23 **Abstract**

24 Surface disturbances above a cave have the potential to impact cave dripwater discharge,
25 isotopic composition and solute concentrations, which may subsequently be recorded in the
26 stalagmites forming from these dripwaters. One such disturbance is wildfire, however the
27 effects of wildfire on cave chemistry and hydrology remains poorly understood. Using
28 dripwater data monitored at two sites in a shallow cave, beneath a forest, in southwest
29 Australia, we provide one of the first cave monitoring studies, conducted in a post-fire
30 regime, which seeks to identify the effects of wildfire, and post-fire vegetation dynamics, on
31 dripwater $\delta^{18}\text{O}$ composition and solute concentrations. We compare our post-wildfire $\delta^{18}\text{O}$
32 data with predicted dripwater $\delta^{18}\text{O}$ using a forward model based on measured hydro-climatic
33 influences alone. This will help to delineate hydro-climatic and fire-related influences on
34 $\delta^{18}\text{O}$. Further we also compare our data with both data from Golgotha Cave - which is in a
35 similar environment but was not influenced by this particular fire - as well as regional
36 groundwater chemistry, in an attempt to determine the extent to which wildfire affects
37 dripwater chemistry. We find in our forested, shallow cave, $\delta^{18}\text{O}$ is higher after the fire
38 relative to modelled $\delta^{18}\text{O}$. We attribute this to increased evaporation due to reduced albedo
39 and canopy cover. While the solute response post-fire varied between the two drip sites: at
40 Site 1a, which had a large tree above it but was lost in the fire, we see a response reflecting
41 both a reduction in tree-water use and a removal of nutrients (Cl, Mg, Sr and Ca) from the
42 surface and subsurface. Solutes such as SO_4 and K maintain a high concentration, which we
43 believe is due to the abundance of above ground ash. At Site 2a, which was covered by
44 lower-middle storey vegetation, we see a solute response reflecting evaporative concentration
45 of all studied ions (Cl, Ca, Mg, Sr, SO_4 and K) similar to the trend in $\delta^{18}\text{O}$ for this drip site.
46 We open a new avenue for speleothem science in fire-prone regions, focusing on the
47 geochemical records of speleothems as potential paleo-fire archives.

48 **1 Introduction**

49 Caves are observatories, that preserve invaluable geochemical archives of past-climates; in
50 the form of speleothems (stalagmites, stalactites and flowstones). The existing paradigm in
51 speleothem science has largely focused on establishing paleoclimate proxies in stalagmites
52 (e.g. McDermott et al., 2001; Treble et al., 2008; Woodhead et al., 2010). While these proxies
53 are useful for reconstructing paleoclimates, their interpretations may hold a predisposed bias
54 towards using these proxies as indicators of paleoclimate only.

55 To avoid this bias, we need to consider the sensitivity of these proxies to the effects of local
56 environmental factors like in our case, fire. This is especially important as incorporating this
57 perspective may not only be used to correct the climate proxy interpretation, but also yield
58 novel information about paleo-environments. Paleo-environmental proxies are verified by
59 conducting process-based in-cave monitoring studies. However, in-cave monitoring has
60 predominantly focused on understanding the extent to which dripwater $\delta^{18}\text{O}$ (Lachniet,
61 2009), dripwater solute concentrations (Fairchild and Treble, 2009), speleothem calcite
62 growth (Wong et al., 2011) and cave CO_2 processes (Breecker et al., 2012), are affected by
63 climate. Further, such studies have largely been restricted to mid to high latitude climate
64 regions where precipitation (P) is larger than actual evapotranspiration (AET), and climate is
65 likely to be a major control on dripwater composition.

66 In water-limited regions, dripwater chemistry is influenced to a greater extent by
67 environmental factors such as evaporation (E) (Pape et al., 2010; Cuthbert et al., 2014;
68 Rutledge et al., 2014) and transpiration (T), (Tremaine and Froelich, 2013; Treble et al.,
69 2016). Wildfires, common in water-limited regions, are agents of change than can
70 dramatically alter evaporation and transpiration rates by destroying vegetation. The potential
71 impacts of vegetation loss from fire are both short-term and long-term. The short-term

72 impacts could include: (1) an increase in evaporation rates due to changes in albedo and/or
73 lack of shading (Silberstein et al., 2013); (2) a reduction in transpiration from reduced tree
74 water use; (3) a reduction in soil microbial and root CO₂ production (Coleborn et al., 2016);
75 (4) a decrease in cave CO₂ due to the destruction of vegetation (Wong et al., 2010), which
76 could influence in-cave prior calcite precipitation (PCP); (5) the addition of plant ash to the
77 soil profile, increasing concentrations of Ca, K, Mg, and S (Grove et al., 1986; Yusiharni and
78 Gilkes, 2012a); and (6) altered infiltration patterns (González-Pelayo et al., 2010). While
79 long-term impacts include: (1) the spatial redistribution of nutrients (Abbott and Burrows,
80 2003); (2) regrowth impacts on water balance and nutrient flux (Treble et al., 2016); and (3) a
81 reduction in total soil CO₂ due to the destruction of CO₂ sequestering microbial communities
82 and plant roots, both significant sources of soil CO₂ (Coleborn et al., 2016). Despite the fact
83 that wildfires regularly affect water-limited regions, their impacts on $\delta^{18}\text{O}$ and solute
84 concentrations in cave dripwater have not been reported.

85 We analyse the composition of cave dripwater over five years (August 2005 - March 2011) of
86 cave monitoring in Yonderup Cave, a shallow cave system, in southwest Australia. Our
87 monitoring followed an intense wildfire in February 2005 that burnt 1200 ha of Yanchep
88 National Park. The fire was hot enough to calcine and fracture the limestone observed at the
89 caves entrance (Supplementary Fig. 1). We compare our monitoring data to the regional
90 groundwater geochemistry and published monitoring data (Treble et al. 2015) from Golgotha
91 Cave in southwest Australia (lat. 36.10° S, long. 115.05° E). Our analysis provides one of the
92 first analyses of the response of dripwater $\delta^{18}\text{O}$ and solute concentrations to post-wildfire
93 conditions in shallow caves located in the tree rooting zone.

94

95 **2 Site description**

96 Our study was conducted in Yonderup Cave in Yanchep National Park (lat 31.5475° S, long
97 115.6908° E), 20 km north of Perth, southwestern Australia (Fig. 1A). This region has a
98 Mediterranean climate characterised by dry hot summers and cold wet winters with a 25-year
99 (1990 to 2015) average annual surface temperature of 15.1°C and rainfall of 664 mm with
100 85% of rainfall falling between May and October. Yonderup Cave is located in the young
101 Quaternary Tamala Limestone Formation, a porous, partially lithified calcareous coastal dune
102 sand. This karst process is said to be “syngenetic” with karstification occurring
103 simultaneously with lithification of the host rock (Jennings, 1964; Fairchild and Baker,
104 2012).

105 Yonderup Cave is situated in a tuart forest (*Eucalyptus gomphocephala*), with mature tuart
106 trees 30 m high, and an understory of shrubs and trees standing 5-10 m high, Sheoak trees
107 (*Allocasuarina fraseriana*) approx. 5-15 m high, and Balga trees (*Banksia attenuata*, *Banksia*
108 *menziesii*, *Banksia grandis*, *Allocasuarina fraseriana*, *Xanthorrhoea pressii*). Tree roots are
109 exposed in the cave, both in the roof (fine roots), and cave floor (thick tap roots). In February
110 2005, the area above the cave was burnt in an intense wildfire (Fig. 1B, Department of Parks
111 and Wildlife, pers. comm., 2015), substantially modifying vegetation above the cave
112 including the death of mature trees and complete removal of canopy and understorey.

113 Over the period of August 2005 to March 2011, two drip sites in Yonderup Cave (Site 1a and
114 Site 2a), were monitored for their chemical and hydrological variations. These two sites are
115 22.8 m apart (Site 2a east of Site 1a, ~ 1 m slope towards the East), located at similar depths
116 below the surface (~ 4 m) within the same chamber (~ 7 m height) and partially separated by
117 a large boulder fall-in. We use an existing cave survey to determine the location of each cave
118 drip site relative to the ground surface (Fig. 1C). A soil depth survey was conducted within 5
119 m of each site (Supp. Table 3), along with visual vegetation/ground surface observations

120 post-fire. Soil depths were measured every meter with a dynamic soil penetrometer in north,
121 south, east and west directions and averaged soil depth above each site were calculated.

122 Site 1a, 30 m from the cave entrance, has a drip source within a large cluster of soda-straw
123 stalactites known as the 'Wheatfield' (Supp. Figure 2B). This circular feature is
124 approximately 1 m across and as it appears in an otherwise very sparsely decorated part of the
125 ceiling, suggesting that it represents a focused flow path into the cave. The land surface
126 above this site is flat with 70% coverage by shallow soil (average 124 mm thickness) and the
127 remaining surface is exposed bedrock (approx. 30%). A tuart tree, located directly above Site
128 1a, burnt and collapsed during the 2005 wildfire which resulted in the entire removal of
129 canopy cover above Site 1a. No other trees are close enough to provide shade on the surface
130 above Site 1a.

131 In contrast, Site 2a situated 50 m from the cave entrance is in a highly decorated part of the
132 cave known as the 'Cathedral' characterised by large icicle shaped stalactites. Above Site 2a,
133 the soil cover is thicker (200 mm) and more homogenous with no bedrock exposure, and no
134 trees directly above, however there is a partial canopy cover from adjacent trees ~15 m away.

135

136 **3 Data collection**

137 Cave dripwater was collected from 1L high-density polyethylene (HDPE) collection vessels
138 at the two sites Site 1a and Site 2a between August 2005 and March 2011 (~5.5 years) at
139 approximately bi-monthly intervals. The water was separated into three aliquots: two aliquots
140 were filtered with 0.45 μm mixed-cellulose filters into two 50 ml polypropylene bottles for
141 major and minor ion determination; the third was stored with zero-headspace in a 12 ml
142 amber glass bottle for stable isotopes. All aliquots were refrigerated below 5°C until analysis.
143 Anion concentrations (Cl and SO_4) were determined using a Dionex DX-600 ion

144 chromatograph with self-regenerating suppressor on one aliquot. The second aliquot was
145 acidified to 2% HNO₃ in the collection bottle and used for cation concentrations (Ca, K, Mg,
146 Na, Si and Sr) using a Thermo Fisher inductively coupled plasma-atomic emission
147 spectrometer (ICP-AES) ICAP7600 at the Australian Nuclear Science and Technology
148 Organisation (ANSTO) facility. An internal standard with concentrations approximating the
149 cave waters was included in each cation batch to check for between-run reproducibility.

150 Dripwaters collected between August 2005 and May 2008 were analysed for $\delta^{18}\text{O}$ using
151 Isotope-Ratio Mass Spectrometry (IRMS) at the Australian National University (see Treble et
152 al., 2013 for method). The remaining dripwaters were analysed for $\delta^{18}\text{O}$ and $\delta^2\text{H}$ at ANSTO
153 using the Cavity Ring Down Spectroscopy (CRDS) method. Additionally, as there was
154 sufficient remaining water in the stored aliquots analysed by IRMS for Site 2a, these were
155 also re-analysed using CRDS to obtain a complete time series for $\delta^2\text{H}$. After Jan 2007
156 dripwater volume at Site 1a became insufficient to collect all three aliquots. Collections of
157 aliquots were prioritised in the following order: 1) stable isotopes; 2) cations and; 3) anions.

158 At each cave visit for dripwater sampling, drip rates were manually recorded using a
159 stopwatch and the level of water accumulated in the bottles was recorded to the nearest 100
160 ml. Weekly discharge was estimated using a drip volume of 0.2 ml per drip (Collister and
161 Matthey, 2008). When timing drip intervals became impractical, only the bottle level was
162 recorded. Thus in order to represent the data in common units we needed to use the Collister
163 and Matthey, 2008 drip volume in order to convert all our discharge data into volume data. We
164 use both sets of measurements from the overlapping period to convert volume to discharge
165 for when direct measurements for drip interval using the stop watch were lacking. The
166 calculations are provided in the supplementary info as excel sheets.

167 To distinguish dry and wet periods we applied a residual mass curve (RMC), (Hurst, 1951) to
168 monthly P - AET data. The RMC is the cumulative sum of the monthly anomaly calculated
169 from the 22 year mean and used to generate a time series of cumulative potential water
170 surplus or deficit starting from Jan 2000, highlighting trends in above average or below
171 average P – AET, we refer to this calculation as cumulative water balance (CWB) throughout
172 the rest of this paper.

173 Unpublished monthly $\delta^{18}\text{O}$ and $\delta^2\text{H}$ rainfall data (2005 – 2011) from Perth were obtained
174 from ANSTO. We used modelled regional precipitation (P) and actual evapotranspiration
175 (AET/F_{WE} is the sum of soil evaporation and transpiration by vegetation based on Priestly-
176 Taylor equations) from the Australian Water Availability Project (AWAP) (Raupach et al.,
177 2009; Raupach et al., 2011) with monthly parameters, to determine P – AET. AWAP
178 precipitation (P), actual evapotranspiration (AET/F_{WE}) and rainfall $\delta^{18}\text{O}$ data were then used
179 as input to the forward model (detailed in the next section) to predict cave dripwater $\delta^{18}\text{O}$
180 composition under various hydro-climatic scenarios. Predictions are based solely on P - AET
181 data which are then compared to the dripwater observations.

182 Monthly rainfall $\delta^{18}\text{O}$ and $\delta^2\text{H}$ compositions were amount weighted and fitted with a linear
183 regression (Hughes and Crawford, 2012) and compared to the long-term groundwater mean
184 obtained from Turner and Thorpe (2001) and the cave dripwater to determine whether
185 evaporation has affected cave dripwater isotopic composition (see section 4).

186 Post-fire solute and $\delta^{18}\text{O}$ data from Yonderup Cave dripwater are also compared to other
187 relevant published data. These include, long term Perth rainfall $\delta^{18}\text{O}$ from Turner and Thorpe
188 (2001), and local Yanchep rainfall solute data from Hingston and Gailitis, (1976), and
189 published dripwater data from Golgotha Cave, located 300 km south of Yanchep. Golgotha
190 Cave has been monitored since 2005 (Treble et al. 2013; 2015; 2016; Mahmud et al 2015).

191 The climate at Golgotha Cave is also Mediterranean, but receives annual mean rainfall of
192 approx. 795 mm, which is 23% higher than Yanchep. Both caves are located within the
193 Tamala Limestone Formation, however the caves vary in depths: Golgotha Cave is
194 significantly deeper than Yonderup approx. 30 - 35 m. Golgotha Cave is covered by a more
195 extensive forest of mixed marri/karri (*Eucalyptus calophylla* / *Eucalyptus diversicolor*) trees
196 and this site has not experienced an intense wildfire since 1992 and no prescribed burns since
197 2006. However, the prescribed burn at Golgotha Cave was much less intense and it was more
198 controlled than the fire that is reported in our study.

199

200 **4 Forward model**

201 We use the forward model employed by Baker et al., (2010). This model uses monthly
202 rainfall $\delta^{18}\text{O}$, monthly (P – AET), from 2003 to 2011 (we use 2003 to 2005 data as a ‘warm
203 up’ period to avoid edge effects), and adjustable bedrock flow thresholds for seepage flow
204 and fracture flow to predict dripwater $\delta^{18}\text{O}$ based on hydro-climatic influences. Seepage flow
205 and fracture flow thresholds are hydrological P - AET thresholds that are required for
206 infiltrating water to enter seepage or fracture reservoirs (for further details see Baker and
207 Bradley, 2010). The Tamala Limestone, retains high primary porosity thus seepage flow is
208 likely to be dominant whilst fracture flow is less dominant and only likely to be activated
209 during high infiltration (Treble et al., 2013; Mahmud et al., 2015).

210 Water that enters the seepage reservoir is modelled as a Gaussian distribution. A maximum
211 residence time of 3 years is set; this reflects the dominating seepage or matrix flow type at
212 our site, the shallow depth (4 m) and the potential for capillary barrier effects to impact
213 hydrology in this region (Mahmud et al., 2015). Further a minimum residence time of 10
214 months is required, to maintain the observed year round discharge at both sites. The model

215 allows for the mean and standard deviation to be specified for these functions. Being
216 conservative we specify the minimum residence time of 10 ± 2 months. In contrast, the
217 fracture-fed flow is instantaneously passed through the system (i.e. with a travel time of less
218 than one month). In the model we can adjust the (P – AET) thresholds required for flow into
219 the seepage reservoir and the threshold required for it to spill into the fracture flow. The
220 seepage and fracture-fed components are mixed in the overlying bedrock reservoir, before
221 predicting dripwater $\delta^{18}\text{O}$ composition. By request the authors can supply the forward model
222 as a spread sheet.

223 We tested a full range of seepage and fracture possibilities. This suite of model runs helps to
224 place constraints on $\delta^{18}\text{O}$ variability that can be explained by hydro-climatic variability alone.
225 We compare these scenarios to the observed dripwater $\delta^{18}\text{O}$ at our sites, to assist in our
226 interpretation of the post-fire dripwater $\delta^{18}\text{O}$ response.

227 **5 Results**

228 A time series of monthly P – AET, cumulative water balance (CWB), discharge, dripwater
229 $\delta^{18}\text{O}$, and ion concentrations for Sites 1a and 2a from August 2005 – March 2011 are shown
230 in Figure 2.

231

232 **5.1. Water balance**

233 Firstly, we observe a distinct seasonality in the water availability (P – AET) (Fig. 2A), where
234 winter months generate an excess (P > AET), while summer months generate a deficit (P <
235 AET). Further, CWB shows three distinct trends throughout the monitoring period: 1) a
236 decline over the period of January 2006 to June 2006, consistent with very low excess in P -
237 AET; 2) an overall rise from June 2006 to February 2010; 3) a decrease in P - AET from
238 February 2010 to September 2010. Site 1a and 2a display moderate and similar discharge
239 rates, at the start of the monitoring period that continue until July 2006; Site 1a an average of
240 90 ml \pm 21 per week and Site 2a an average of 92 ml \pm 23 per week. This coincides with
241 infiltration indicated by positive CWB (Fig. 2B). In July 2006, Site 1a dramatically increased
242 discharge five-fold to 468 ml/week on one cave visit, but had decreased to 55 ml \pm 3 ml per
243 week on the subsequent visit two weeks later and was completely dry, three months later.
244 This site has not re-activated since (Department Parks and Wildlife, pers. comm.). Site 2a
245 shows much less variation in discharge overall, but contains smooth long-term trends. Two
246 periods of higher discharge are observed in August 2005 to May 2006 (average 92 ml \pm 23
247 ml per week) and April 2008 to February 2009 (average 93 ml \pm 29 ml per week), both
248 coinciding with positive trends in CWB.

249

250

251 **5.2 Water isotopes**

252 Dripwater $\delta^{18}\text{O}$ from Site 1a (Fig. 2C) shows no seasonal pattern but we see a steady increase
253 of 1‰ to January 2007, then a further steeper rise of 1.5‰ in June 2007, after which the drip
254 ceases. Dripwater $\delta^{18}\text{O}$ from Site 2a presents an overall increasing trend rising from -3‰ to
255 +0.7‰ over the monitoring period with a 6-month quasi-seasonal signal (approx. 2‰ range)
256 that peaks in cooler months (June to October) generally coinciding with months when
257 infiltration from rainfall occurs. We hypothesise that the $P < \text{AET}$ environment in drier
258 summer months isotopically enriches soil water, but this only arrives at the cave when
259 seepage thresholds are exceeded in periods of $P > \text{AET}$ (winter months).

260

261 We forward modelled our rainfall isotopic data in order to predict drip-water $\delta^{18}\text{O}$ under
262 various hydro-climatic scenarios (Fig. 3). Our sensitivity analyses of hydrological residence
263 times and thresholds showed that seepage residence times, less than 10 months resulted in the
264 seasonal cessation of dripwater, which is not observed at our sites. Therefore, a minimum
265 seepage residence time is required to match our observations. Further, seepage threshold
266 values greater than 40 mm ($P - \text{AET}$) also resulted in the cessation of our drip site. Thus
267 seepage threshold must be below 40 mm ($P - \text{AET}$) to match our observation. Next we varied
268 the fracture threshold between 15 mm and 1000 mm, the wide range reflecting our
269 uncertainty over this parameter. However, we know that seepage flow is dominant at these
270 sites (Mahmud et al., 2015). This suggests two things, first, the seepage threshold is low,
271 second, the threshold required for water to ‘overflow’ from the seepage reservoir to fracture
272 reservoir must be significantly higher than the seepage threshold. We note that scenarios with
273 a lower fracture threshold (10 – 15 mm) show high variability in comparison to sites with a
274 seepage dominated flow and no fracture flow (10 – 1000 mm). Based on the variable

275 morphology of stalactites and stalagmites at our sites we interpret discharge to be a
276 combination of seepage and fracture flow, but with seepage clearly dominating. Hence we
277 chose the 15 – 100 mm scenario to represent the hydrology at our cave site (Fig. 3). Our
278 forward-modelled dripwater $\delta^{18}\text{O}$ mean is -4.1‰, slightly less than the mean of Perth rainfall
279 (-3.1‰). The time series of modelled dripwater $\delta^{18}\text{O}$ (Fig. 2C) starts and remains at ~ -4.2‰
280 until February 2006 where it dips slightly before rising sharply to -3‰ where it remains
281 steady until February 2007. Here it begins a step-wise decline; declining from February to
282 March 2007 by 0.5‰ and remaining stable again until February 2008. It then shows a further
283 step-decline in March 2008 to -4.5‰, where it remains at approximately this value, albeit
284 with a few small variations on timescales of months, until the end of the monitoring period.

285 In all meaningful modelled scenarios i.e. ones that have full year flow and test the full range
286 of hydrological variability, estimated dripwater $\delta^{18}\text{O}$ cannot replicate the higher observed
287 dripwater $\delta^{18}\text{O}$ which are +1‰ to +3‰ higher compared to modelled (Fig. 3). This clearly
288 suggests another factor is affecting dripwater $\delta^{18}\text{O}$ composition: likely near-surface
289 evaporation.

290

291 To investigate an evaporation effect, we plot cave dripwater along the local meteoric water
292 line (LMWL, weighted LSR) to test for isotopic enrichment (Fig. 4). Figure 4 shows that
293 while the least squares regression (LSR) for cave dripwater falls within the standard error (\pm
294 0.45‰) of the slope for the local meteoric water line (LMWL, weighted LSR), drip water
295 isotopic composition is concentrated towards heavier $\delta^{18}\text{O}$ and $\delta^2\text{H}$. These results are
296 consistent with evaporation in a high humidity environment as has been observed in semi-
297 arid cave environments elsewhere (e.g. Cuthbert et al., 2014). Adopting Cuthbert's
298 classification, our data falls under a *type 1* scenario reported in Cuthbert et al., (2014). In the

299 *type 1* scenario, $\delta^{18}\text{O}$ and $\delta^2\text{H}$ do not deviate from the LMWL but are shifted along the
300 LMWL towards higher values, as is the case with our data (Fig. 4). This means that our data
301 are similarly impacted by evaporation occurring in a high humidity environment.

302

303 **5.3 Water Solutes**

304 There are significant differences in solute concentrations and trends between the two sites
305 (Fig. 2E, 2F, 2G and 2H). Solute concentrations are typically higher at Site 1a versus Site 2a
306 and they demonstrate opposite trends post-fire. At Site 1a, Cl, Ca, Mg and Sr decline overall,
307 although this trend is step-wise for Ca, and reverses for Cl ~ 6 months before the drip ceases.
308 The trends in these solutes at Site 1a are inconsistent with the declining CWB during this
309 period (Fig 2A), as we would expect a drying trend reflected through the evaporative
310 concentration of solutes. In contrast at Site 2a, Cl and other solute concentrations show a
311 direct relationship to CWB (i.e. increasing solute concentration with decreasing CWB from
312 2006 until mid-2008 followed by decreasing solute concentrations with increasing CWB.

313 Trends in SO_4 and K are more subtle than for other solutes: at Site 1a, K shows a slight
314 decline from the beginning of the monitoring until early 2007 and then has a small rise prior
315 to drips ceasing. Although harder to judge in the shorter SO_4 time series, SO_4 also shows a
316 small rise before drips cease, similar to K. Trends in K and SO_4 for Site 2a are more subtle,
317 although they both increase slightly over time. K and SO_4 concentrations are, two to three
318 times higher at Site 1a versus Site 2a and are considerably higher than those recorded at
319 Golgotha Cave (Table 1). We also note that initial Cl and other solute concentrations at Site
320 1a are twice that at Site 2a.

321

322 **6 Discussion**

323

324 **6.1 Post-fire hydrology**

325 Discharge at Site 1a is inconsistent with CWB: discharge rose as rainfall fell below the long-
326 term mean ($P < AET$) (Fig. 2A and 2B), suggesting that Site 1a received a localised increase
327 in discharge despite the declining input from rainfall. In contrast, discharge at Site 2a is more
328 closely related to the cumulative water balance (CWB), with higher discharge coinciding
329 with periods of higher water surplus and lower discharge with lower water surplus.

330 Chloride is a chemically conservative and highly soluble solute (Graedel and Keene, 1996),
331 and its concentrations in dripwater will therefore reflect concentration/dilution effects (Tooth
332 and Fairchild, 2003; Tremaine and Froelich, 2013). Chloride concentrations at Site 2a
333 increase during the period of declining CWB (2006 to mid-2008) suggesting that evaporation
334 is concentrating Cl. Rising $\delta^{18}O$ and other solutes over this period are also consistent with
335 increased evaporation. From mid-2008 onwards, when CWB is positive ($P > AET$), Cl
336 decreases, consistent with an increase in infiltration and thus dilution (Fig. 2E).

337 At Site 1a higher discharge also coincides with falling Cl concentrations also suggesting
338 dilution (Fig. 2B, 2D). However, we note this coincides with a highly negative CWB i.e. drier
339 than normal conditions. This suggests in this case, a non-climatic driver has influenced
340 infiltration. We propose that a reduction in localised transpiration, following the 2005 fire,
341 may be driving this. Deeply-rooted trees within the area have been reported to produce high
342 Cl concentrations in the unsaturated zone (Turner et al., 1987). Site 1a had a tuart tree
343 directly above it and tree roots are visible above Site 1a in the cave, but not at Site 2a. The
344 proximity of the tree to Site 1a is the most likely explanation for the higher solute
345 concentrations here (Treble et al., 2016). The death of the tree in the 2005 fires would remove
346 the previous transpiration demand and hence result in effective dilution of the solutes during

347 infiltration, as observed. However, this reduction in transpiration would have been abrupt but
348 we observe a response lasting 1.5 years after the fire. This could be due to a number of
349 reasons; firstly, the minimum residence time is 10 months (for a year of continuous
350 discharge) so a delay in the response is to be expected. Second, this occurred during a period
351 in which the soil moisture deficit would have been larger than average, so a larger volume of
352 cumulative infiltration would be needed to overcome this deficit and move the more dilute
353 solute into the cave.

354 It is also possible the decrease in concentrations reflect the diminishing element
355 concentrations after an immediate flush of the more soluble ash-derived material (i.e. the tail
356 of a solute pulse). However, post-fire, highly soluble solutes like Cl, will still reflect dilution
357 due to increased discharge. So, it is likely that we are seeing a decline in these elements due
358 to a combination of the removal of these nutrients from the surface and subsurface, and
359 dilution.

360

361 In the broader context we look at the differences in Cl at Yonderup Cave vs Golgotha Cave.
362 Both caves are ~5 km from the coastline, so they likely have a similar amount of Cl aerosol
363 deposition. Yet, post-fire Cl values at Yonderup Cave, are more than double the Cl
364 concentrations from Golgotha Cave (Table 1). Further, within cave variability in Cl
365 concentrations at Yonderup Cave are twice that at Golgotha Cave (Table 2). While variations
366 in vegetation density (along with wildfire history) may have some role to play in the
367 difference in mean dripwater Cl at each location, the higher within cave variability at
368 Yonderup Cave (Table 2), suggests a post-fire setting increases variability in dripwater
369 chemistry. The impact of this is discussed further and a conceptual model (Fig. 6) devised
370 later in section 6.3.

371 **6.2 Post-fire carbonate chemistry**

372 Similar to Cl, concentrations of carbonate metals (Mg, Ca and Sr) at Site 1a also decrease;
373 this reflects solutes being diluted due to reduced tree water-use. However, we note that at Site
374 1a, Ca, for example, declines twice as much (in concentration, ~75 %) in comparison to Cl
375 (~30%). Thus for Ca, another mechanism along with dilution is required to explain its non-
376 linear step-like decline (Fig. 2G).

377 There are a number of mechanisms that could influence post-fire Ca concentrations. First, we
378 consider increased near-surface evaporation inducing prior calcite precipitation (PCP).
379 Increased evaporation, can saturate solutes relative to calcite in karstic waters and promote
380 degassing. Further, evaporation will slow the flow increase water-rock interaction times in
381 the remaining water. Both of these conditions are ideal for PCP. Both our sites show evidence
382 of PCP: the $\ln(\text{Sr}/\text{Ca})$ vs $\ln(\text{Mg}/\text{Ca})$ slopes in our data agree with the diagnostic range for
383 PCP (a slope of + or - 0.88; Fig. 5B) (Sinclair et al., 2011). Expressed as a time series (Fig.
384 5A), we see $\ln(\text{Sr}/\text{Ca})$ and $\ln(\text{Mg}/\text{Ca})$ increase simultaneously with $\delta^{18}\text{O}$ and Cl (Fig. 2),
385 suggesting that evaporation is indeed the common driving mechanism and is inducing PCP at
386 Site 1a. For further information on PCP processes we recommend the reader to Fairchild et
387 al., 2000; Sinclair 2011 and Treble et al., 2015.

388 A second mechanism influencing post-fire Ca concentrations may be the addition of plant ash
389 (Yusiharni and Gilkes, 2012a) and highly soluble CaO (produced by the burning of exposed
390 surface rock to the fire; Yusiharni and Gilkes, 2012b). Further, it is possible that the Ca
391 decline may also reflect a decrease in Ca being leached post-fire that may have followed an
392 earlier spike in Ca concentrations from the above. The extent to which each process is
393 affecting the Ca concentration is difficult to assess in our data, especially since our
394 monitoring did not commence until 6 months after the fire, and processes such as PCP and
395 the addition of Ca from plant-ash are difficult to constrain.

396 We now consider other carbonate metals: Mg and Sr, at Site 1a to further constrain our
397 interpretation. We find Mg and Sr decline by ~30% (in terms of relative concentration). Thus
398 it is likely that the same process affecting Cl is also affecting Mg and Sr, that is, dilution, a
399 decline in leaching of biomass-sourced ash, or some combination of both. Ca concentrations
400 decline by a relatively larger amount (75%) suggesting that additional processes are
401 specifically affecting Ca. The rise in Mg/Ca at Site 1a strongly suggests that the remaining
402 portion of the Ca decline may be attributed to PCP (Fig. 5A).

403 At Site 2a, a rising trend, reflects the concentration of solutes due to a rise in post-fire
404 evapotranspiration, evidenced by increasing $\delta^{18}\text{O}$ and Cl, evaporation of near-surface water
405 stores (Fig. 2F, 2G and 2H respectively), and possibly to some extent, an increase in
406 transpiration from vegetation recovery for Cl (Treble et al., 2016). Additionally, Ca
407 concentrations also show a quasi-seasonal response, interpreted from the Mg/Ca time series
408 to be driven by PCP, possibly due to seasonal P – AET (supported by similar seasonality in
409 dripwater $\delta^{18}\text{O}$; Fig. 2C) although in-cave PCP could also be contributing (Treble et al.,
410 2015).

411 Sulphate and K post-fire at Site 1a are abnormally high in concentration, approximately three
412 times higher in comparison to Site 2a (Figs. 2H, 2I; Tables 1, Table 2). This is
413 counterintuitive to the initial dilution signal (owing to a decrease in tree water-use)
414 interpreted for the other solutes. While at Site 2a, SO_4 and K increase similar to other solutes,
415 consistent with evaporative concentration (from post-fire conditions) and an increase in
416 transpiration from (vegetation recovery). These observations suggest that there was an
417 increase in the availability of SO_4 and K after the fire at Site 1a despite a decrease in tree-
418 water use here (Fig. 2H and 2I).

419

420 We note the majority of aboveground SO_4 is predominantly stored within the lower to middle
421 storey of the forest (O'Connell and Grove, 1996), and post-fire soils contain 23% more S and
422 16% more K than pre-fire soils due to biomass-sourced ash deposition (Grove et al., 1986).
423 So SO_4 and K concentrations at each site may respond differently since the amount of
424 available SO_4 and K above each site is influenced by the amount of biomass burnt above the
425 site. Further, the dissolution rates of ash minerals containing these elements could also affect
426 the rate at which these nutrients are leached from the surface and subsurface and
427 subsequently their concentrations in dripwaters. We propose that the large amount of biomass
428 burnt above Site 1a – the tuart tree - is responsible for the much higher concentrations of SO_4
429 and K at Site 1a dripwater relative to Site 2a. We also propose that the increase in near-
430 surface evaporation from 2007 onwards drives even higher concentrations of SO_4 and K (Fig
431 2H and 2I). Site 2a, which has much less pre-fire biomass, has much lower SO_4 and K
432 concentrations, consistent with our argument. Here, these solutes show a steady increasing
433 trend over the monitoring period. This is consistent with increased evapotranspiration post-
434 fire, which is also evident in the other solutes.

435 Now, we compare our Yonderup Cave results to those of Golgotha Cave to put SO_4 and K
436 concentrations into context. Golgotha Cave, last experienced a wildfire in 1992 and a
437 controlled low-temperature prescribed burn in 2006, while Yonderup experienced a high
438 intensity burn in 2005. Firstly, we see five and ten times higher within cave differences in
439 SO_4 and K (respectively) at Yonderup Cave than we do at Golgotha Cave (Table 2). Also,
440 concentrations at Yonderup Cave are up to four and three times higher in SO_4 and K
441 (respectively) at Yonderup Cave than at Golgotha Cave (Table 1). These results coupled with
442 the difference between Cl compositions at Yonderup vs. Golgotha presents a clear case for
443 more variability in burnt sites in comparison to unburnt sites.

444

445 **6.3 A multi-proxy fire signal in dripwater**

446 Here we propose post-fire scenarios for both sites at Yonderup Cave (refer to conceptual
447 model Fig. 6) that account for the altered dripwater chemistry that is observed post-wildfire.

448 A straight-forward relationship between cumulative water balance (CWB), discharge and Cl
449 concentrations at Site 2a, suggests increased concentration of solutes (Ca, Mg, Sr, K and SO₄)
450 in response to an increase in near-surface evaporation (Fig. 2C and 2D).

451 In contrast solutes such as Cl, Mg, Sr, Ca at Site 1a show a declining trend. We have argued
452 that this declining trend in these solutes is due to two underlying processes. First, a decrease
453 in tree water-use (transpiration) due to the death of the tuart tree in the wildfire. Tuart trees
454 are deeply-rooted, having adapted their root systems to access water from both the surface
455 and subsurface. These roots have been found to generate potential energy between the tree
456 and the soil to extract water and nutrients. Specifically, mature tuart trees generate a pressure
457 gradient ranging from -0.86 ± 0.11 MPa (summer) to -0.35 ± 0.02 MPa (winter) (Drake et al.,
458 2011). So the death of the tuart tree in the wildfire had a significant local effect on hydrology
459 at Site 1a resulting in an increase in discharge and dilution of solutes (Cl, Mg, Sr and Ca).
460 Our study suggests that the consequent reduction in transpiration may not be immediately
461 detected in dripwater, owing to transit time through the limestone and the requirement for
462 overcoming a soil moisture deficit during drier than average climatic conditions.
463 Hydrological effects such as ‘capillary barriers’ can also slow down vertical transport of
464 infiltrating waters at our site (Mahmud et al., 2015).

465 Second, the decline in solutes at Site 1a could be the result of a gradual return to pre-fire
466 concentrations following a pulse of increased input of solutes from ash (e.g. Site 1a scenario).
467 A contribution of SO₄ and K from burnt biomass may explain their relatively high
468 concentrations.

469 Further, isotopic composition at Site 1a show that $\delta^{18}\text{O}$ is offset from modelled hydro-
470 climatic $\delta^{18}\text{O}$ by $\sim+1\text{‰}$ suggesting increased near-surface evaporation post-fire which we
471 attribute to the reduction of shading from the tuart tree post-fire - even in $P > \text{AET}$ periods
472 (Fig. 2C). And post-2007, when $P < \text{AET}$ conditions arrive, $\delta^{18}\text{O}$ rises even higher and
473 discharge declines. Eventually, due to the persistent duration of $P < \text{AET}$ conditions Site 1a
474 ceased dripping owing to eventual depletion of the near-surface reservoir feeding this drip.

475 Site 2a also shows higher $\delta^{18}\text{O}$, during the post-fire period, which we attribute to an increase
476 in near-surface evaporation as a result of low albedo and reduced vegetation cover. The case
477 for evaporation at this site is supported by the rise in Cl and other solutes. The possibility of
478 an immediate spike in solutes from ash and a long-term decline from leaching, as was
479 discussed for Site 1a, is limited here, as there was less biomass available to burn above Site
480 2a. Therefore, we interpret increased evaporation and transpiration from regrowth post-fire to
481 be the dominant forcing at this site, similar to the findings of Treble et al. (2016).

482 We propose that differences in surface vegetation above sites can influence site specific drip
483 chemistry. For example, we interpret Site 1a was influenced by a reduction in transpiration
484 after the fire, due to the forcing biomass above the site; which may also have been a source of
485 post-fire ash at this site. At Site 2a the response to the fire was primarily an increase in near-
486 surface evaporation owing to changes in surface albedo. This variability within the cave
487 response at Yonderup Cave is significant, so too is the comparison between Yonderup Cave
488 drip chemistry and the drip chemistry at Golgotha Cave. The latter more generally highlights
489 that an intense wildfire has variable, but multi-year effects on dripwater composition in
490 shallow caves.

491 From this we propose that post-fire condition persist up-to 5 – 10 years' post-fire, affecting
492 dripwater $\delta^{18}\text{O}$ and solute concentrations. We would expect a full recovery, of $\delta^{18}\text{O}$ and

493 solute concentrations back to pre-fire levels within 10 - 20 years as a result of revegetation
494 growth (Treble et al., 2016) and re-establishment of vegetation cover and pre-fire albedo.

495

496 **7 Application for a speleothem paleo-fire signal**

497 Our post-wildfire dripwater response from $\delta^{18}\text{O}$ was a 2‰ increase above that predicted by a
498 hydro-climatic model, and measured regional groundwater and Golgotha Cave $\delta^{18}\text{O}$ data. If
499 this signal is preserved at equilibrium in speleothems this is equivalent to some of the largest
500 interpreted climatic changes seen in the Quaternary record. This highlights the significance
501 of the findings in our study, which suggests a fire signal could in fact be misinterpreted as
502 climate variability. Furthermore, the impact of the decrease in Ca dissolution from the
503 limestone bedrock could have a significant effect on speleothem growth rate.

504 However, before attributing $\delta^{18}\text{O}$ and growth rate abnormalities to fire, we must remember
505 there are a number of processes that effect speleothem $\delta^{18}\text{O}$. Thus it is important that a multi-
506 proxy approach, which uses isotopic composition as well as a suite of trace elements (sourced
507 from both soil and bedrock), is used to separate fire from other forcings such as climate and
508 other local factors. Further, our study was conducted in a shallow cave environment, where
509 perhaps the overlying vegetation can exert a more dominant forcing on dripwater hydrology
510 and chemistry relative to deeper caves. Deeper caves have more complex hydrology
511 (McDonald and Drysdale, 2007); this involves mixing with other flow paths, which are
512 possibly not fire affected. This may result in the smoothing of the fire signal; making it
513 harder to isolate. Further, a fire signal in cave dripwater and stalagmites may be much subtler
514 in grassland environment in comparison to a forested environment as changes in the biomass
515 would be smaller and vegetation recovery presumable faster (Coleborn et al., 2016). We

516 recommend searching for fire signals in shallow cave environments in the tree rooting zone in
517 forested areas.

518 One further approach that may help to differentiate fire and climate signals in a stalagmite
519 would be to use multivariate statistical techniques such as principal component analyses
520 (PCA). Using this technique, we would expect one component to reflect a bedrock/hydro-
521 climatic signal and another to preserve a local soil/vegetative forcing. The soil/vegetative
522 component could preserve the impact of a fire on stalagmite composition, in trace elements
523 like S, and K. Further, it is also possible an immediate spike in solutes (Mg, Ca, Cl, Sr, S, K
524 and P) from post-fire ash may be preserved in stalagmites and colloid associated metals, such
525 as Al, Fe and Cu from an increase in discharge post-fire. Future studies of this kind will open
526 a new avenue in speleothem research; speleothems as archives of paleo-fire.

527

528

529 **8 Conclusions**

530 We isolate a post-wildfire response by comparing a recently burnt cave monitoring site with
531 forward modelled $\delta^{18}\text{O}$, which predicts $\delta^{18}\text{O}$ based on hydro-climatic factors, and nearby cave
532 monitoring and groundwater data. We provide a novel analysis of the multi-year impacts
533 wildfire has on cave dripwater. Our analysis shows a strong hydrologic relationship between
534 surface environments and shallow caves that are located within the tree rooting zone. This
535 finding is especially important in water-limited environments ($P < ET$) as the overlying
536 vegetation can exert controls on the cave hydrogeochemical environment.

537 A post-wildfire dripwater response is clearest in $\delta^{18}\text{O}$ and Cl due to their sensitivity to
538 variation in near-surface evaporation (both $\delta^{18}\text{O}$ and Cl) and transpiration (Cl). Cl is a
539 conservative ion and hence is driven mainly by dilution/evaporation. Cl declines post-fire
540 at Site 1a which we interpret as dilution of the water store that the dead tree previously
541 exploited. In contrast, Cl increases at Site 2a, sympathetically with $\delta^{18}\text{O}$, consistent with an
542 increased evaporative demand on shallow water stores driven by post-fire reduction in
543 shading and reduced albedo. SO_4 and K are also important as at sites with abundant biomass
544 they can be leached at high concentrations as they are made more abundant in post-fire soils
545 due to the ash generated from a fire. Other solutes such as Mg, Sr and Ca support the
546 dominant local forcing at the site post-fire and can be extremely powerful when using a
547 multi-proxy approach.

548 We propose a conceptual model for a multi-year post-wildfire cave dripwater response in
549 forested water-limited regions. This involves a 5 - 10 yr response of: 1) higher $\delta^{18}\text{O}$ and Cl in
550 cave dripwater due to increased evaporation and decreased shading after the wildfire; 2)
551 increased K and SO_4 due to the leaching of biomass-sourced ash, particularly in areas with
552 large biomass; and 3) increased variability in Mg, Sr and Ca due to changes in evaporation,

553 transpiration and water-rock interactions post-fire. We may expect a recovery within 10-20
554 years after the wildfire and a restore to pre-fire isotopic and trace element concentrations as a
555 result of increased bio-productivity from forest regrowth and a re-establishment of canopy
556 cover.

557

702 Table 2. Summary of differences in mean concentration of solutes and isotopic composition of solutes among sites at Yonderup and Golgotha
 703 caves. We see that Cl, SO₄, K and δ¹⁸O values, at both sites are distinctly different. Specifically, the solutes have higher concentrations and δ¹⁸O
 704 is higher at Yonderup Cave in comparison to Golgotha Cave.

Site Differences

713

714

715

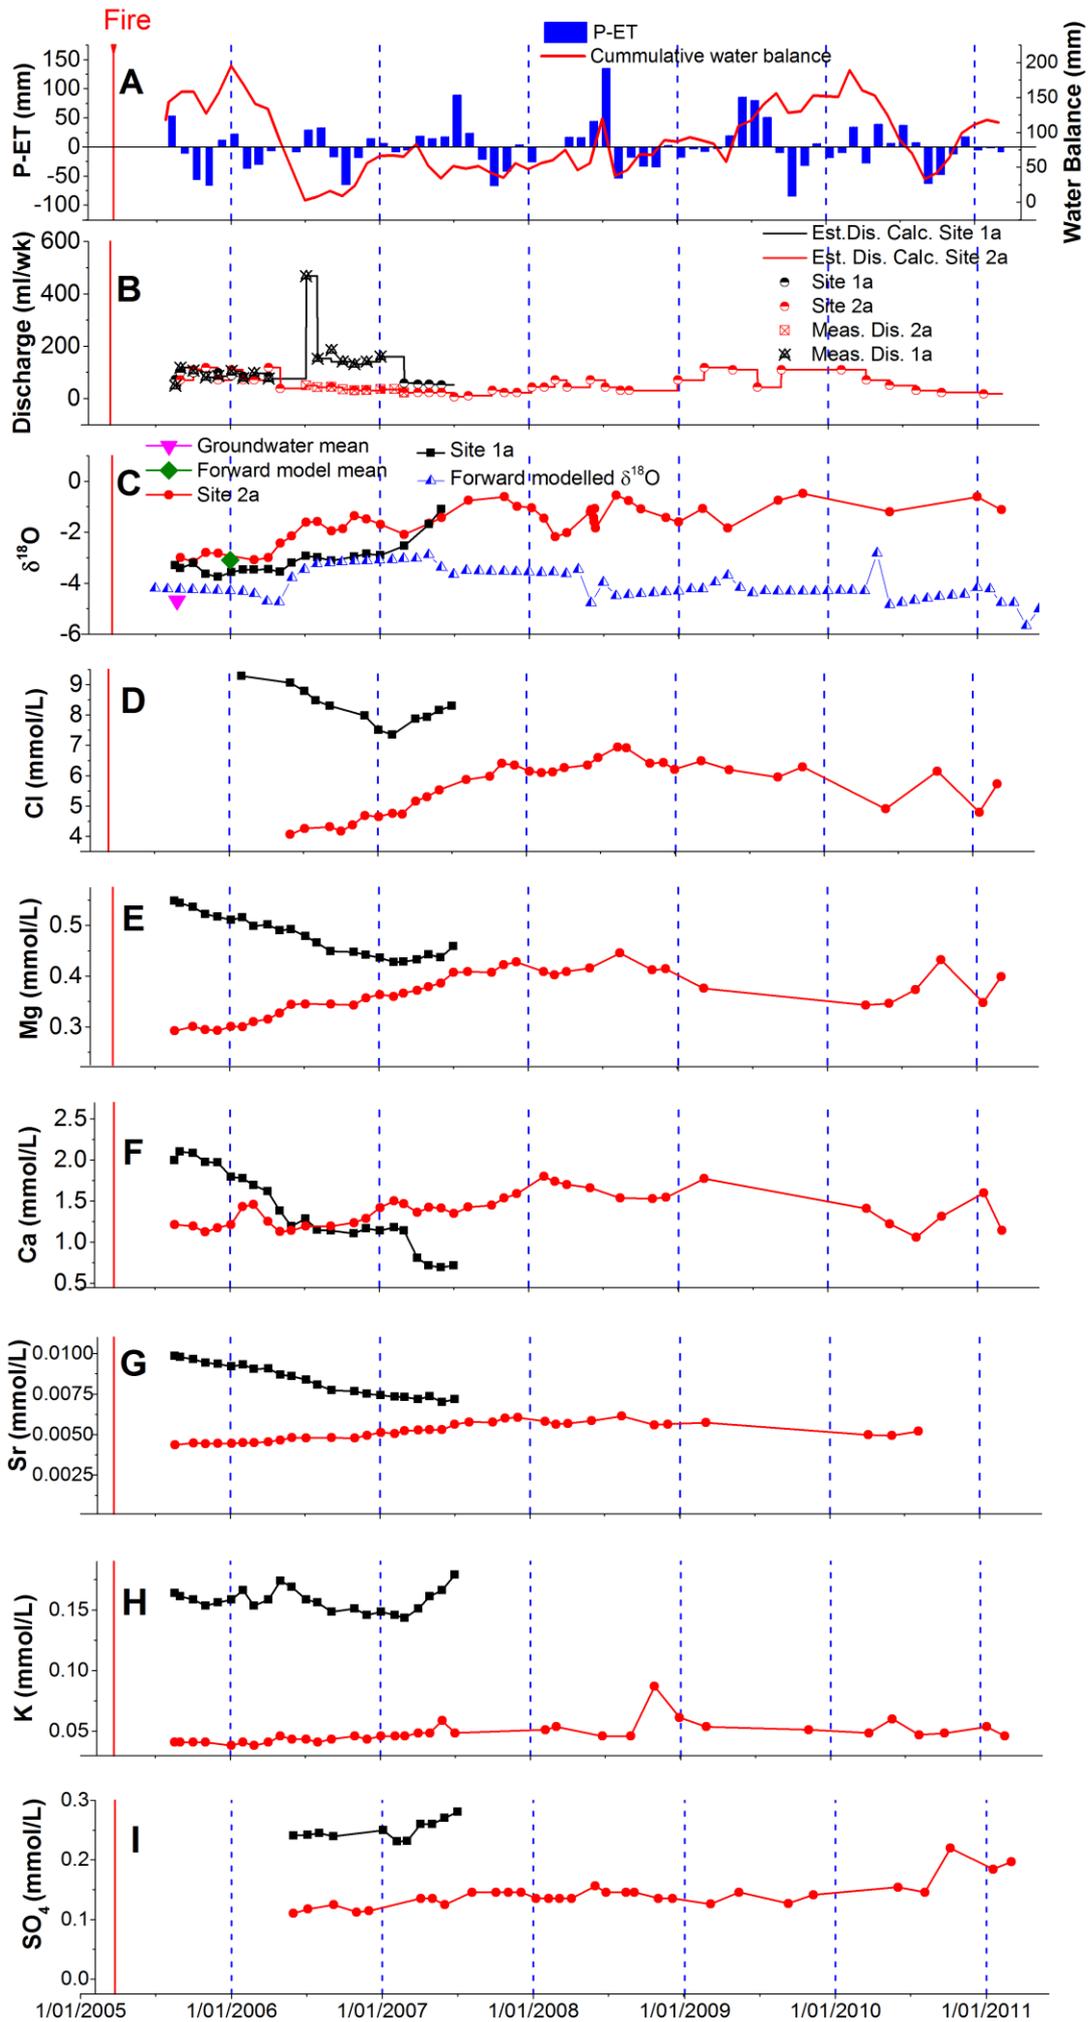

716

717 Figure 1. Geographical location of our study site (A), a post fire photograph of the area (B)
 718 taken in August 2005 a photo of recovering shrubs and grass post wildfire, and (C) a map of
 719 Yonderup cave to scale originally surveyed by Watts and Henley, (1973).

720

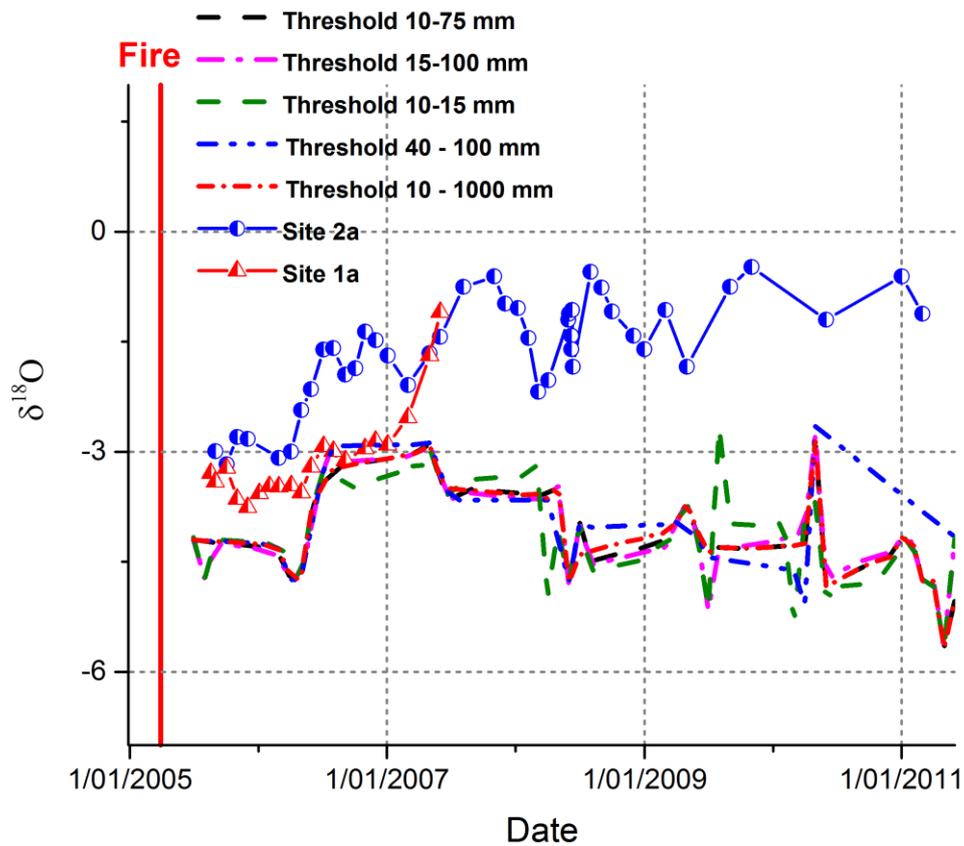

721

722

741 Figure 2. Presents a post-fire time series of data from Site 1a and Site 2a. Note: Site 1a dries
742 up in June 2007. (A) Precipitation – actual evapotranspiration (P – AET), shows seasonal
743 variations of excess (above threshold) and deficiency (below threshold) on a monthly scale
744 overlaid with cumulative surface water balance. (B) Discharge is given in ml/week. Actual
745 measured discharge data is given in blue (Site 1a) and Black (Site 2a) while estimated data is
746 given in (red) this is then inferred to give measured discharge. Site 1a shows a spike in
747 measured discharge in August 2006 and a consequent decrease until the site is dry, while Site
748 2a shows little variability in discharge throughout the monitoring period. (C) Shows observed
749 $\delta^{18}\text{O}$ composition of cave dripwater from Site 1a and Site 2a with the forward modelled $\delta^{18}\text{O}$
750 (red) and mean modelled $\delta^{18}\text{O}$ (orange) and long-term groundwater $\delta^{18}\text{O}$ mean (pink). (D) Cl
751 declines at Site 1a until Feb where it shows a slight increase until the drip becomes dry, while
752 Site 2a shows a steady increase until in July 2007 where it stabilizes for the remainder of the
753 monitoring period. (E) Post-fire response shows a decline in Mg at Site 1a until dry and a
754 steady increase at Site 2a until in Dec 2007 where it remains stable. (F) Site 1a shows step
755 wise decline in Ca at Site 1a until dry, while at Site 2a a very gradual increase until June 2007
756 is seen while the remainder of the monitoring period remains steady. (G) Response for Sr
757 shows Site 1a declining and Site 2a peaking in Dec 2007; an identical response to Mg and at
758 both sites. (H) K post-fire at Site 1a shows high concentrations, triple that of Site 2a but
759 stable, while at Site 2a shows a slight increase over time. (I) SO_4 both Site 1a and Site 2a
760 show a slight increasing trend over time. But Site 1a has more than double the initial absolute
761 concentration in comparison to Site 2a, similar to other solutes.

762

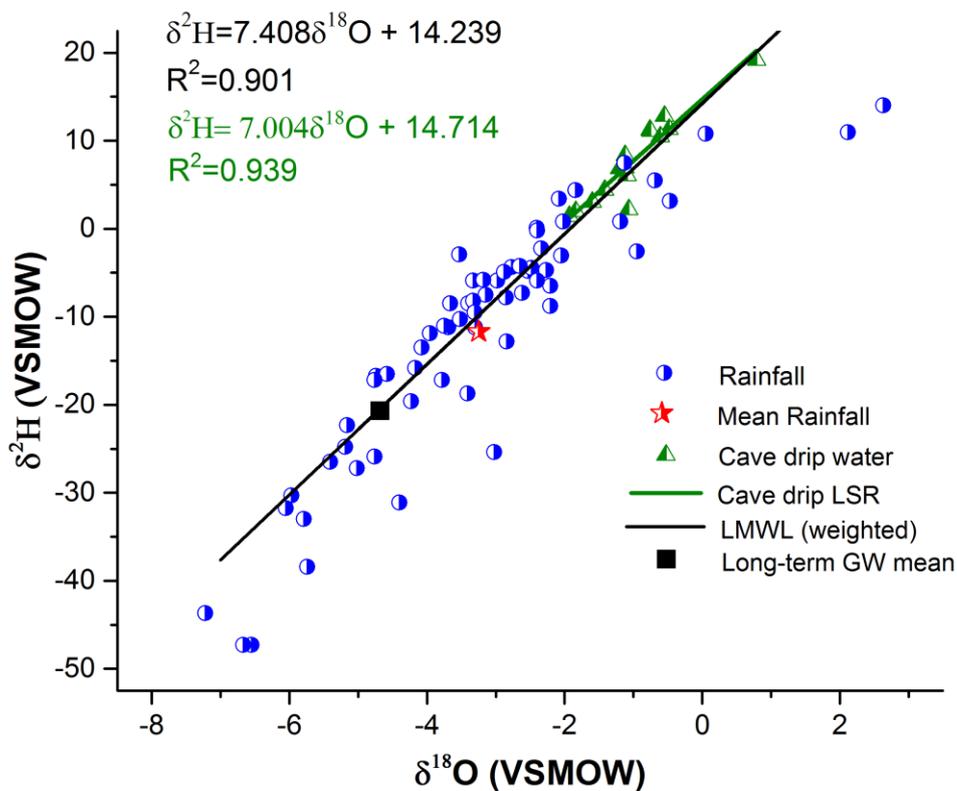

764

765 Figure 3. Modelled dripwater $\delta^{18}\text{O}$ outputs under varying thresholds in our forward model

766 (model from Baker et al., 2010) which accounts for climatic and various epikarst threshold

767 values that control isotopic values. Given no output matches observed dripwater composition

768 we can infer that a localised factor has influenced isotopic compositions

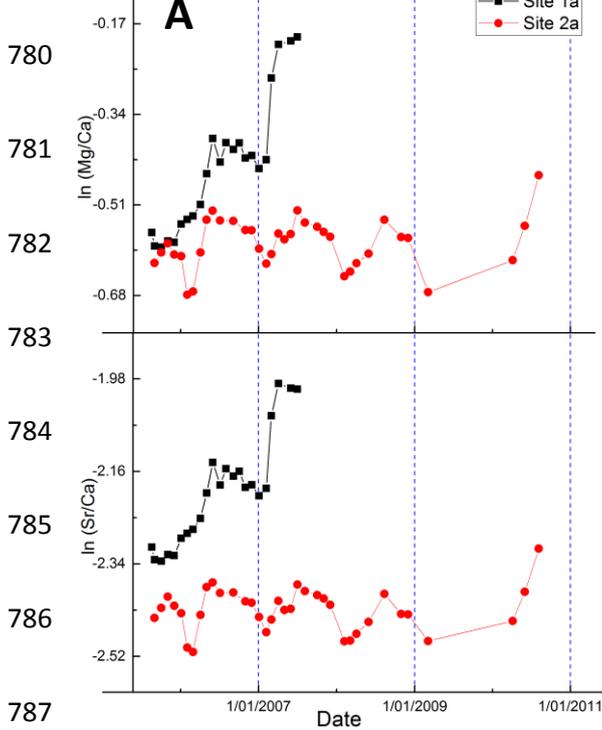

770

771 Figure 4. Shows compositions of $\delta^2\text{H}$ against $\delta^{18}\text{O}$ of our rainfall data (blue) during the
 772 monitoring period (ANSTO, unpublished), cave dripwater (red), long-term local groundwater
 773 mean (black) (0 – 10 ka, n=43, Southern Perth Basin from Turner and Thorpe, (2001)), and
 774 rainfall mean (red). A least squares regression (LSR) is plotted for cave dripwater (red line)
 775 and falls close to the local meteoric water line (LMWL, black) which is calculated using a
 776 weighted least squares regression (WLSR) using Hughes and Crawford, (2011).

777

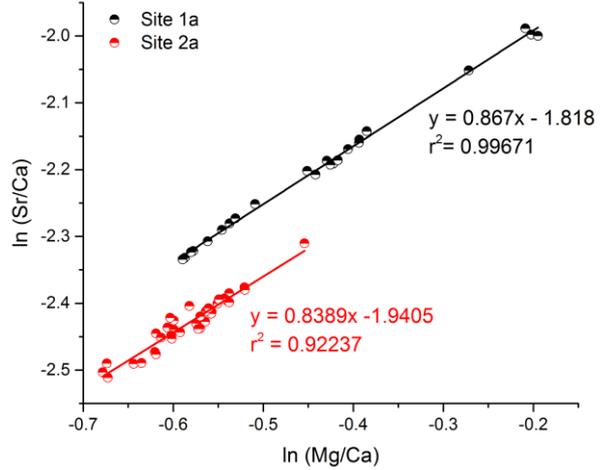

778

779

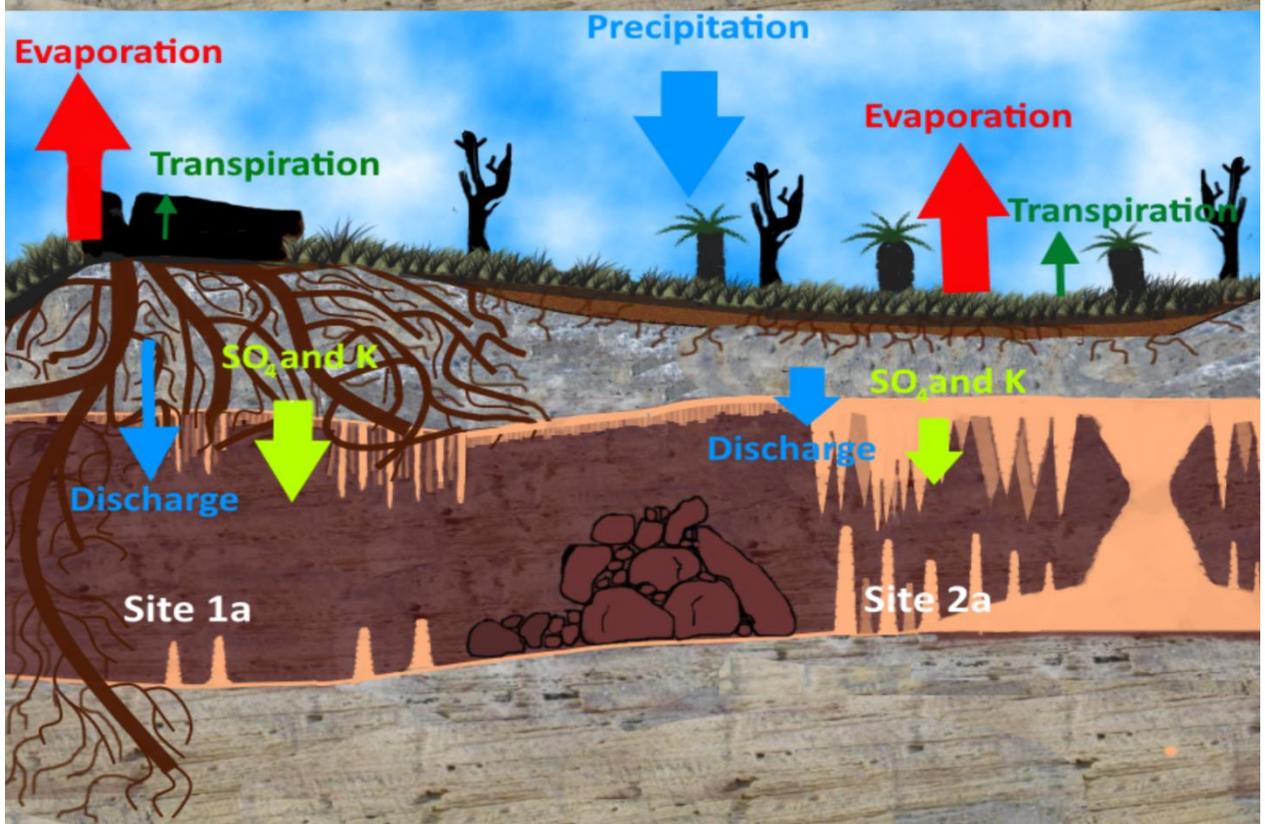

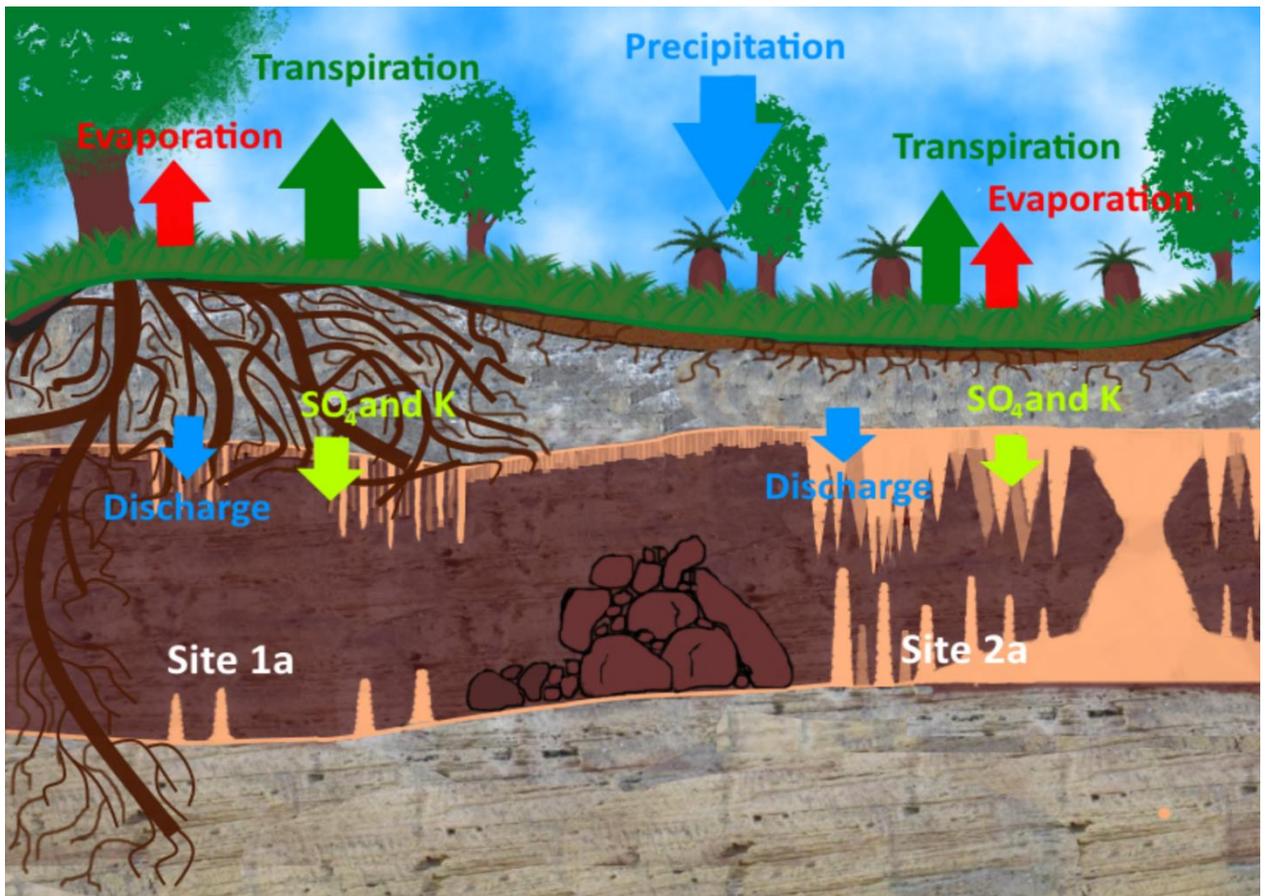

787

B

788 Figure 5. (A) A time series of $\ln(\text{Sr}/\text{Ca})$ vs. $\ln(\text{Mg}/\text{Ca})$. Site 1a shows a clear enrichment in
789 Mg/Ca and Sr/Ca , or an increase in PCP, post-2007, driven by evaporation. Site 2a on the
790 other hand shows quasi-seasonal variational in $\ln(\text{Mg}/\text{Ca})$ and $\ln(\text{Sr}/\text{Ca})$, suggesting here PCP
791 is likely dominated by seasonality. (B) Shows that at both sites, $\ln(\text{Mg}/\text{Ca})$ vs. $\ln(\text{Sr}/\text{Ca})$ falls
792 within the diagnostic range of PCP (a slope of + or - 0.88) suggesting PCP is occurring.

794 Figure 6) Evaporation (red) increases post-fire at both sites due to a reduction in albedo and
795 vegetation cover while precipitation (blue) remains the same and initial transpiration (green)
796 decreases, but recovers over time. Site 2a shows higher $\delta^{18}\text{O}$ and an increase in
797 concentrations of solutes including SO_4 and K (lime) due to evaporation and slow increase in
798 transpiration due to vegetation recovery, with cumulative water balance (CWB) remaining
799 the same. While Site 1a shows, higher $\delta^{18}\text{O}$ in response to increased evaporation and a
800 decline in solute concentrations in response to increased discharge and a decrease in
801 transpiration and removal of nutrients from the surface and subsurface. However, since SO_4
802 and K are from biomass-sourced ash, the tuart tree above this site acts as a source of
803 increased SO_4 and K. Discharge increased immediately (blue). But the drip became inactive
804 one year after the fire due to an increase in evaporation, which outweighed the reduction in
805 transpiration (green), leading to depletion of the near-surface reservoir feeding Site 1a and an
806 in active drip site.
