11

12 **Abstract.** For understanding water and solute transport processes knowledge about the respective hydraulic
13 properties is necessary. Commonly, hydraulic parameters are estimated via pedo-transfer functions using soil
14 texture data to avoid cost intensive measurements of hydraulic parameters in the laboratory. Therefore, current
15 soil texture information is only available at coarse spatial resolution of 250 m to 1000 m. Here, a method is
16 presented to derive high-resolution (15 m) **spatial** topsoil texture patterns for the meso-scale Attert catchment
17 (Luxembourg, 288 km²) from 28 images of ASTER thermal remote sensing. A principle component analysis of
18 the images reveals the most dominant thermal patterns (principle components, PCs) that are related to 212
19 fractional soil texture samples. Within a multiple linear regression framework, distributed soil texture information
20 is estimated and related uncertainties are assessed. An overall root mean squared error of 12.7 percentage points
21 (pp) lies well within and even below the range of recent studies on soil texture estimation, while requiring sparser
22 sample setups and a less diverse set of basic spatial input. **This approach will improve the generation of spatially
23 distributed topsoil maps, particularly for hydrologic modeling purpose, and will expand the usage of thermal
24 remote sensing products.**

25

26 **1 Introduction**

27 The prediction of (sub-)surface water and solute transport processes, from the plot to the basin scale, heavily rely
28 on spatial information of soil hydraulic properties (SHPs). However, the measurement of SHPs in the field or in
29 the lab is very time consuming and expensive with regard to equipment and labor costs (Durner and Lipsius, 2005).
30 To reduce experimental efforts and cost, SHPs are often estimated via so-called pedotransfer-functions from other
31 soil properties that are easier and cheaper available; examples of relevant properties are soil texture, bulk density
32 or organic carbon content (Pachepsky and Rawls, 2004).

1 Standard soil texture information, from country to global levels, is available from a variety of sources. They vary
2 in resolution, method of production and quality. Exemplary soil texture sources on country to global level are JRC
3 (2015), FAO (2015), ISRIC (2015), USDA (2015), or AAFC (2015). The spatial resolutions of these products
4 differ between 250 m and 1000 m. The product quality is defined by usually sparse sample data and additional
5 spatial information ranging from topography, landform observations, remote sensing products, or expert
6 knowledge. Also applied interpolation techniques and landscape evolution models, as well as pattern estimation
7 methods control the quality of derived spatial soil texture products. In general, texture information have a coarse
8 spatial resolution, and partly consist only of qualitative information, thus are characterized by large uncertainties
9 which are hard to quantify.

10 However, many current applications, e.g. land surface models, heavily rely on high-resolution products in the
11 range of 100 m and less (precision farming: 10-50 m, e.g. Selige et al., 2006, or Sadler et al., 1998; flood
12 forecasting: 50-100 m, e.g. de Roo et al., 2003, or Reed et al., 2007; etc.). Any quantification of uncertainties with
13 regard to map information is missing most of the time, but would be essential in order to evaluate the quality and
14 reliability of model predictions.

15 This study uses thermal remote sensing (RS) data in combination with plot measurements to generate spatially
16 distributed soil texture maps. Physical relations between surface temperature, thermal radiation, soil water content,
17 and soil texture have been widely demonstrated in studies to determine soil texture characterizations (diurnal
18 temperature range: Wang et al., 2015; multispectral data: Ahmed and Iqbal, 2014; partial regressions with thermal
19 spectra: Dhawale, 2015). If time series of thermal RS data are available, the concept of thermal inertia is applicable
20 to gain information on soil texture. Thermal inertia is the spatially varying tendency of the land surface to resist
21 changes in temperature forced by energy input. Responsible for these spatial differences in inertia are patterns of
22 thermal conductivity, density, and specific heat capacity of the land surface material (Rees and Rees, 2013;
23 Minacapilli et al., 2012). However, thermal observations of land surface are non-linear integrals over all three
24 dimensions in space of the occurring materials (Hall et al., 1995; Betts et al., 1996). These integrals consider spatial
25 averaging, as well as thermal emission and propagation from sub surface thermal sources up to vegetation.
26 Parameters that influence the surface temperature are incoming radiation, land use, albedo, and available water
27 content. Especially the latter is strongly controlled by soil texture, which subsequently should influence the thermal
28 inertia signature as given by the temporal patterns of surface temperature.

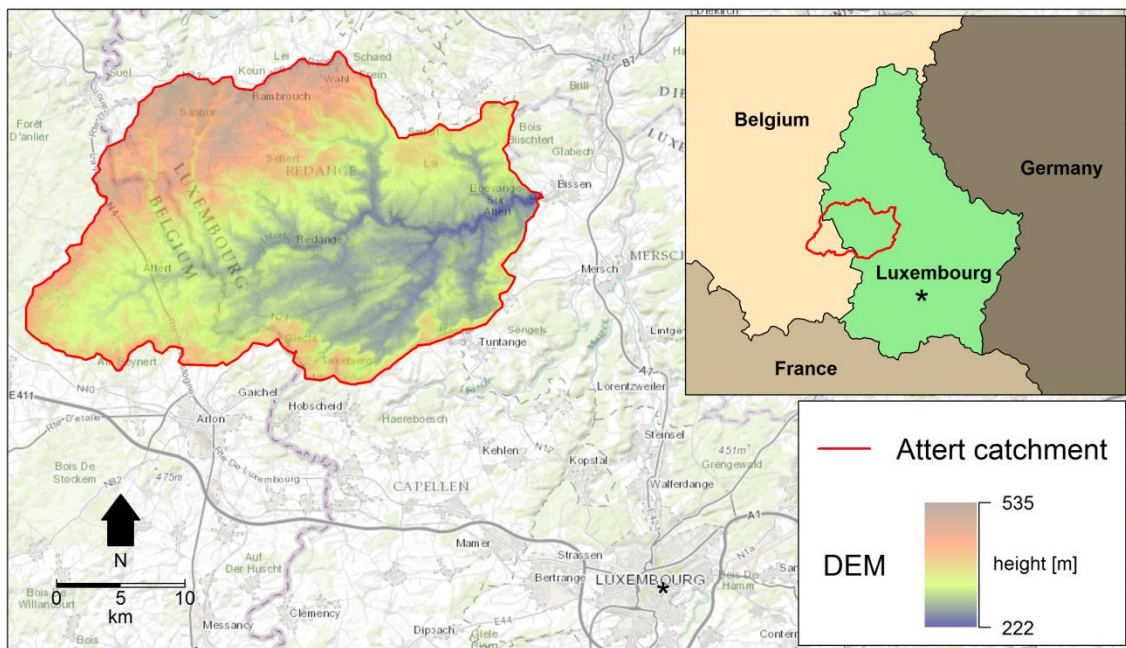

29 In a previous investigation, Müller et al. (2014) have utilized principal component analysis (PCA) for a statistical
30 extraction of dominant patterns within an ASTER thermal infrared (TIR) time series. The produced principal
31 components (PCs) are independent and will be used here to derive stable patterns that are related to soil texture
32 classes. A multi-linear regression estimator (MLRE) is used in this context. The MLRE is able to establish and
33 estimate a functional relationship between the PCs and the fractional texture information from multiple soil texture
34 samples within a catchment. The resulting spatially high-resolution soil texture maps are analyzed for their
35 plausibility, estimator robustness and uncertainty.

36 The rest of the manuscript is organized as follows: Section 2 introduces the test site, the implemented and auxiliary
37 data, as well as methods applied and developed. Section 3 shows and discusses the results of the estimator setups
38 and its cross validations. Finally, section 4 reviews main findings and gives overall conclusions.

2 Data and Methods

2.1 Test site

The research area for this case study is the Attert catchment (mid-western Luxembourg, Fig. 1), the target site of the German DFG research project CAOS ("Catchments as Organised Systems") (CAOS, 2015; see also Zehe et al., 2014). The catchment has a size of 288 km² for the gauge in Bissen and stretches from 222 m to 535 m above sea level. Collated in former studies (Müller et al., 2014), a spatial dataset containing land cover, geology, elevation data, and qualitative agricultural soil information is available (see Fig. 2). A schist massif in the north and sandstone lifts in the far south embrace the undulating central marl area (SGL, 2003). The dominant land use is agriculture (65.4%), followed by forests (29.7%) and settlements and other sealed areas (4.8%) (Corine land cover; EEA, 1995). The monthly mean temperature ranges from 0 °C in January to 18 °C in July (1971-2000); the climate is pluvial oceanic.

Figure

1. The position of the Attert catchment with superimposed elevation data. The gauge Bissen, Luxembourg, defines the catchment boundaries.

The existing agricultural soil map (1:100.000; SPP, 1969; Fig. 2, bottom) lacks of quantitative descriptions but give hints on spatial patterns of soil texture and its systematic distribution: Silt explicitly occurs in four out of the six existent soil classes in the area; clay soils are observed in the North West and sandy soils occur in the South East. Thus, relations between geology and soil can be observed, particularly for schists and clay in the northwestern, and sandstone and sand in the southeastern region.

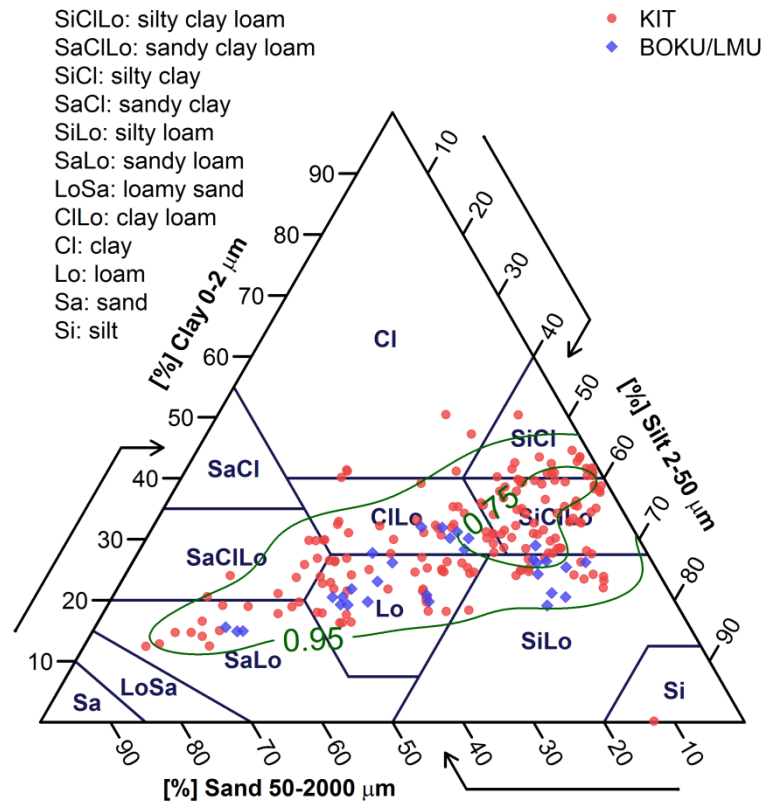

1
 2 **Figure 2. Corine land cover (upper left), geology data (upper right), and agriculturally relevant soil information (bottom**
 3 **left) of the Attert catchment. The sites of the two sample sets are marked for KIT (Karlsruhe Institute of Technology;**
 4 **red circles) and BOKU/LMU (University of Natural Resources and Life Sciences/Ludwig-Maximilians-Universität;**
 5 **blue diamonds).**

6 2.2 Soil data

7 A number of 212 soil samples were taken within the first 15 cm of the topsoil mineral horizon during different
 8 fieldwork activities throughout the Luxembourg part of the Attert catchment (Fig. 2, lower panel). Project members
 9 from KIT (Karlsruhe Institute of Technology) took 125 out of these samples as undisturbed ring samples of 250
 10 ml volume for various hydro-pedologic analyses and as reference samples for runoff-modeling purposes. The other
 11 87 samples were taken by project members from BOKU/LMU (University of Natural Resources and Life Sciences,
 12 Vienna/Ludwig-Maximilians-Universität, Munich) from 30 sites in an attempt to close spatial and systematic gaps
 13 between the existing sample plots as disturbed ring samples of 250 ml volume for measuring soil texture. The
 14 latter sites were chosen based on agricultural soil classes, geology, and land use information trying to cover the
 15 full spectrum of different classes and the full catchment extent. These sites were sampled multiple times within a
 16 radius of 1 m to achieve information on local uncertainty. The texture samples were analyzed based on sieving
 17 and sedimentation analysis after ISO 11277 in two different laboratories at the KIT and LMU. Due to slight
 18 differences in standards with regard to removal of organic compounds and the use of suspension aids, the data
 19 were linearly homogenized by analyzing eight samples in both laboratories and correcting the small biases with
 20 linear models for the three fractions.

21 The resulting texture distribution is given in Fig. 3. The samples are visualized within the classification system of
 22 the USDA. The sampled textures consist of merely high silt fractions (mainly 40-60%), lower clay fractions
 23 (mainly 20-40%) and a wide range of sand fractions (0-80%). The dominant soil types are silty clay loam (SiCilo),
 24 loam (Lo) and clay loam (Cilo).

25

1
 2 **Figure 3.** The categorical distribution of the homogenized soil samples by KIT (red circles), and BOKU/LMU (blue
 3 diamonds) is noted within the USDA classification scheme. The symbols are semitransparent to better visualize
 4 accumulations. Data from both laboratories overlap properly. Additionally, the estimated probability density is shown
 5 in dark green as contours for quantiles of the theoretical distribution of observable soil textures. The 0.95 contour
 6 delimits the area, 95% of the textures are lying within; the 0.75 contour defines 75% of the textures, respectively.

7
 8 Data from sites with multiple measurements (up to three samples per site) are not aggregated and, hence, include
 9 local uncertainties within a radius of 0.5 m for soil texture. From the multiple sampled sites, an average local
 10 standard deviation of the samples of 4.9 pp for clay fractions can be found; for silt and sand variations are slightly
 11 higher with 7.8 pp, respectively 8.7 pp (overall: 7.1 pp). It is noticeable that the local standard deviation is half the
 12 size of the deviation of the full sample dataset with 8.5 pp for clay, 14.2 pp for silt and 18.9 pp for sand (overall:
 13 16.7 pp).

14 2.3 Remote sensing data and deduction of principle components

15 We used the ASTER (advanced spaceborne thermal emission and reflection radiometer) instrument on board of
 16 the TERRA satellite (Fujisada, 1995) in course of this study. The satellite has a sun-synchronous orbit, with a
 17 repetition rate from 4 up to 16 days, passing the catchment at 11:40 am CET. As described in Müller et al. (2014),
 18 channel 13 (10.25-10.95 μm) is used exclusively, as thermal signals in this wavelength are least altered by
 19 absorption in the atmosphere. The remote sensing time series then is processed for reaching 15 m resolution geo-
 20 referenced top-of-atmosphere (TOA) temperatures (see Müller et al., 2014, for details). The used ASTER data set

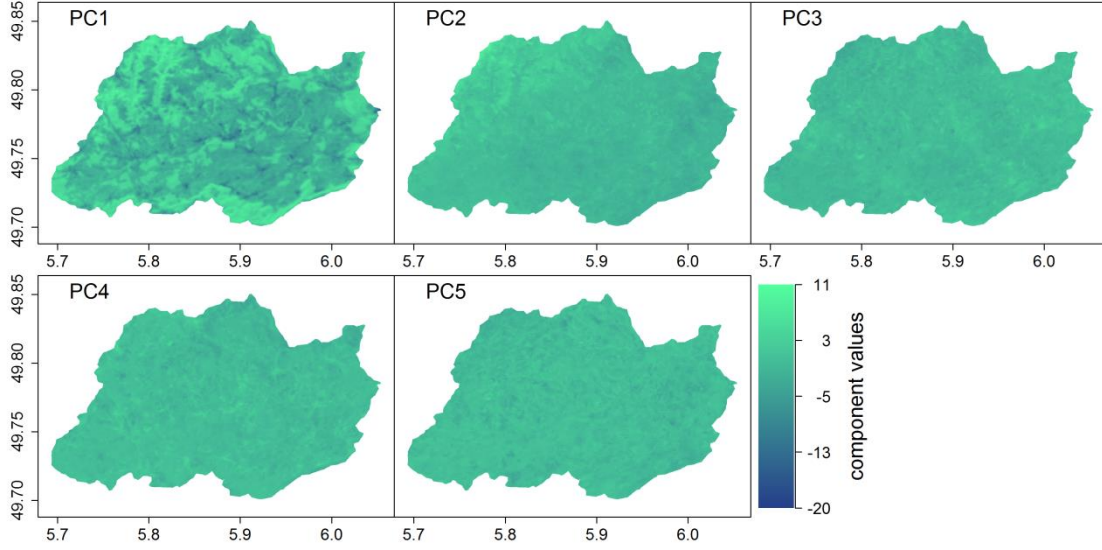

1 consists of 28 snow and rather cloud free images from the period January 2001 to June 2012 (Fig. 4, lower panel).
 2 Figure 4 illustrates four exemplary TOA temperature images from the time series with representative patterns for
 3 each season (a-1 to a-4) and the available dates (b). Winter is under-represented with two images, as images with
 4 snow cover but no cloud cover are rare. Half of the images (15) are from spring months; summer and autumn are
 5 represented by six and five images respectively. Based on optical data, it was found that the largest fraction of bare
 6 soil in the area is found in late spring, late summer and early fall (15 images are covering these situations).
 7 Based on the 28 TOA temperature time series data, principle components (PCs; PC1-PC28) are calculated as
 8 described in Müller et al. (2014). The components of a PCA are orthogonal and represent linear independent spatial
 9 patterns. They are ranked by the proportion of explained variance in the original temperature pattern time series,
 10 which gives information on their dominance and stability within the whole time series. The PCs do not contain
 11 specific information about spatial auto-correlation of the patterns but inherit the interior organization from the
 12 thermal time series.

13
 14 **Figure 4. a) Seasonal examples of the temperature time series patterns (winter 1, spring 2, summer 3, and autumn 4).**
 15 **b) Overview of the dates of the TIR image time series some statistical information (mean and absolute ranges).**

16 Müller et al. (2014) could show some relation between the most dominant PCs and observable patterns of land use
 17 or geology. The first five most dominant PCs are illustrated exemplarily in Fig. 5; it can be observed that with
 18 increasing numbering, the explained variance and pattern immanent gradients of component values decrease. PC1
 19 and PC2 show similarities to the Corine land cover pattern and geology pattern (Fig. 2), **comprehensively described**
 20 **by Müller et al., 2014.** To avoid any influence from highly modified surfaces where no influence of soil texture on

1 the TOA temperature can be expected, artificially covered areas (Fig. 2, upper left panel, in red) are cut out from
 2 the PCs based on Corine land cover data.

3
 4 **Figure 5. The first five components of the PCA of time series data, sorted by decreasing explained variance.**

5 **2.4 Multiple linear regression estimator (MLRE)**

6 The relationship between soil texture data of the collected soil samples and PCs derived from time series of TIR
 7 data is analyzed by multiple linear regression. Three main steps are executed to provide soil texture maps,
 8 individually for each particle size fraction. First, an automatically parameterized Box-Cox transformation (BCT)
 9 is performed to the particle size fraction data in order to guarantee normality of the residuals (Box and Cox, 1964;
 10 Sakia, 1992; Osborne, 2010; Chun and Griffith, 2013). Then, PCs are chosen based on their significance level (p-
 11 values from F-tests) for the multiple linear regression (MLR). At last, the results of the MLRE are restricted to
 12 values between 0 and 100% for each particle size fraction with a sigmoidal capping function on top of the MLR.

13 Overall, the MLR is set up by

$$14 \quad \hat{x}_\lambda = \beta_0 + \beta_1 PC1 + \beta_2 PC2 + \dots + \beta_n PCn + \epsilon, \quad (1)$$

15 with the PCs $PC1 \dots PCn$, the corresponding regression coefficients $\beta_{0\dots n}$ and residuals ϵ to estimate the soil texture
 16 fraction \hat{x}_λ . For an unbiased estimation of $\beta_{0\dots n}$, the residuals ϵ have to be normally distributed $N(0, \sigma)$ (Chun and
 17 Griffith, 2013).

18 The BCT is applied by

$$19 \quad x'_\lambda = \begin{cases} \frac{x^\lambda - 1}{\lambda}, & \lambda \neq 0 \\ \ln(x), & \lambda = 0 \end{cases}, \quad (2)$$

20 where x is the soil data before transformation, x' after transformation and λ is a parameter estimated from the data
 21 or error distribution to achieve normality. An optimal λ is estimated by an iterative Monte Carlo procedure
 22 allowing λ to range between $[-5, 5]$ with an accuracy of 0.01 to guarantee finding a global minimum. Tests for
 23 normality of the residuals are executed subsequently.

1 To restrict the MLR predictions to the natural limits of 0-100% share of a fraction, sigmoidal capping functions
 2 (Franklin, 2013) are used. A sigmoidal function generally is differentiable, with a non-negative (“S”) or non-
 3 positive (“Z”) first derivative, one minimum and one maximum. The presented approach uses the following
 4 implementation:

$$5 \quad \mathit{sig}(x) = L + (U - L) * \begin{cases} \left(1 - e^{-\left(\frac{x-sp}{sl}\right)^2}\right), & \text{if } x \geq sp \\ L, & \text{else} \end{cases}, \quad (3)$$

6 where L and U are the lower and upper limits (here: 0% and 100%), sp is the position of the start of the positive
 7 gradient and sl adapts the steepness of this gradient. These two gradient parameters are optimized for reducing the
 8 root mean square error between corrected regression estimator and sample data as much as possible.

9 2.5 Cross-validation

10 Cross validation (CV) is a common strategy for the evaluation of model performance and the quantification of
 11 uncertainties (Arlot and Celisse, 2010). CV schemes can differ in the size of training and validation subsamples.
 12 Here, four different CV schemes are applied to analyze potential changes in the uncertainty level resulting from
 13 different sample sizes: First, a simple leave-one-out (LOO) strategy was applied, where all but one sample point
 14 are included for model identification, and the remaining data points are used for model evaluation. This procedure
 15 is repeated so that each point ($n=212$) is left out once, and model performance in form of the root mean squared
 16 error (RMSE) between measurement and prediction can be calculated.

17 Three further CV variants are applied to analyze the effect of sample size reduction on the prediction performance.
 18 For this, the sample size is divided into 10%- (CV10), 20%- (CV20) and 50%- (CV50) sized validation subsets
 19 with respectively 90%-, 80%- and 50%-sized training subsets. The random process of validation-set-generation is
 20 repeated $n=212$ times in order to have an equal number of evaluations for all CV variants. The performance of the
 21 MLRE prediction during validation is again evaluated using the RMSE for each particle class.

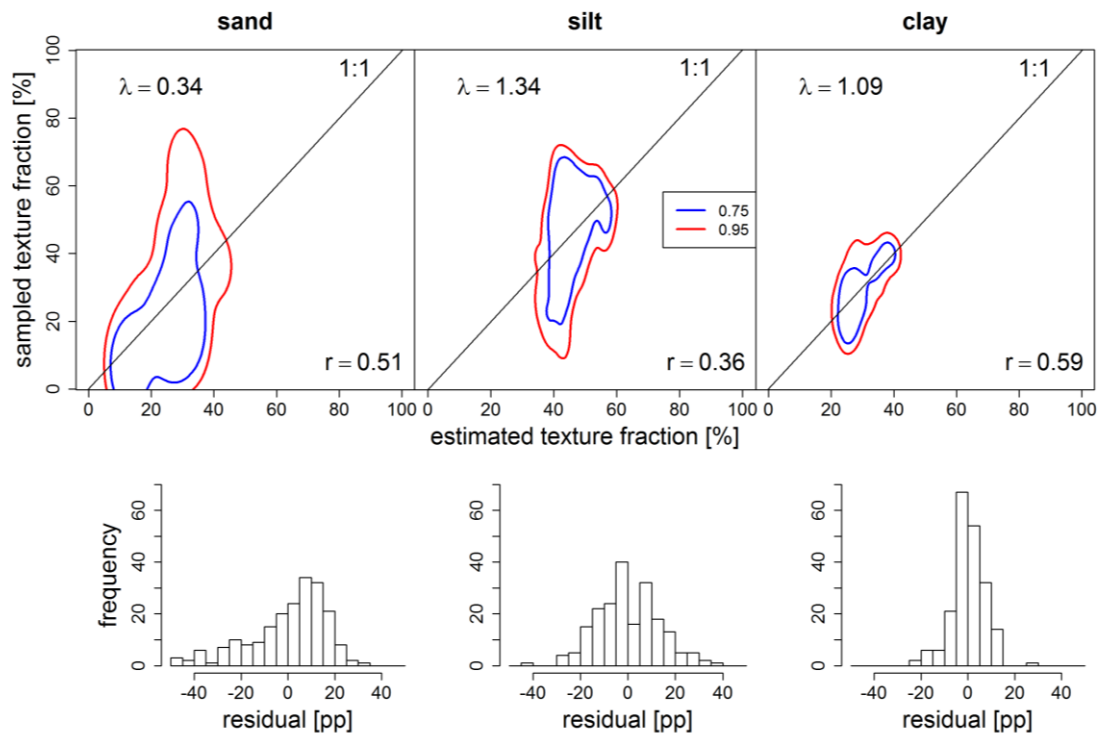

22 3 Results

23 3.1 Sample data and soil texture maps

24 First, F-tests were performed to evaluate the MLRE model performance with regard to the number of different
 25 PCs considered as regressors, as well as to all possible combinations of PCs (for a given number of regressors).
 26 The p-value of the F-tests represents the probability of the (soil texture) data given the Null-hypothesis (H_0) that
 27 all regression coefficients are zero. Low p-values are taken as an overall indication for the “relevance” of the
 28 MLRE. Results showed that significant p-values (< 0.05) occurred most often when the first five PCs were
 29 incorporated, whereby a number of three PCs out of the first five components performed best. Lowest p-values for
 30 sand are assessed with a MLR based on PC1, PC2, and PC3; for silt, the most adequate combination is PC2, PC4,
 31 and PC5 and for the determination of clay PC2, PC3, and PC4 are used (given the full data set).

32 The results of the MLRE are illustrated in Fig. 6. Upper panels show the distribution contours of the 95%- (red)
 33 and 75%-quantiles (blue) for the estimation of different particle fractions, while the lower panels show the
 34 respective distribution of residuals. Sand and clay show higher Pearson correlation coefficients ($r > 0.5$), while silt

1 is showing a lower value ($r = 0.36$). The optimal λ -values for the BCT indicate almost normally distributed
 2 residuals for clay, while for silt, the error distribution is skewed left and for sand, the distribution is skewed right.
 3 The overall RMSE for the three texture fraction estimators is 12.7 pp, partitioned into 16.2 pp for sand, 13.0 pp
 4 for silt and 7.1 pp for clay. Hence, the MLR shows a well-defined relation for clay, while sand shows good
 5 correlations with few extreme outliers. For silt the system shows low correlations with a smaller variation of errors
 6 (compare Wang et al, 2015).

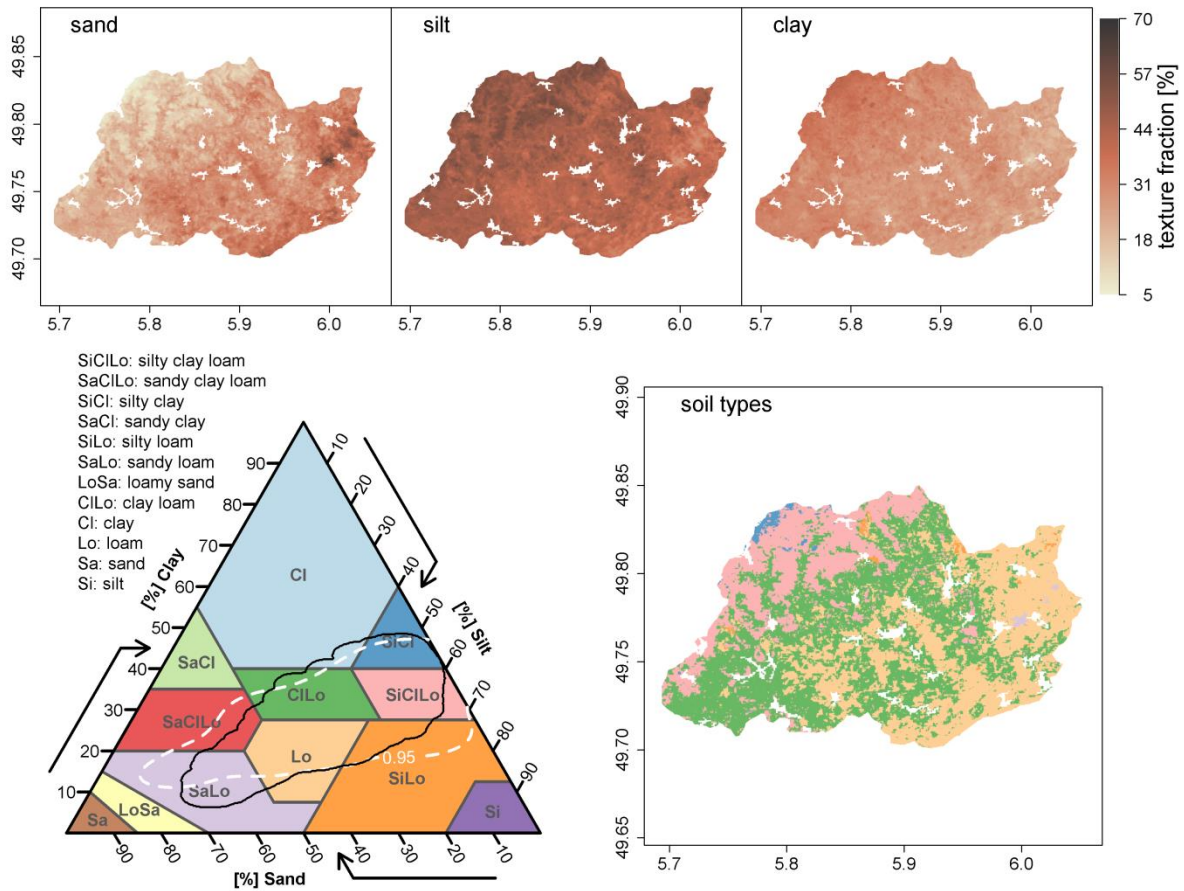

7
 8 **Figure 6. MLRE results for predicting sand, silt, and clay fractions estimated with three components of the PCA data.**
 9 **The distribution contours (upper panels) show the sampled versus the estimated texture data after BCT and sigmoidal**
 10 **capping. 95%- (red outline) and 75%-quantiles (blue outline) are shown. λ -values of the BCT (upper left) and Pearson**
 11 **correlation coefficient r between the sample and estimator data (lower right) are also noted. The lower panels show the**
 12 **respective distributions of residuals [estimator - data] and their skewness related to the BCT λ -values after back**
 13 **transformation.**

14 The MLRE calibrated with the complete field sample set is then used to calculate fully distributed texture maps.
 15 Figure 7 shows the resulting soil texture maps. Each texture fraction is modeled separately with the aforementioned
 16 PC combination. Finally, the three texture fractions are translated into USDA soil types, which are then mapped
 17 back into the catchment (Fig. 7, lower right). A comparison of predicted and observed texture data shows a large
 18 overlap between both (Fig. 7, lower left).

19 The distribution of soil texture conforms to the distribution of the soil characteristics displayed in the available
 20 qualitative agricultural soil maps (Fig. 2). Clay is dominant in the north, rather sandy soils can be found in the
 21 south and mainly silty soils prevail in the remaining parts of the catchment. Further analysis of the soil texture
 22 distribution reveals relations to topographic structures, different land cover types and geology (Fig. 1 and 2). **The**

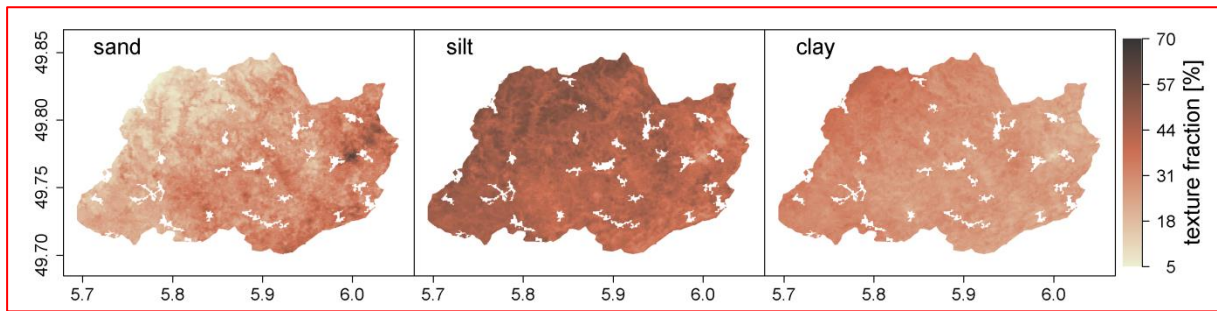

- 1 distribution of different modeled soil textures change along slopes from top (fine) to bottom (coarse) or between
- 2 riparian (sandy) and agricultural (silty) areas. Clay soil mainly appears in schist areas.

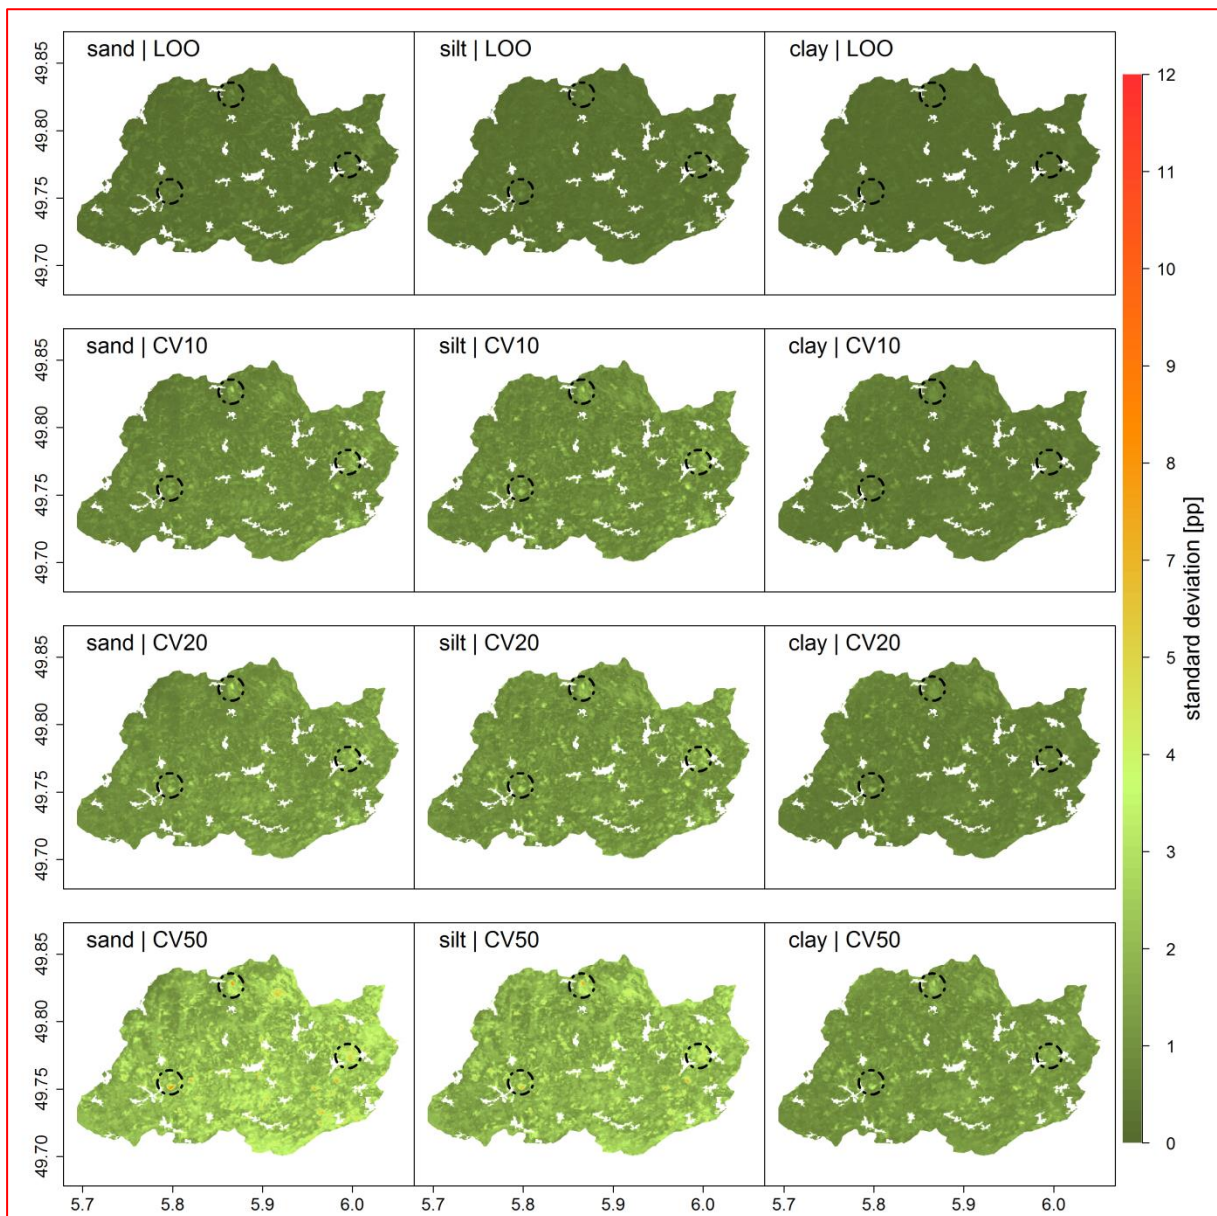

- 3
- 4 **Figure 7: Result maps for texture fractions for the MLRE predictions based on the full data set are shown (upper**
- 5 **panels). Lower left: Texture triangle with the resulting data distribution (black outline) compared to the 95%-quantile**
- 6 **distribution estimation of the measured samples (dashed white) from Fig. 4, providing the color legend for the soil type**
- 7 **map (lower right). Therein, artificial areas (from Corine land cover) are ignored (white).**

8 3.2 Cross validation results

- 9 Figure 8 shows the spatial patterns of pixel-based standard deviation of the resulting 212 maps of soil texture
- 10 fraction. For each different CV variant as well as for all 212 CV runs, an F-test based selection for the choice of
- 11 PCs as described in 3.1 has been performed. The mean texture fraction results from the cross validation runs, e.g.
- 12 **CV50 (Figure 8)**, agree with the overall result and differences in absolute texture fraction are small when compared
- 13 to results illustrated in Fig. 7. The patterns of valley structures and bedrock distribution can be observed here as
- 14 well.

1
2 **Figure 8: Exemplary mean value maps of soil texture fractions estimated with the CV50 CVS from the possible 212**
3 **different data sets. There are no significant differences between the different mean value maps for the different CVSs.**
4 **Moreover, differences to the maps based on the full sample set are minor (compare Fig. 7).**
5 Statistical indices allow further analysis of the similarities. The spatial average of the coefficient of variation
6 (c.o.v.; $|\sigma/\mu|$) between all model results, i.e. from CV schemes and the full data set, shows values of below of 0.1
7 for all texture fractions and underlines the visual impression of small deviations. Supported by the constant RMSE
8 values throughout different variants of the CVs (sand: ~16.6 pp, silt: ~13.4 pp, clay: ~7.2 pp; compare Tab. 1),
9 MLREs indicate a stable behavior in the estimation of spatial texture fraction. The overall RMSE for the different
10 CVs is around 10.9 pp and hence little lower than for the full dataset (12.7 pp). However, silt and sand fractions
11 are higher by ca. 0.5 pp and clay by ca. 0.15 pp.

1
 2 **Figure 9.** Spatial patterns of standard deviations for the different CV variants (rows) of soil texture fractions (columns)
 3 calculated from the estimators for the 212 different randomly selected data sets. Hotspots of high uncertainty (5 pp and
 4 above; **exemplary spots are circled on all 12 maps**) can only be observed with CV50 subsets and within sand and silt
 5 fractions.

6
 7 These values indicate higher uncertainties for silt and sand fractions. This uncertainty is attributed to a higher
 8 variation in distribution characteristics within the sample data sets that is increased by decreasing the number of
 9 used samples. **Another possible source for this high uncertainty is the small thermal gradient within the range of**
 10 **widely different silt fractions at common surface temperatures (Farouki, 1982). This gradient is most sensitive to**
 11 **a low number of measurements.**

12 In contrast to the stable mean results, textural standard deviation in Fig. 9 varies more. Clay fraction maps show
 13 least deviation, while highest deviation is observed in least-sampled sandstone areas in the southeast of the

1 catchment and the lower lands near the gauge. Cross-validation based uncertainties occur as expected: maximum
 2 standard deviations rise with increasing size of the validation data sets, and therefore less calibration data.

3
 4 **Table 1: Root mean square error (RMSE) values for the sample data from the different Cross validation (CV) variants**
 5 **by particle size and overall. The results are noted in percentage points [pp]. The different CV variants (LOO, CV10,**
 6 **CV20, and CV50) show similar values for the RMSEs between sample and estimated fractions sand, silt, and clay within**
 7 **the 212 subsets for the CVS (column 2 - 4). Additionally, the approximately constant overall RMSE for all fractions and**
 8 **samples within the CVSs' subsets is noted (column 5).**

CV	RMSE per particle size [pp]			overall RMSE [pp]
	sand	silt	clay	
LOO	16.58	13.37	7.18	10.80
CV10	16.64	13.42	7.25	10.87
CV20	16.56	13.30	7.11	10.80
CV50	16.89	13.54	7.34	11.00

9
 10 Exceptional high deviations are highly localized throughout the subsets and show areas of higher uncertainty for
 11 the estimated texture classes. These outliers are stable, spatially and throughout the CV variants. These deviation
 12 hot spots can occur due to soils being out of the range of sampled soil types or specific land cover.

13 However, the automatically optimized choice of PCs for the regression estimators is quite constant throughout the
 14 sample data subsets in the different CV variants. For all three texture classes, PC2 is used by 100% of the estimator
 15 setups, the pattern that resembles geology. The main variation within the texture fractions is then added for

- 16 a) sand by using PC3 (99% of the setups) and PC1 (65%),
- 17 b) silt by using PC4 (81% of the setups) and PC5 (54%) or PC1 (47%), and
- 18 c) clay by using PC3 (100% of the setups) and PC4 (84%),

19 with number of different variants increasing with the size of the validation data. This also hints at a slight
 20 inconsistency within the measured data. Nonetheless, the overall estimator choice seems to be relatively uniform,
 21 especially for clay and sand fractions.

22 23 **4 Discussion and conclusion**

24 This study investigates the potential of estimating distributed soil texture fractions with time series of thermal
 25 remote sensing data. Elementary thermal patterns (PCs) are extracted from the time series with PCA and are used
 26 as inputs in a MLR model framework to estimate soil texture fractions. The MLRE model is calibrated and
 27 evaluated against a set of 212 measured soil texture data using four different cross validation variants. After
 28 calibration, it is applied for the generation of soil texture and soil types maps based on the distributed PCs
 29 information.

1 The MLRE prediction uncertainties expressed as overall RMSE when using the full data set for calibration is 12.7
2 pp (sand – silt – clay: 16.2 pp – 13.0 pp – 7.1 pp) and does not change significantly with in different CV variants.
3 Given local measurement uncertainties of 7.1 pp for all fractions (sand – silt – clay: 8.7 pp – 7.8 pp – 4.9 pp), the
4 model induced uncertainty component might be in the range of 3 - 8 pp, varying for the different fractions. The
5 stability of RMSE and choice of PCs reveal the reliability of this simple estimator setup, a distinct relation between
6 the basic patterns, observed with thermal remote sensing, and the soil texture samples.

7 A review of different approaches presented in the literature, often using more complex methods or input data,
8 reveals similar or even higher uncertainties. For example, McBratney et al. (2000) list RMSE for clay content
9 based on 85 samples within an only 42 ha sized and less heterogeneous area. They test different estimator types in
10 their work: 7.6-8.2 pp for interpolation methods and 6.2-8.9 pp for regression techniques (regression trees to neural
11 networks) with combinations of ancillary information (terrain data, yield data, and electromagnetic measurements)
12 with a resolution of 200 m. The here presented MLRE based on PCs achieves similar uncertainty values for clay
13 while using less complex methods and input in a more complex terrain. Wang et al. (2015) reach uncertainties of
14 10.7-15.5 pp for sand and 4.6-6.5 pp for clay, using a regression model on diurnal temperature range data from a
15 derived land surface remote sensing product with a rather inapplicable coarse resolution of 1 km for a catchment
16 of 5130 km² with 62 soil samples. The product resulting from the MLRE approach is of higher resolution while
17 providing similar deviations. Modelling soil texture inversely (40 m) from soil moisture, measured with a passive
18 microwave radiometer, performed by Santanello et al. (2007) for a watershed of 148 km², leads to RMSE values
19 of 12-28 pp for sand, 14-25 pp for silt and 0-8 pp for clay fractions. This inversion requires a complex model
20 (Noah Land surface model; Noah-LSM, 2015), however, results in a much larger range of uncertainty. Overall,
21 the herein presented estimator method requires the least temporal resolution of remote sensing data and least
22 amount of additional data, notably none, with a simple regression method. Furthermore, the density of required
23 measurements is low compared to the mentioned studies.

24 Our study also demonstrates that extracted PCs from time series of thermal images contain the necessary spatial
25 information to delineate distributed soil texture information. The different CV variants show that an appropriate
26 uncertainty range can be obtained with around 100 training samples for roughly 300 km² with a target resolution
27 of 15 m. Analyzing the deviation maps for the different CV variants (Fig. 8) reveals hotspots of diverging relations
28 between sample data and PCs. These maps can be used to further reduce uncertainty by localizing effective
29 additional sample locations.

30 **A different option, but presumably equally suitable, than using PCs is the direct delineation of thermal inertia maps**
31 **from hydraulic soil properties for given time steps and soil moisture states, as shown in Murray and Verhoef**
32 **(2007). This option requires the description of the same (amount of) spatially distributed soil hydraulic properties**
33 **as used in pedo-transfer functions and, therefore, does not simplify data collection.**

34 **The presented** approach works well within the current resolution of 15 m and with a sparse temporal resolution,
35 but should also work for different setups of spatial and temporal resolution, with a reasonable minimum variation
36 in the time series. Hence, this approach is possible to handle many applications within hill slope, catchment, and
37 up to continental extent with comparably small sampling effort and definite uncertainties.

1 The presented data can help to improve the generation of topsoil maps, especially without the need of proper soil
2 genesis descriptions. These maps then can be utilized for medium scale catchment setups of eco-hydrological
3 models, especially within (near) ungauged basins. The basic thermal remote sensing time series can also be
4 obtained from other sensors with different resolutions, such as Landsat (60-100 m) or MODIS (1 km). Only few
5 measurements are necessary as long as the spatial extent of the thermal remote sensing data and taken samples
6 cover the statistical distribution of catchment characteristics.

7 Further applications of this PCA based MLRE to assess spatial distributions of bulk density, topsoil organic matter,
8 vegetation density, or even fraction of absorbed photosynthetic active radiation (FPAR) will be subject to further
9 research. In addition, **feasibility studies on the utilization of different remote sensing time series, ranging from**
10 **microwave or visible imagery to mixed databases and comparison to model output are issues of ongoing studies.**

11 **Acknowledgements**

12 We want to thank the German Research Foundation (DFG) and the Austrian Science Fund (FWF) for funding this
13 research through the CAOS (Catchments as Organised Systems) Research Unit (DFG: FOR 1598, Grant
14 SCHU1271/5-1; FWF: I 2142-N29). We also want to thank the LPDAAC (Land Processes Distributed Active
15 Archive Center) for providing free ASTER data. We thank Loes van Schaik, Elisabeth Thiem, Liya Sun, and the
16 student staff for their fieldwork and the laboratory analysis, especially, Thomas Weiss for his work in the LMU
17 laboratory, as well as the Lippmann Research Institute, Luxembourg, for arranging access to the catchment.
