup>th</sup> and early 21<sup>st</sup> centuries has had a negligible  
583 influence on PET over the period of study. However, the previous studies were concerned with  
584 open-water Penman evaporation, which has a simpler (proportional) dependence on wind speed  
585 than the Penman-Monteith PET considered here (Schymanski and Or, 2015).

586 The air temperature trend in this study of  $0.21 \pm 0.15$  K decade<sup>-1</sup> in GB is consistent with  
587 observed global and regional trends (Hartmann et al., 2013; Jenkins et al., 2008). The  
588 temperature trend is responsible for a large contribution to the trend in PET, although the large  
589 negative contribution from the specific humidity (as well as a small negative contribution from  
590 wind speed) means that the overall trend is smaller than the temperature trend alone.

591 Although the contribution is smaller than that of air temperature, the trends in LW radiation in  
592 these datasets contribute to between 15% and 28% of the trends in PET and between 27% and  
593 46% of the trends in the radiative component. Observations of LW radiation are often uncertain,  
594 but the trend in this dataset, although small, is consistent with observed trends (Wang and Liang,  
595 2009), as well as with trends in the WFDEI bias-corrected reanalysis product (Weedon et al.,  
596 2014).

597 Increasing solar radiation has been shown to increase spring and annual AED, contributing to  
598 between 18% and 50% of the fitted trend in annual PET, and to between 43% and 53% of the  
599 fitted trend in spring PET. Two main mechanisms can be responsible for changing solar  
600 radiation – changing cloud cover and changing aerosol concentrations. Changing aerosol

601 emissions have been shown to have had a significant effect on solar radiation in the 20<sup>th</sup> century.  
602 In Europe, global dimming due to increased aerosol concentrations peaked around 1980,  
603 followed by global brightening as aerosol concentrations decreased (Wild, 2009). Observations  
604 of changing continental runoff and river flow in Europe over the 20<sup>th</sup> century have been  
605 attributed to changing aerosol concentrations, via their effect on solar radiation, and thus AED  
606 (Gedney et al., 2014).

607 In this study we use the duration of bright sunshine to calculate the solar radiation, using  
608 empirical coefficients which do not vary with year, so aerosol effects are not explicitly included.  
609 The coefficients used in this study to convert sunshine hours to radiation fluxes were  
610 empirically derived in 1978; the derivation used data from the decade 1966-75, as this period  
611 was identified to be before reductions in aerosol emissions had begun to significantly alter  
612 observed solar radiation (Cowley, 1978). Despite this, the trend in SW radiation in the current  
613 dataset from 1979 onwards ( $1.4 \pm 1.4 \text{ W m}^{-2} \text{ decade}^{-1}$ ) is consistent, within uncertainties, with  
614 that seen over GB in the WFDEI data ( $0.9 \pm 1.1 \text{ W m}^{-2} \text{ decade}^{-1}$ ), which is bias-corrected to  
615 observations and includes explicit aerosol effects (Weedon et al., 2014).

616 It has been suggested that aerosol effects also implicitly affect sunshine duration since in  
617 polluted areas, there will be fewer hours above the official 'sunshine hours' threshold of 120  
618  $\text{Wm}^{-2}$  (Helmes and Jaenicke, 1986). Several regional studies have shown trends in sunshine  
619 hours that are consistent with the periods of dimming and brightening across the globe (eg  
620 Liley, 2009; Sanchez-Lorenzo et al., 2009; Sanchez-Lorenzo et al., 2008; Stanhill and Cohen,  
621 2005), and several have attempted to quantify the relative contribution of trends in cloud cover  
622 and aerosol loading (e.g. Sanchez-Lorenzo and Wild (2012) in Switzerland, see Sanchez-  
623 Romero et al. (2014) for a review). Therefore, it may be that some of the brightening trend seen  
624 in the current dataset is due to the implicit signal of aerosol trends in the MORECS sunshine  
625 duration, although this is likely to be small compared to the effects of changing cloud cover.

626 The trends in the MORECS sunshine duration used in this study are consistent with changing  
627 weather patterns which may be attributed to the Atlantic Multidecadal Oscillation (AMO). The  
628 AMO has been shown to cause a decrease in spring precipitation (and therefore cloud cover) in  
629 northern Europe over recent decades (Sutton and Dong, 2012), and the trend in MORECS  
630 sunshine hours is dominated by an increase in the spring mean. This has also been seen in  
631 Europe-wide sunshine hours data (Sanchez-Lorenzo et al., 2008). On the other hand, the effect  
632 of changing aerosols on sunshine hours is expected to be largest in the winter (Sanchez-Lorenzo

633 et al., 2008). However, it would not be possible to directly identify either of these effects on the  
634 sunshine duration without access to longer data records.

635 The inclusion of explicit aerosol effects in the coefficients of the Angstrom-Prescott equation  
636 would be expected to reduce the positive trend in AED in the first two decades of the dataset,  
637 and increase it after 1980. Gedney et al. (2014) attribute a decrease in European solar radiation  
638 of  $10 \text{ W m}^{-2}$  between the periods 1901-10 and 1974-80, and an increase of  $4 \text{ W m}^{-2}$  from 1974-  
639 84 to 1990-99 to changing aerosol contributions. Applying these trends to the current dataset,  
640 with a turning point at 1980, would double the overall increase in solar radiation in Great  
641 Britain, which would lead to a 40 % increase in the overall trend in PET. So, if this effect were  
642 to be included, it would confirm the results found in this paper.

643 Trends in temperature and cloud cover in the UK are expected to continue into the coming  
644 decades, with precipitation expected to increase in the winter but decrease in the summer  
645 (Murphy et al., 2009). Therefore it is likely that AED will increase, increasing water stress in  
646 the summer when precipitation is lower and potentially affecting water resources, agriculture  
647 and biodiversity. This has been demonstrated for southern England and Wales by Rudd and  
648 Kay (2015), who calculated present and future PET using high-resolution RCM output and  
649 include the effects of  $\text{CO}_2$  on stomatal opening.

650 The current study is concerned only with the effects of changing climate on AED and has  
651 assumed a constant bulk canopy resistance throughout. However, plants are expected to react  
652 to increased  $\text{CO}_2$  in the atmosphere by closing stomata and limiting the exchange of gases,  
653 including water (Kruijt et al., 2008), and observed changes in runoff have been attributed to this  
654 effect (Gedney et al., 2006; Gedney et al., 2014). It is possible that the resulting change of  
655 canopy resistance could partially offset the increased atmospheric demand (Rudd and Kay,  
656 2015) and may impact runoff (Gedney et al., 2006; Prudhomme et al., 2014), but further studies  
657 would be required to quantify this.

## 658 **6 Conclusion**

659 This paper has presented a unique high-resolution observation-based dataset of meteorological  
660 variables and AED in Great Britain since 1961. Key trends in the meteorological variables are  
661 (i) increasing air temperature and specific humidity, consistent with global temperature trends;  
662 (ii) increasing solar radiation, particularly in the spring, consistent with changes in aerosol  
663 emissions and weather patterns in recent decades; (iii) decreasing wind speed, consistent with  
664 observations of global stilling; and (iv) increasing precipitation, driven by increasing winter

665 precipitation in Scotland. The meteorological variables were used to evaluate AED in Great  
666 Britain via calculation of PET and PETI. It has been demonstrated that including the  
667 interception component in the calculation of PETI gives a mean estimate that is overall 8%  
668 larger than PET alone, with strong seasonality and spatial variation of the difference. PET was  
669 found to be increasing by  $0.021 \pm 0.021$  mm d<sup>-1</sup> decade<sup>-1</sup> over the study period. With the  
670 interception component included, the trend in PETI is weaker, and over GB is not significant at  
671 the 5% level. The trend in PET was analytically attributed to the trends in the meteorological  
672 variables, and it was found that the dominant effect was that increasing air temperature was  
673 driving increasing PET. This is largely compensated by the associated increase in specific  
674 humidity, as the water cycle is intensified under climate change and by decreasing wind speed.  
675 However, the PET increase is also driven by increasing solar radiation, particularly in the  
676 spring.

677 In addition to providing meteorological data for analysis, the meteorological variables provided  
678 are sufficient to run LSMs and hydrological models. The high spatial (1 km) and temporal  
679 (daily) resolution will allow this dataset to be used to study the effects of climate on physical  
680 and biological systems at a range of scales, from local to national.

### 681 **Data Access**

682 The data can be downloaded from the Environmental Information Platform at the Centre for  
683 Ecology & Hydrology. The meteorological variables can be found at  
684 <https://catalogue.ceh.ac.uk/documents/80887755-1426-4dab-a4a6-250919d5020c>,  
685 while the PET and PETI can be accessed at  
686 <https://catalogue.ceh.ac.uk/documents/d329f4d6-95ba-4134-b77a-a377e0755653>.

### 687 **Author contribution**

688 EB, JF and DBC designed the study. JF, ACR, DBC and ELR developed code to create  
689 meteorological data. ELR created the PET and PETI. ELR and EB analysed trends. ELR, EB,  
690 ACR and DBC wrote the manuscript.

### 691 **Acknowledgements**

692 The meteorological variables presented are based largely on GB meteorological data under  
693 licence from the Met Office, and those organisations contributing to this national dataset  
694 (including the Met Office, Environment Agency, Scottish Environment Protection Agency  
695 (SEPA) and Natural Resources Wales) are gratefully acknowledged. The CRU TS 3.21 daily

696 temperature range data were created by the University of East Anglia Climatic Research Unit,  
697 and the WFD air pressure data were created as part of the EU FP6 project WATCH (Contract  
698 036946). Collection of flux data was funded by EU FP4 EuroFlux (Griffin Forest); EU FP5  
699 CarboEuroFlux (Griffin Forest); EU FP5 GreenGrass (Easter Bush); EU FP6 CarboEuropeIP  
700 (Alice Holt , Griffin Forest, Auchencorth Moss, Easter Bush); EU FP6 IMECC (Griffin  
701 Forest); the Forestry Commission (Alice Holt); the Natural Environment Research Council,  
702 UK (Auchencorth Moss, Easter Bush).  
703 Thanks to Nicola Gedney and Graham Weedon for useful discussions.  
704 This work was partially funded by the Natural Environment Research Council in the  
705 Changing Water Cycle programme: NERC Reference: NE/I006087/1.  
706

## 707 **Appendix A: Data validation**

708 Meteorological data were downloaded from the European Fluxes Database Cluster  
709 (<http://gaia.agraria.unitus.it>) for four sites positioned around Great Britain. Two were woodland  
710 sites (Alice Holt (Wilkinson et al., 2012; Heinemeyer et al., 2012) and Griffin Forest (Clement,  
711 2003)), while two had grass and crop cover (Auchencorth Moss (Billett et al., 2004) and Easter  
712 Bush (Gilmanov et al., 2007; Soussana et al., 2007)). Table A1 gives details of the data used.  
713 The data are provided as half-hourly measurements, which were used to create daily means,  
714 where full daily data coverage was available. The daily means of the observed data were  
715 compared to the daily data from the grid square containing the site and the Pearson correlation  
716 ( $r^2$ ), mean bias and root mean square error (RMSE) were calculated. For each site, monthly  
717 means were calculated where the full month had available data, then a climatology calculated  
718 from available months. The same values were calculated from the relevant grid squares, using  
719 only time periods for which observed data were available.

720 Fig. A1 shows the comparison of the data set downward SW radiation against daily mean air  
721 temperature observed at the four sites. Fig. A2 shows the mean-monthly climatology of the  
722 daily values. The observed values of the mixing ratio of water vapour in air were compared  
723 with values calculated from the meteorological dataset, using the equation

$$724 \quad r_w = q_a \left( \frac{m_a}{m_w} \right)$$

725 where  $m_a$  is the molecular mass of dry air and  $m_w$  is the molecular mass of water. The  
726 comparisons are shown in Figs. A3 and A4.

727 Table A2 shows the  $r^2$ , mean bias and RMSE for each of the variables included in the validation  
728 exercise. The correlations indicate a good relationship between the dataset variables and the  
729 independent observations at the sites, while the mean-monthly climatologies demonstrate that  
730 the data represent the seasonal cycle well.

## 731 **Appendix B: Trend maps**

732 Fig. B1 shows the rate of change of each of the meteorological variables at the 1 km resolution,  
733 while Fig. B2 shows the rate of change of the PET, PETI, and the two components of PET at  
734 the same resolution. This shows that the regional trends are consistent with spatial variation and  
735 are not dominated by individual extreme points.

## 736 **Appendix C: Derivatives of PET**

737 The wind speed affects the PET through the aerodynamic resistance. The derivative with respect  
 738 to wind speed is

$$739 \quad \frac{\partial E_P}{\partial u_{10}} = \frac{(\Delta + \gamma)E_{PA} - \gamma \frac{r_s}{r_a} E_{PR}}{u_{10} \left( \Delta + \gamma \left( 1 + \frac{r_s}{r_a} \right) \right)}. \quad (C1)$$

740 The downward LW and SW radiation affect PET through the net radiation, and the derivatives  
 741 are

$$742 \quad \frac{\partial E_P}{\partial L_d} = E_{PR} \frac{\epsilon}{R_n} \quad (C2)$$

$$743 \quad \frac{\partial E_P}{\partial S_d} = E_{PR} \frac{(1 - \alpha)}{R_n}. \quad (C3)$$

744 The derivative of PET with respect to specific humidity is

$$745 \quad \frac{\partial E_P}{\partial q_a} = \frac{E_{PA}}{q_a - q_s}. \quad (C4)$$

746 The air temperature affects PET through the saturated specific humidity and its derivative, the  
 747 net radiation and the air density, so that the derivative of PET with respect to air temperature is

$$748 \quad \frac{\partial E_P}{\partial T_a} = E_{PR} \left( \frac{\gamma \left( 1 + \frac{r_s}{r_a} \right)}{T_a^2 \left( \Delta + \gamma \left( 1 + \frac{r_s}{r_a} \right) \right)} \left[ T_{sp} \left( \sum_{i=1}^4 i a_i T_r^{i-1} + \frac{\sum_{i=1}^4 i a_i T_r^{i-1}}{\sum_{i=1}^4 i(i-1) a_i T_r^{i-2}} + \frac{2(1-\epsilon) \sum_{i=1}^4 i a_i T_r^{i-1} q_s}{\epsilon} \right) - \right. \right. \\
 749 \quad \left. \left. 2T_a \right] - \frac{4\epsilon\sigma T_a^4}{R_n} \right) + E_{PA} \left( \frac{\Delta}{q_s - q} - \frac{1}{T_a} - \frac{\Delta}{T_a^2 \left( \Delta + \gamma \left( 1 + \frac{r_s}{r_a} \right) \right)} \left[ T_{sp} \left( \sum_{i=1}^4 i a_i T_r^{i-1} + \frac{\sum_{i=1}^4 i a_i T_r^{i-1}}{\sum_{i=1}^4 i(i-1) a_i T_r^{i-2}} + \right. \right. \right. \\
 750 \quad \left. \left. \left. \frac{2(1-\epsilon) \sum_{i=1}^4 i a_i T_r^{i-1} q_s}{\epsilon} \right) - 2T_a \right] \right). \quad (C5)$$

1183

1184 Table 1. Description of input meteorological variables

Variable (units)	Source data	Ancillary files	Assumptions	Height
Air temperature (K)	MORECS air temperature	IHDTM elevation	Lapsed to IHDTM elevation	1.2 m
Specific humidity (kg kg <sup>-1</sup> )	MORECS vapour pressure, air temperature	IHDTM elevation	Lapsed to IHDTM elevation  Constant air pressure	1.2 m
Downward LW radiation (W m <sup>-2</sup> )	MORECS air temperature, vapour pressure, sunshine hours	IHDTM elevation	Constant cloud base height	1.2 m
Downward SW radiation (W m <sup>-2</sup> )	MORECS sunshine hours	IHDTM elevation  Spatially-varying aerosol correction	No time-varying aerosol correction	1.2 m
Wind speed (m s <sup>-1</sup> )	MORECS wind speed	ETSU average wind speeds	Wind speed correction is constant	10 m
Precipitation (kg m <sup>-2</sup> s <sup>-1</sup> )	CEH-GEAR precipitation	-	No transformations performed	n/a
Daily temperature range (K)	CRU TS 3.21 daily temperature range	-	No spatial interpolation from 0.5° resolution.  No temporal interpolation (constant values for each month)	1.2 m

---

Surface air pressure (Pa)	WFD air pressure	IHDTM elevation	Mean-monthly values from WFD used (each year has same values). Lapsed to IHDTM elevation. No temporal interpolation (constant values for each month).	n/a
---------------------------	------------------	-----------------	---	-----

---

1185  
1186

1187 Table 2: Rate of change of annual means of meteorological and potential evapotranspiration  
 1188 variables in Great Britain. Bold indicates trends that are significant at the 5% level. The  
 1189 ranges are given by the 95% CI.

Variable	Rate of change $\pm$ 95% CI				
	Great Britain	England	Scotland	Wales	English lowlands
Air temperature (K dec <sup>-1</sup> )	<b>0.21 <math>\pm</math> 0.15</b>	<b>0.23 <math>\pm</math> 0.14</b>	<b>0.17 <math>\pm</math> 0.12</b>	<b>0.21 <math>\pm</math> 0.15</b>	<b>0.25 <math>\pm</math> 0.17</b>

1190

1191 Table 3. Contributions to the rate of change of PET and its radiative and aerodynamic  
 1192 components. For each variable, the first column shows the contribution calculated using  
 1193 regional averages, along with the associated 95% CI. The second column shows the  
 1194 contribution calculated at 1 km resolution, then averaged over each region. The uncertainty on  
 1195 this value is difficult to calculate as the pixels are highly spatially correlated, so the  
 1196 uncertainty range from the regional analysis is used in Fig. 13.

a) Contribution to rate of change of PET ( $\text{mm d}^{-1} \text{decade}^{-1}$ )												
	Air temperature		Specific humidity		Wind speed		Downward LW		Downward SW		Total

1197

1198

1199 Table 4. Contribution of the trend in each variable to the trends in annual mean PET and its  
 1200 radiative and aerodynamic components as a percentage of the fitted trend in PET and its  
 1201 components.

a) Potential evapotranspiration (PET)						
	Air temperature	Specific humidity	Wind speed	Downward LW	Downward SW	Total
England	154 %	-88 %	-22 %	17 %	47 %	108 %
Scotland	150 %	-74 %	-23 %	26 %	18 %	97 %
Wales	200 %	-130 %	-38 %	28 %	50 %	109 %
English lowlands	142 %	-77 %	-20 %	15 %	45 %	105 %
Great Britain	155 %	-87 %	-23 %	19 %	31 %	96 %
b) Radiative component of PET						
	Air temperature	Specific humidity	Wind speed	Downward LW	Downward SW	Total
England	-47 %	n/a	40 %	28 %	71 %	92 %
Scotland	-42 %	n/a	62 %	46 %	36 %	102 %
Wales	-34 %	n/a	69 %	29 %	52 %	116 %
English lowlands	-53 %	n/a	35 %	27 %	86 %	95 %
Great Britain	-44 %	n/a	46 %	31 %	53 %	87 %
c) Aerodynamic component of PET						
	Air temperature	Specific humidity	Wind speed	Downward LW	Downward SW	Total
England	245 %	-115 %	-48 %	n/a	n/a	82 %
Scotland	68 %	-14 %	-33 %	n/a	n/a	21 %
Wales	-135 %	72 %	-42 %	n/a	n/a	-105 %
English lowlands	282 %	-126 %	-47 %	n/a	n/a	109 %
Great Britain	168 %	-76 %	-44 %	n/a	n/a	48 %

1202  
 1203

1204 Table A1. Details of sites used for validation of meteorological data.

Site (ID)	Latitude	Longitude	Years	Land cover	Citation
Alice Holt (UK-Ham)	51.15	-0.86	2004-2012	Deciduous broadleaf woodland	(Wilkinson et al., 2012; Heinemeyer et al., 2012)
Griffin Forest (UK-Gri)	56.61	-3.80	1997-2001, 2004-2008	Evergreen needleleaf woodland	(Clement, 2003)
Auchencorth Moss (UK-AMo)	55.79	-3.24	2002-2006	Grass and crop	(Billett et al., 2004)
Easter Bush (UK-EBu)	55.87	-3.21	2004-2008	Grass	(Gilmanov et al., 2007; Soussana et al., 2007)

1205

Table A2. Correlation statistics for meteorological variables with data from four sites.

a) Air temperature			
Site	$r^2$	Mean bias	RMSE
Alice Holt	0.95	0.10 K	1.17 K
Griffin Forest	0.94	0.21 K	1.17 K
Auchencorth Moss	0.98	-0.02 K	0.78 K
Easter Bush	0.97	-0.46 K	0.96 K
b) Downward SW radiation			
Site	$r^2$	Mean bias	RMSE
Alice Holt	0.94	-3.01 W m <sup>-2</sup>	22.92 W m <sup>-2</sup>
Griffin Forest	0.85	-4.90 W m <sup>-2</sup>	31.29 W m <sup>-2</sup>
Auchencorth Moss	0.91	14.27 W m <sup>-2</sup>	27.96 W m <sup>-2</sup>
Easter Bush	0.88	5.73 W m <sup>-2</sup>	27.15 W m <sup>-2</sup>
c) Mixing ratio			
Site	$r^2$	Mean bias	RMSE
Alice Holt	0.90	-0.02 mmol mol <sup>-1</sup>	1.09 mmol mol <sup>-1</sup>
Griffin Forest	0.76	0.08 mmol mol <sup>-1</sup>	1.56 mmol mol <sup>-1</sup>
d) Wind speed			
Site	$r^2$	mean bias	RMSE
Alice Holt	0.88	1.24 m s <sup>-1</sup>	1.45 m s <sup>-1</sup>
Griffin Forest	0.59	1.36 m s <sup>-1</sup>	1.81 m s <sup>-1</sup>
Auchencorth Moss	0.63	-0.38 m s <sup>-1</sup>	1.37 m s <sup>-1</sup>
Easter Bush	0.82	0.44 m s <sup>-1</sup>	1.03 m s <sup>-1</sup>
e) Surface air pressure			
Site	$r^2$	Mean bias	RMSE
Griffin Forest	0.05	-0.42 hPa	1.38 hPa
Auchencorth Moss	0.01	-1.06 hPa	1.57 hPa
Easter Bush	0.03	0.01 hPa	1.33 hPa

1208

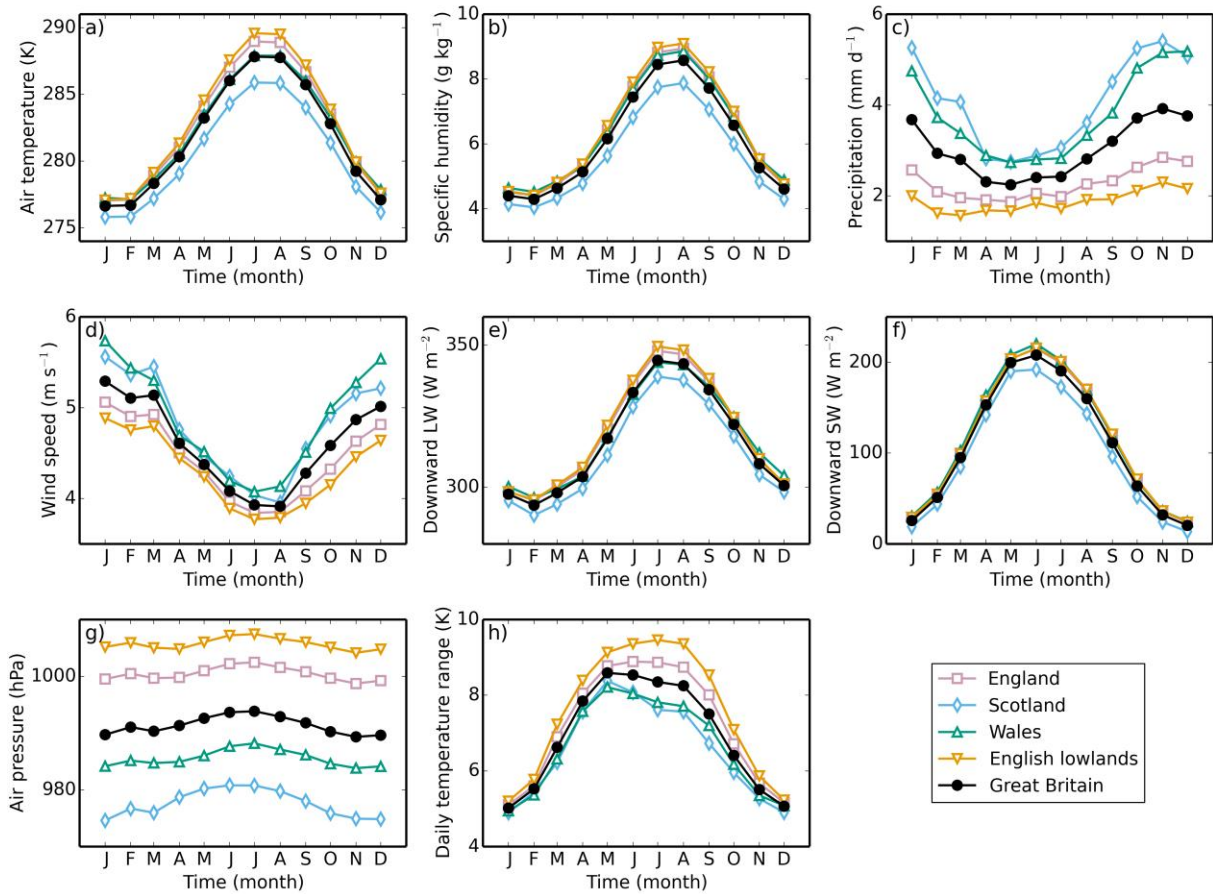

1209 Figure 1. Means of the meteorological variables over the years 1961-2012. The variables are  
 1210 a) 1.2 m air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e)  
 1211 downward LW radiation, f) downward SW radiation, g) surface air pressure, h) daily air  
 1212 temperature range.

1213

1214 Figure 2. The regions used to calculate the area means. The English lowlands are a sub-region

1215 of England. England, Scotland and Wales together form the fifth region, Great Britain.

1216

1217 Figure 3. Mean monthly climatology of meteorological variables, a) 1.2 m air temperature, b)  
 1218 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f)  
 1219 downward SW radiation, g) surface air pressure, h) daily air temperature range, for five  
 1220 different regions of Great Britain, calculated over the years 1961-2012.

1221

1222

1223 Figure 4. Plot of data set air temperature against daily mean air temperature at four sites. The  
 1224 dashed line shows the one to one line, while the solid line shows the linear regression, the  
 1225 equation of which is shown in the lower right of each plot, along with the  $r^2$  value, the mean  
 1226 bias and the RMSE. The sites are a) Alice Holt; b) Griffin Forest; c) Auchencorth Moss; d)  
 1227 Easter Bush.

1228

1229

1230

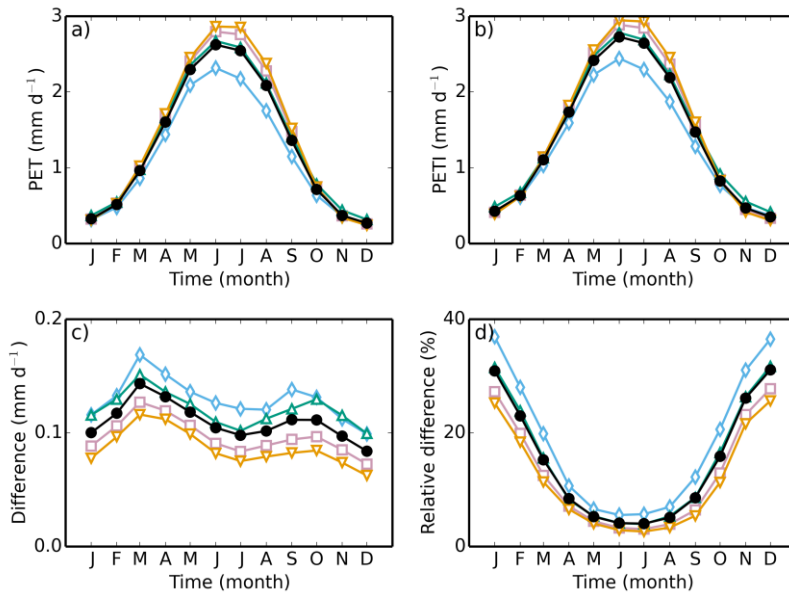

1231 Figure 5. Mean monthly climatology of the dataset (blue, solid lines) and observed air  
1232 temperatures (black, dashed lines), calculated for the period of observations. The thicker lines  
1233 show the means, while the thinner lines show the standard errors on each measurement. Sites  
1234 as in Fig. 4.

1235

1236

1237 Figure 6. Mean a) PET, b) PETI, c) absolute difference between PETI and PET and d) relative  
 1238 difference calculated over the years 1961-2012.

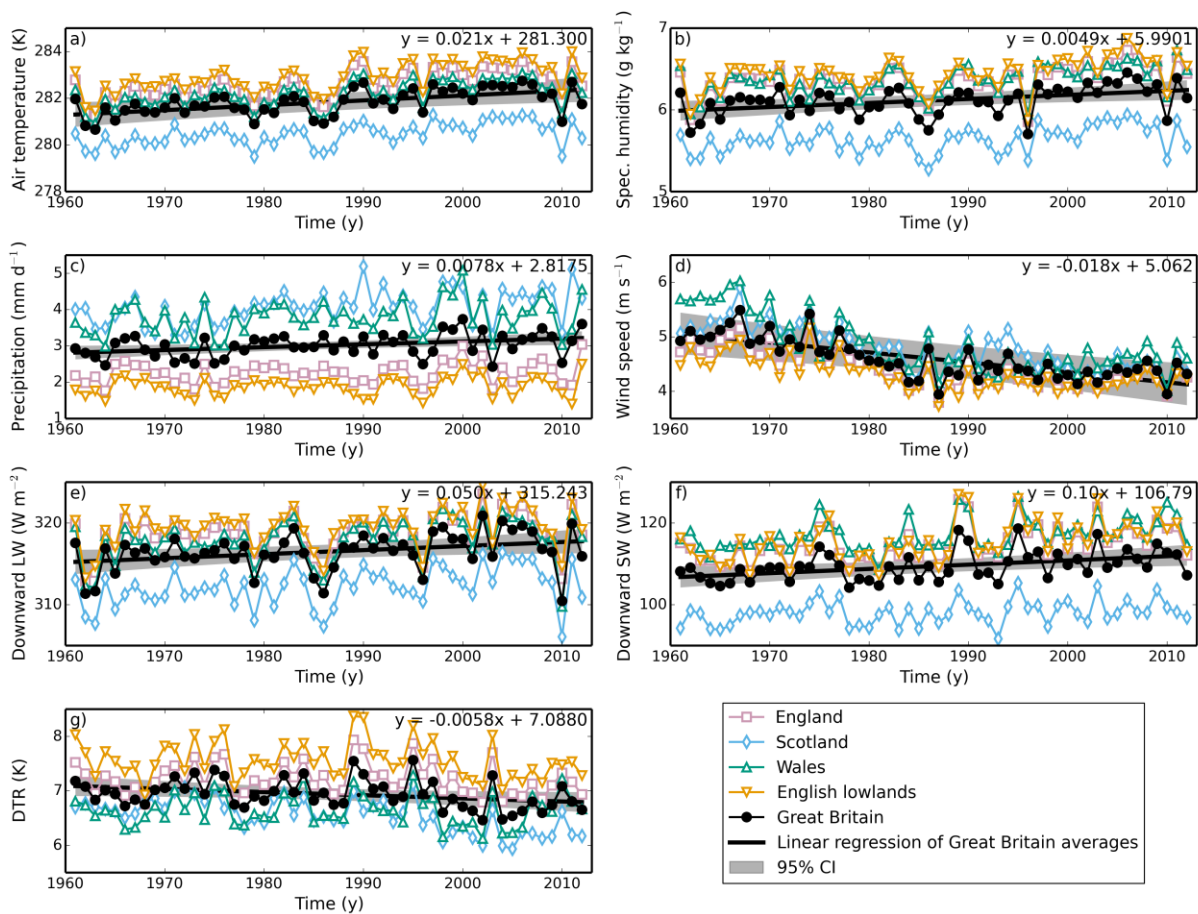

1239

1240 Figure 7. Mean monthly climatology of a) PET, b) PETI, c) absolute difference between PETI  
 1241 and PET, d) relative difference, for five different regions of Great Britain, calculated over the  
 1242 years 1961-2012. Symbols as in Fig. 3.

1243

1244 Figure 8. Mean-monthly climatology of the a) radiative and b) aerodynamic components of the  
 1245 PET for five different regions of Great Britain, calculated over the years 1961-2012. Symbols  
 1246 as in Fig. 3.

1247

1248 Figure 9. Annual means of the meteorological variables, a) 1.2 m air temperature, b) 1.2 m  
 1249 specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f)  
 1250 downward SW radiation, g) daily air temperature range, over five regions of Great Britain. The  
 1251 solid black lines show the linear regression fit to the Great Britain annual means, while the grey  
 1252 strip shows the 95% CI of the same fit, assuming a non-zero lag-1 correlation coefficient. The  
 1253 equation of this fit is shown in the top right-hand corner of each plot.

1254

1255 Figure 10. Annual means of a) PET and b) PETI for five regions of Great Britain. Symbols as  
 1256 in Fig. 9.

1257

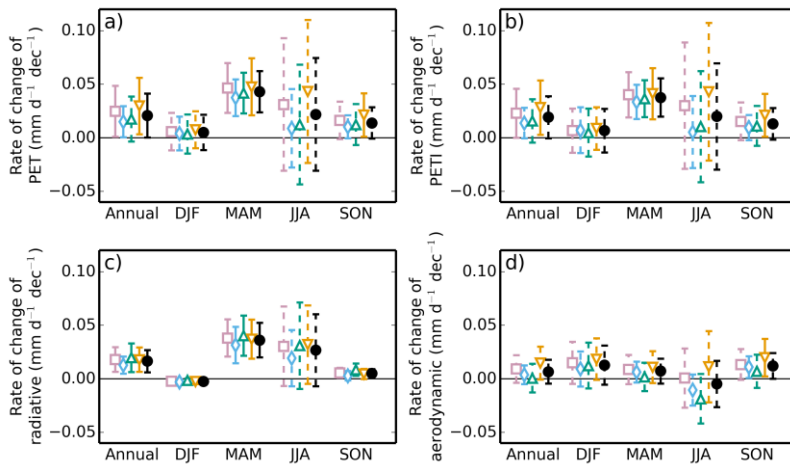

1258

1259 Figure 11. Rate of change of annual and seasonal means of meteorological variables, a) 1.2 m  
 1260 air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward  
 1261 LW radiation, f) downward SW radiation, g) daily air temperature range, for five regions of  
 1262 Great Britain for the years 1961-2012. Error bars are the 95% CI calculated assuming a non-  
 1263 zero lag-1 correlation coefficient. Solid error bars indicate slopes that are statistically significant  
 1264 at the 5% level, dashed error bars indicate slopes that are not significant at the 5% level.

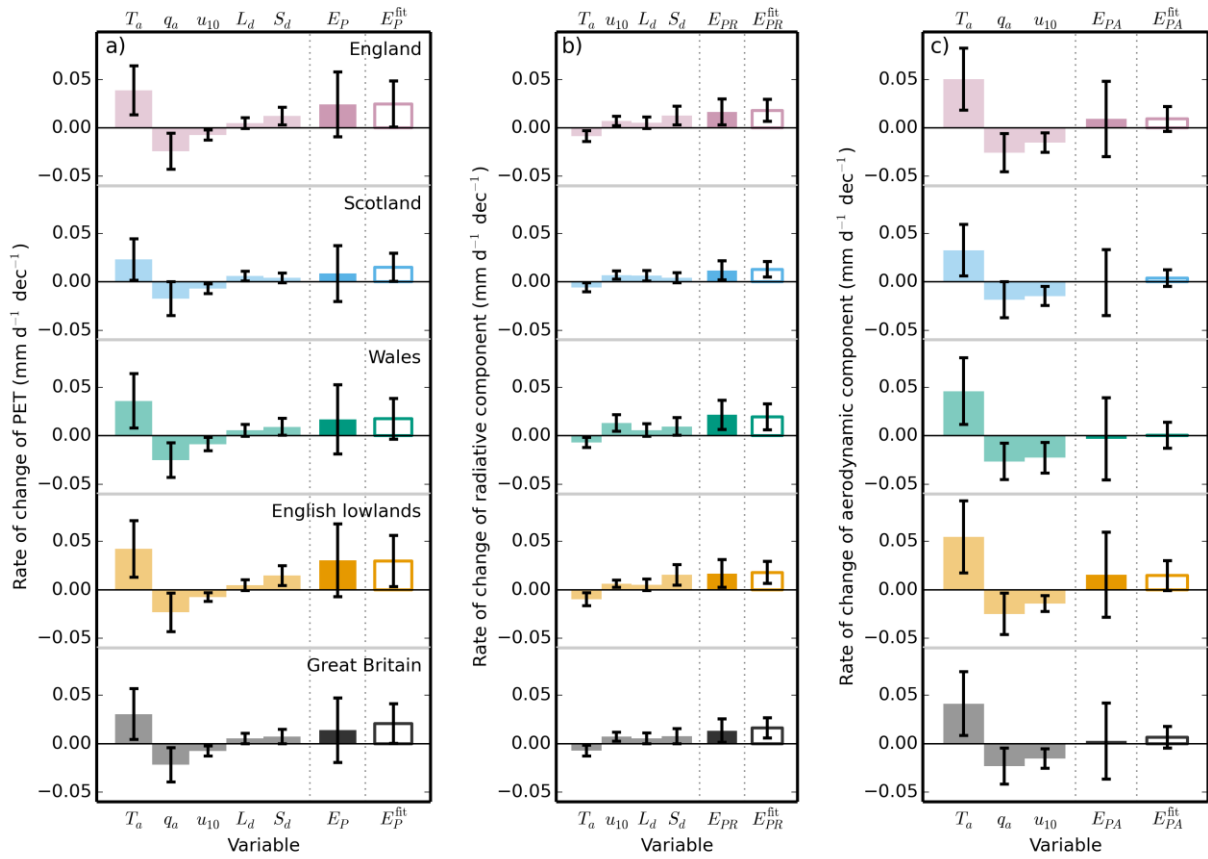

1265

1266

1267 Figure 12. Rate of change of annual and seasonal means of a) PET, b) PETI, c) the radiative  
 1268 component of PET and d) the aerodynamic component of PET for five regions of Great Britain  
 1269 for the years 1961-2012. Symbols as in Fig. 11.

1270

1271 Figure 13. The contribution of the rate of change of each meteorological variable to the rate of  
 1272 change of a) PET, b) the radiative component and c) the aerodynamic component. The first five  
 1273 (four; three) bars are the contribution to the rate of change of annual mean PET from the rate  
 1274 of change of each of the variables, calculated per pixel, than averaged over each region. Each  
 1275 bar has an error bar showing the 95% CI on each value. Since the pixels are highly spatially  
 1276 correlated, we use the more conservative CI calculated by applying this analysis to the regional  
 1277 means. The next bar is the sum of the other bars and shows the attributed rate of change of  
 1278 annual mean PET. The final bar shows the slope and its associated CI obtained from the linear  
 1279 regression of the mean annual PET for each region.

1280

1281

1282 Figure A1. Plot of data set downward SW radiation against daily mean downward SW radiation

1283 at four flux sites. Symbols and sites as in Fig. 4.

1284

1285

1286

1287 Figure A2. Mean monthly climatology of the dataset (blue, solid lines) and observed air  
1288 temperatures (black, dashed lines), calculated for the period of observations. Symbols as in Fig.  
1289 5, sites as in Fig. 4.

1290

1291

1292 Figure A3. Plot of mixing ration calculated using dataset meteorology against daily mean  
 1293 observed mixing ratio at four sites. Symbols as in Fig. 4. The sites are a) Alice Holt and b)  
 1294 Griffin Forest.

1295

1296

1297

1298 Figure A4. Mean monthly climatology of the dataset (blue, solid lines) and observed mixing  
1299 ratio (black, dashed lines), calculated for the period of observations. Symbols as in Fig. 5. Sites  
1300 as in Fig. A3.

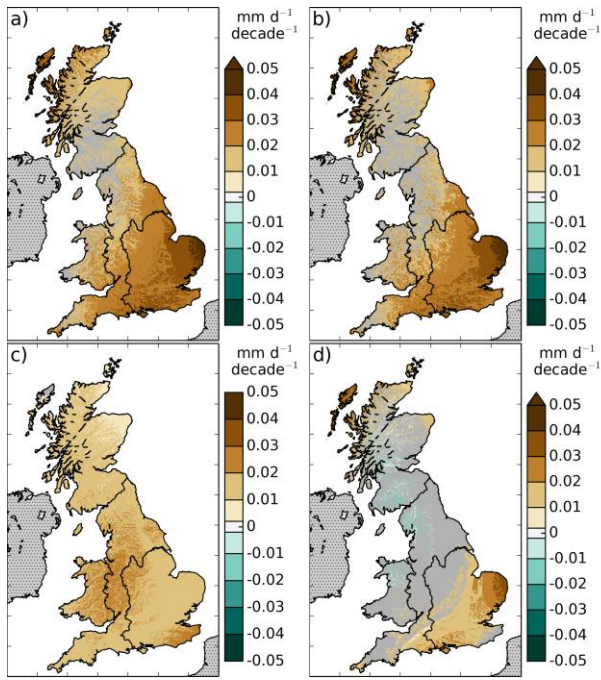

1301

1302

1303 Figure B1. Rate of change of the meteorological variables, a) 1.2 m air temperature, b) 1.2 m  
 1304 specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f)  
 1305 downward SW radiation, g) surface air pressure, h) daily air temperature range over the period  
 1306 1961-2012. Areas for which the trend was not significant are shown in grey.

1307

1308

1309 Figure B2. Rate of change of a) PET, b) PETI, c) the radiative component of PET, d) the  
 1310 aerodynamic component of PET over the period 1961-2012. Areas for which the trend was  
 1311 not significant are shown in grey.
