14

15 **Abstract**

16 Glacial lake outburst floods (GLOFs) pose a significant threat to downstream communities and
17 infrastructure due to their potential to rapidly unleash stored lake water. The most common
18 triggers of these GLOFs are mass movement entering the lake and/or the self-destruction of the
19 terminal moraine due to hydrostatic pressures or a buried ice core. This study initially uses
20 previous qualitative and quantitative assessments to understand the hazards associated with eight
21 glacial lakes in the Nepal Himalaya that are widely considered to be highly dangerous. The
22 previous assessments yield conflicting classifications with respect to each glacial lake, which
23 spurred the development of a new holistic, reproducible, and objective approach based solely on
24 remotely sensed data. This remote hazard assessment analyzes mass movement entering the lake,
25 the stability of the moraine, and lake growth in conjunction with a geometric GLOF to determine
26 the downstream impacts such that the present and future risk associated with each glacial lake
27 may be quantified. The new approach is developed within a hazard, risk, and management
28 action framework with the aim that this remote assessment may guide future field campaigns,
29 modeling efforts, and ultimately risk-mitigation strategies. The remote assessment was found to
30 provide valuable information regarding the hazards faced by each glacial lake and results were
31 discussed within the context of the current state of knowledge to help guide future efforts.

1

2 **1 Introduction**

3 Glacial lakes outburst floods (GLOFs) unleash stored lake water often causing enormous
4 devastation downstream that can include high death tolls as well as the destruction of valuable
5 lands and costly infrastructure. As the number and area of glacial lakes continues to increase
6 (Bajracharya and Mool, 2009; Bolch et al., 2011; Gardelle et al., 2011; Carrivick and Tweed,
7 2013), the risk associated with these GLOFs increases as well. An assessment of previous
8 GLOFs reveals the most common cause of failure is mass movement (snow, ice, and/or rock)
9 entering the lake (Richardson and Reynolds, 2000; Wang et al., 2012; Emmer and Cochachin,
10 2013) and subsequently overtopping and eroding the damming moraine. Other triggering
11 mechanisms may include dam settlement and/or piping, the degradation of an ice-cored moraine,
12 the rapid input of water from extreme events, and seismic events (Westoby et al., 2014). Events
13 that occur over a relatively short time period, i.e., minutes to days, such as mass movement
14 entering the lake, intensive rainfall, or intensive snowmelt are referred to as dynamic events,
15 while other events that occur over longer periods of time are referred to as self-destruction or
16 long-term causes (Yamada, 1998; Emmer and Cochachin, 2013). Emmer and Cochachin (2013)
17 highlight the complexity of these self-destructive events as they lump the failure from the
18 degradation of buried ice, hydrostatic pressure, and/or the effects of time all together due to the
19 difficulty of distinguishing the exact cause of failure. Similarly, Richardson and Reynolds
20 (2000) were unable to identify the cause of over 23% of the GLOFs in their study due to a lack
21 of information. This uncertainty regarding other mechanisms of failure stresses the importance
22 of taking a holistic approach towards assessing the hazard of these glacial lakes that accounts for
23 the various triggering mechanisms and the stability of the moraine.

24 Methods have been developed to characterize the hazard and risk associated with glacial lakes in
25 Cordillera Blanca (Reynolds, 2003; Hegglin and Huggel, 2008; Emmer and Vilímek, 2013;
26 Emmer and Vilímek, 2014), New Zealand (Allen et al., 2009), North America (Clague and
27 Evans, 2000; O'Connor et al., 2001; McKillop and Clague, 2007a, b), the Swiss Alps (Huggel et
28 al., 2004b; Nussbaumer et al., 2014), the Himalaya (Wang et al., 2008; ICIMOD, 2011; Wang et
29 al., 2012; Fujita et al., 2013; Worni et al., 2013), the Tibetan Plateau (Wang et al., 2011), and
30 other parts of high mountain Asia (Bolch et al., 2011; Mergili and Schneider, 2011). These

1 methods vary considerably based on the parameters considered, the level of importance placed
2 upon each parameter, the amount and type of required input data, their ability to be transferred to
3 other regions, and their levels of objectivity. Emmer and Vilímek (2013) applied a suite of
4 existing hazard assessments to glacial lakes in Cordillera Blanca and found good agreement
5 between the various methods despite the various studies using different parameters, various
6 amounts of qualitative and quantitative information, and being developed for specific regions.
7 This good agreement suggests it may be feasible to accurately classify the hazard of a glacial
8 lake and shows the parameters may be qualitative or quantitative as long as the developed
9 analysis and thresholds are objective.

10 Unfortunately, the use of various approaches can also lead to different classifications of the
11 hazard associated with an individual glacial lake. Imja Tsho (Tsho is Tibetan for lake), located
12 in the Everest region of Nepal, provides an excellent example of these conflicting classifications.
13 Some studies have stated that Imja Tsho is safe (Watanabe et al., 2009; Fujita et al., 2013), a
14 very low risk (Hambrey et al., 2008), or a moderate risk (Budhathoki et al., 2010). Conversely,
15 ICIMOD (2011) identified Imja Tsho as one of six glacial lakes in Nepal that is a high priority
16 for further investigation and currently remediation efforts to reduce its hazard are under way
17 (UNDP, 2013). These remediation efforts and a similar project completed at Tsho Rolpa (Rana
18 et al., 2000) are excellent steps forward for Nepal with respect to addressing the hazards
19 associated with its glacial lakes. However, it is important that these efforts and resources are
20 properly directed to ensure the development of the most cost-effective, Nepal-specific methods
21 for successfully reducing the risk of glacial lakes as practiced by the Peruvians since the 1950s
22 (Carey, 2010). Conflicting classifications of Imja Tsho suggest relief efforts may be misguided
23 if the lake is indeed safe and also send mixed signals to the general public and downstream
24 communities that these studies are meant to assist. Another good example of these conflicting
25 reports is Chamlang South Tsho (also referred to as West Chamlang), where one study stated the
26 lake was not particularly dangerous (Byers et al., 2013) while another stated the lake was
27 potentially dangerous (Lamsal et al., 2016) despite having access to the same data sets.

28 These various assessments and conclusions highlight the importance of (1) developing a clear
29 and straight forward holistic method for assessing the hazard associated with a glacial lake and
30 (2) constructing a framework that guides management actions for a given glacial lake that
31 accounts for the various levels of data collection, modeling, and field campaigns. An additional

1 aspect that is important to incorporate is how the hazard associated with these glacial lakes will
2 change as the glacier and glacial lakes continue to evolve. This is especially important when one
3 considers that successful remediation strategies on hazardous lakes often take more than a
4 decade to secure funding and implement (Quincey et al., 2007).

5 This study assesses the performance of existing hazard assessment methods on potentially
6 dangerous glacial lakes in Nepal to determine how well they agree with one another. These
7 existing studies are used as the basis for developing a new holistic approach that is objective,
8 repeatable, and uses readily available information such that it may be applied to any glacial lake.
9 This approach will be developed within a management action framework such that it may be
10 used to guide future field campaigns, research, and ultimately risk-mitigation strategies
11 associated with hazardous glacial lakes.

12

13 **2 Study Area**

14 This study assesses the hazard and risk of GLOFs at eight glacial lakes in the Nepal Himalaya
15 (Figure 1). Six of these glacial lakes were identified by ICIMOD (2011) as being high priority
16 for further investigation: Tsho Rolpa, Lower Barun Tsho, Imja Tsho, Lumding Tsho (also
17 referred to as Tsho Og), Chamlang South Tsho (also referred to as West Chamlang), and Thulagi
18 Tsho. The other two glacial lakes considered are Chamlang North Tsho (also referred to as Lake
19 464), which was found to be dangerous (Byers et al., 2013) and Dig Tsho, which experienced a
20 GLOF in 1985 (Vuichard and Zimmermann, 1987). The level of investigation of each of lake is
21 highly variable.

22 The three glacial lakes that have received the most attention are Imja Tsho (86°55.5' E, 27°53.9'
23 N, 5007.7 m.a.s.l.), Tsho Rolpa (86°28.6' E, 27°51.7' N, 4527.8 m.a.s.l.), and Thulagi Tsho
24 (84°29.1' E, 28°29.3' N, 4014.8 m.a.s.l.). ICIMOD (2011) provides a detailed review of the
25 development of these lakes and the field investigations that have been performed to measure the
26 bathymetry, use geophysical techniques to identify the presence of buried ice, and broadly
27 investigate the hazard associated with these lakes. Since this study, the stability of their terminal
28 moraines has been investigated (Fujita et al., 2013) and potential GLOFs have been modeled
29 (Khanal et al., 2015). Additionally, a laboratory experiment was conducted to model the stability
30 of Tsho Rolpa (Shrestha et al., 2013) and other detailed investigations of Imja Tsho's bathymetry

1 (Somos-Valenzuela et al., 2014) and potential floods (Bajracharya et al., 2007; Somos-
2 Valenzuela et al., 2015) have been conducted. Tsho Rolpa is also the only glacial lake in Nepal
3 that has been remediated in an effort to reduce its hazard and subsequently was extensively
4 studied in the field prior to its remediation (Richardson and Reynolds, 2000).

5 Dig Tsho (86°35.1' E, 27°52.5' N, 4365.9 m.a.s.l.) has been extensively studied and used as a site
6 to assess and improve GLOF models (Cenderelli and Wohl, 2001; Bajracharya et al., 2007;
7 Westoby et al., 2014; Westoby et al., 2015; Watson et al., 2015). Chamlang South Tsho
8 (86°57.5' E, 27°45.3' N, 4951.8 m.a.s.l.) and Chamlang North Tsho (86°57.3' E, 27°47.0' N,
9 5218.0 m.a.s.l.) were both investigated in the field by Byers et al. (2013), which also included
10 the modeling a GLOF from Chamlang North Tsho. Chamlang South Tsho has since been further
11 investigated using high resolution digital elevation models (DEMs) and a bathymetric survey
12 (Sawagaki et al, 2012; Lamsal et al., 2016). A field investigation was performed at Lower Barun
13 Tsho (87°05.7' E, 27°47.9' N, 4534.5 m.a.s.l.) in 1993 in connection to potential hydropower
14 systems downstream (Mool et al., 2001), but has received little attention since with the exception
15 of a visual field assessment of the terminal moraine and potential triggers (Byers, 2014).
16 Similarly, Lumding Tsho (86°36.8' E, 27°46.8' N, 4819.3 m.a.s.l.) has received little attention
17 beyond documenting its growth (Bajracharya and Mool, 2009) despite being identified as a high
18 priority glacial lake (ICIMOD, 2011). This study addresses this data gap and shows how a new
19 method and framework may be used to prioritize future glacial lake investigations and
20 management actions.

21

22 **3 Existing Methods**

23 **3.1 Summary**

24 The first method that was used to assess the hazard of these eight glacial lakes was a “shotgun
25 approach” to determine how their classifications vary using previous qualitative and quantitative
26 assessment methods. The shotgun approach uses the same studies as Emmer and Vilímek (2013)
27 with the exception of Clague and Evans (2000) and Grabs and Hanisch (1993) as these required
28 site specific knowledge that was not possible to obtain from remote sensing. The use of solely
29 remotely sensed data is one of the main goals of the new method and framework developed in
30 this study. The qualitative methods used were O’Connor et al. (2001), Costa and Schuster

1 (1988), and Wang et al. (2008). Wang et al. (2008) highlights ten hazard parameters, but only
2 gives thresholds for eight of them; therefore, the eight parameters with thresholds are used for
3 this qualitative approach. As a specific hazard rating is unable to be determined from these
4 qualitative approaches, the arithmetic mean of the three is used to rank the glacial lakes.

5 The semi-quantitative method used in the shotgun approach was from Bolch et al. (2011), which
6 was developed for glacial lakes in the Tien Shan using remotely sensed data. Bolch et al. (2011)
7 uses a term called lake area change based on a comparison of lake area to its initial area;
8 however, the initial area of a lake is unclear as they were all small melt ponds at one point in
9 time. Therefore, the lake area change was simplified to give a value of 1 or 0 based on if the
10 lake has grown in the last decade or not, respectively. The quantitative approach of Wang et al.
11 (2011) also used only remotely sensed data with specific thresholds determined from a statistical
12 analysis of 78 lakes in the southeastern Tibetan Plateau. Wang et al. (2011) uses the mean slope
13 of the moraine based on a 100 m buffer around the lake; however, when this was applied to the
14 glacial lakes in this study the mean slope was zero or negative indicating that within the first 100
15 m of the lake the moraine is higher than the lake level. Therefore, the steep lakefront area (SLA)
16 from Fujita et al. (2013) was used as a surrogate for the mean slope of moraine so the method
17 could still be applied and account for the slope of the moraine. A more detailed description of
18 these studies may be found in Emmer and Vilímek (2013). Additionally, a new quantitative
19 approach developed by Emmer and Vilímek (2014) for the Cordillera Blanca was used in this
20 study. The approach assesses five GLOF scenarios: (1) moraine overtopping due to mass
21 movement entering the lake, (2) overtopping from a flood upstream, (3) moraine failure due to
22 mass movement entering the lake, (4) moraine failure from a flood upstream, and (5) failure
23 resulting from a strong earthquake. Unfortunately, the locations of seepage points required for
24 the last scenario were not identifiable from remote sensing, so the dam instability due to piping
25 was not accounted for.

26 **3.2 Application of existing methods**

27 The qualitative hazard assessments show a good deal of variation between the three approaches
28 (Table 1). The arithmetic mean reveals the most dangerous lakes based on these three qualitative
29 approaches are Chamlang North Tsho, Chamlang South Tsho, and Tsho Rolpa, closely followed
30 by the others with the exception of Imja Tsho and Thulagi Tsho. Imja Tsho has a lower value

1 since these methods all use some form of mass movement entering the lake, which currently is
2 not a threat at Imja Tsho. Thulagi Tsho is also not susceptible to ice avalanches and by some
3 methods has a more stable moraine due to the presence of vegetation. The semi-quantitative and
4 quantitative assessments give very different classifications of the hazard associated with each
5 lake (Table 2). Bolch et al. (2011) emphasizes the size of the lake and its ability to expand, so all
6 the large glacial lakes that have expanded over the last decade are ranked as high danger (Imja
7 Tsho, Lower Barun Tsho, Lumding Tsho, Thulagi Tsho, and Tsho Rolpa). The other glacial
8 lakes that have already reached their maximum extent are classified as medium danger. Wang et
9 al. (2011) is the complete opposite since the glacial lakes that have already reached their
10 maximum extent are all high risk or very high risk, while the others are medium or low risk.
11 This conflicting classification is due to the emphasis on parameters associated with mass
12 movement entering the lake, i.e., both the distance and the slope between the lake and the glacier.
13 The large glacial lakes that are still expanding have gentle slopes behind their calving fronts,
14 which cause them to be classified as medium or low.

15 Emmer and Vilímek (2014) classify all the glacial lakes as highly dangerous as they are all
16 susceptible to at least one GLOF scenario. Table 2 shows how many of the five scenarios are a
17 potential threat to each glacial lake. The reason for this classification is that the parameters
18 associated with the mass movement and overtopping scenario are dam freeboard and distance
19 between the glacier and the lake. The eight lakes considered in this study all have outlet
20 channels, so their freeboard by definition is zero. Furthermore, these eight glacial lakes are
21 either in contact or within 600 m of their mother glaciers, which results in this methodology
22 considering them all to be susceptible to this dynamic failure. As Emmer and Vilímek (2014)
23 discussed, the method was developed for scenarios related to Cordillera Blanca such that the
24 framework could be transferred to other regions, but the exact scenarios or parameters used may
25 not be representative of the main threats to other regions. Nonetheless, the assessment yields
26 valuable insight showing Lumding Tsho, Lower Barun Tsho, and Tsho Rolpa have the greatest
27 number of hazard scenarios due to the potential for a flood from a glacial lake upstream, which is
28 important to consider.

29 The shotgun approach shows that the hazard classification of each glacial lake varies greatly
30 depending upon the selected method, which makes classifying the hazard associated with a
31 particular glacial lake difficult. Fortunately, the shotgun approach is useful as it highlights the

1 most commonly used parameters in previous studies. Table 3 shows the most frequently used
2 parameters are mass movement entering the lake, the moraine width-to-height ratio, the presence
3 of buried ice in the moraine, and the distance between the lake and the glacier. These naturally
4 reflect the most common causes of GLOFs, i.e., mass movement entering the lake and the self-
5 destruction of the moraine due to hydrostatic pressure and/or the degradation of buried ice
6 (Richardson and Reynolds, 2000; Wang et al., 2012; Emmer and Cochachin, 2013). Furthermore,
7 many of the other parameters are simply alternative forms of estimating the potential cause of
8 failure, e.g., glacier snout steepness or the distance between the lake and the glacier are surrogate
9 ways to estimate if the lake is susceptible to an avalanche entering the lake. In this manner, the
10 shotgun approach lends insight into the various parameters or methods that were used to estimate
11 different triggering events. The variety of parameters and the frequency of their use highlight the
12 parameters that are important to consider in addition to highlighting the importance of
13 developing a holistic method that accounts for these various forms of failure.

14

15 **4 New Hazard and Risk Framework**

16 The conflicting hazard classifications from the shotgun approach casts uncertainty on the hazard
17 of each glacial lake that can be confusing and misleading to the stakeholders these studies are
18 meant to assist. Furthermore, they cast uncertainty on which glacial lakes should receive more
19 attention through field campaigns and/or detailed analyses and the specific parameters that
20 should be focused on. This study develops a new hazard and risk assessment framework that is
21 holistic, objective, reproducible, and initially relies solely on remotely sensed data. Specifically,
22 this framework focuses on two forms of glacial lake failure: dynamic and self-destructive. The
23 term “self-destructive” failure (Yamada, 1998) is used here to avoid any confusion with long
24 term failures resulting from dynamic causes and lake growth, i.e., as a lake grows its expansion
25 may make it susceptible to mass movement entering the lake from areas that could not
26 previously reach the lake. Figure 2 shows the seven parameters used in this study are potential
27 mass movement entering the lake from (1) a snow/ice avalanche, (2) a rockfall, or (3) an
28 upstream flood, (4) the future expansion of the glacial lake, the stability of the moraine based on
29 (5) the hydrostatic pressure and (6) the presence of buried ice, and (7) the downstream impact.
30 These parameters are all estimated using simplistic models and globally available data sets. The

1 approach is referred to as a “remote” hazard assessment. The integration of site-specific field
2 data, high resolution data sets, and more complex models to improve upon this remote
3 assessment will be detailed in the discussion in conjunction with a brief description of the current
4 state of knowledge for each glacial lake investigated.

5 **4.1 Remote hazard assessment**

6 The remote hazard assessment framework is intended to be used as a launching point for
7 assessing the hazards of glacial lakes. The parameters and models used in this framework are all
8 derived from globally available data sets. The DEM utilized in this study is the ASTER GDEM,
9 which is composed of automatically generated DEMs from the Advanced Spaceborne Emission
10 and Reflection radiometer (ASTER) stereo scenes acquired from 2000 to 2008. The ASTER
11 GDEM V2 (hereon referred to as GDEM) has a horizontal resolution of 30 m and a vertical
12 RMSE of ± 15.1 m for mountainous areas (ASTER GDEM Validation Team, 2011). The
13 GDEM was used in this study instead of the SRTM V4 DEM (Farr et al., 2007) due to its higher
14 resolution and its effect on the flood models is discussed in Section 4.1.4. Landsat imagery
15 (Landsat 4/5 TM, Landsat 7 ETM+, and Landsat 8 OLI TIRS) was also used to delineate the
16 glacial lakes and identify areas of snow, ice, and land. Landsat imagery was selected for this
17 study as it is the highest resolution multi-spectral imagery that is ubiquitous.

18 **4.1.1 Mass movement trajectories**

19 Mass movement entering a glacial lake is a highly hazardous situation for glacial lakes as the
20 entry may cause a tsunami-like displacement wave that can trigger a GLOF. This study
21 considers three types of dynamic failures: snow/ice avalanches, rockfalls, and upstream GLOFs
22 (Figure 2). This section describes the mass movement trajectories for avalanches and rockfalls,
23 while the upstream GLOFs are discussed later (Section 4.1.5). Landsat imagery was used to
24 automatically detect glacierized and non-glacierized areas using a ratio of the NIR and SWIR 1
25 bands with a threshold of 2.2 (Huggel et al., 2004a). In this simplified model, there is no
26 differentiation between snow and ice. Snow/ice avalanche prone areas were identified as any
27 glacierized area with a slope greater than 45° (Alean, 1985), but less than 60° as mass is unlikely
28 to accumulate beyond this threshold (Osti et al., 2011; Shea et al., 2015). Rockfall prone areas
29 were identified as any non-glacierized areas with a slope greater than 30° (Bolch et al., 2011) and

1 less than 60° as well. The lateral moraines were precluded from being rockfall prone areas as
2 they tend to be well developed and are unlikely to lose a large amount of material in one event.
3 A single flow model using the flow direction algorithm in ArcGIS 10.3 in conjunction with a
4 sink-free GDEM was used to model the path of the mass movement.

5 The runout distance of the mass movement trajectories was computed using an average slope
6 threshold of 17° and 20° for avalanches and rockfalls, respectively. However, avalanches with a
7 volume less than 6.67 million cubic meters had a higher average slope threshold based on a log
8 relationship between avalanche volume and average trajectory slope (Huggel et al., 2004b)

9

$$10 \quad \tan(\alpha) = 1.111 - 0.118 \log(V) \quad (1)$$

11

12 The avalanche volume was determined from estimates of avalanche-prone areas and assumed
13 avalanche thickness. Avalanche-prone area was estimated using a variable kernel filter with a
14 90% threshold to determine the maximum avalanche-prone area with each pixel. The variable
15 kernel filter begins with an individual pixel and determines if 90% of the surrounding pixels
16 including itself, i.e., a 3 x 3 pixel grid, are avalanche-prone. If this condition is satisfied, then the
17 kernel filter increases by one pixel, i.e., a 5 x 5 pixel grid, and continues this process until the
18 90% threshold fails. The estimated avalanche-prone area is considered to be the largest area that
19 satisfies the 90% threshold. This study assumed three depths for avalanche thickness (10 m, 30
20 m, and 50 m) from avalanches previously reported in Russia (Huggel et al., 2005) and common
21 estimates in the Swiss Alps (Huggel et al., 2004) due to a lack of avalanche depth data in the
22 Himalaya. These three scenarios were used in conjunction with the avalanche-prone areas to
23 estimate avalanche volume. The avalanche volumes ranged from $2.7 \times 10^4 \text{ m}^3$ to $6.7 \times 10^6 \text{ m}^3$.

24 **4.1.2 Lake expansion**

25 Lake growth is crucial to incorporate into hazard assessments as the expansion of a glacial lake
26 may greatly alter the lake's proximity to potential hazards and increase the volume of water
27 likely released in a GLOF. Mass movement entering the lake is the most common cause of a
28 GLOF, so one must determine if dynamic failure is both a current and/or future threat. Multi-
29 spectral satellite imagery can be used to determine lake expansion rates semi-automatically using

1 the normalized difference water index (NDWI) (McFeeters, 1996), which is a combination of the
2 near-infrared (NIR) and blue bands. In the event that the blue band is not available or the
3 contrast is not clear, the green (Bolch et al., 2008) and/or shortwave infrared (SWIR) bands
4 (Somos-Valenzuela et al., 2014) may be used as a suitable alternative. Bolch et al. (2008) found
5 the NDWI method yielded accurate estimates of lake area compared to manual delineations
6 performed by Bajracharya et al. (2007).

7 One difficulty associated with the NDWI analysis is the objective selection of the threshold used
8 to differentiate land and water. Bolch et al. (2011) found the threshold for Landsat images to
9 range from 0.3 – 0.9 for glacial lakes in northern Tien Shan, but no clear instructions exist for
10 selecting the threshold for each image and glacial lake. Thakuri et al. (2015) used the same
11 technique at Imja Tsho and found the lake area to be constant between July and January each
12 year. They suggested this was due to the lake level being constant, but measurements of lake
13 level were not included. This study uses the same approach with Landsat imagery from 2000 to
14 2015 captured between September and January each year and assumes the width of the lake
15 between the lateral moraines is constant based on the findings from Thakuri et al. (2015) and the
16 assumption of a constant lake level. Two exceptions were made, one for Chamlang North Tsho,
17 which used an image from May as there were less shadows during this time of year and another
18 for the supplementary image of Lower Barun Tsho in 2008, which used an image from the
19 following April. Additionally, no clear sky, non-banded Landsat imagery was available in 2003,
20 2004, and 2008 for Lower Barun Tsho, so an Advanced Spaceborne Thermal Emission and
21 Reflection Radiometer (ASTER) image between September and January was used for these years
22 instead.

23 Thresholds were objectively selected such that the average width of the lake is constant between
24 images. This method forces any changes in lake area to be the result of upglacier and/or
25 downglacier expansion, which was the focus of this study. In the event that clouds or the
26 Landsat 7 stripping caused portions of the lake to have gaps in the imagery, a second Landsat
27 image was used to fill in these missing areas using the same criteria. Additionally, large debris-
28 covered icebergs nearing the calving front that could cause pixels to be misclassified as land
29 instead of water were manually corrected in post-processing.

1 The expansion rate was estimated as the average rate of areal expansion for all the 10 year
2 intervals available, i.e., if yearly delineations were available from 2000 to 2015, then the six
3 values of the 10 year expansion were averaged to estimate the areal expansion rate. These
4 expansion rates were used in conjunction with ice thickness estimates to determine future lake
5 extents. The ice thickness data used in this study is from the GlabTop2 model (Frey et al., 2014),
6 which estimates the ice thickness from a DEM and glacier outlines. The ice thickness of the
7 glaciers in this study was upwards of 250 m thick behind the calving front of some lakes. The
8 bed topography of the glaciers was computed as the ice thickness subtracted from the surface
9 elevation, which was used to identify potential overdeepenings, i.e., locations in the bed
10 topography that are sinks and allow the lake to expand.

11 Future lake projections were estimated using the average areal expansion rates based on all 10
12 year intervals over the next 50 years such that the lake's risk to future dynamic failures could be
13 assessed. Glacier flowlines were used to guide the direction of the expansion. The lake level
14 was assumed to be constant over the next 50 years and was estimated as the average elevation of
15 all the lake pixels based on the lake extent from 2000 as this elevation should be relatively
16 constant over the time period when DEMs for the GDEM were being captured.

17 **4.1.3 Hydrostatic pressure**

18 The exact cause of failure associated with a moraine that spontaneously fails without any
19 external influence is difficult to pinpoint, but is commonly referred to as “self-destruction”
20 (Yamada, 1998; Emmer and Cochachin, 2013). One cause of self-destruction is when the
21 hydrostatic pressure, the pressure a column of water exerts on the moraine, exceeds the structural
22 capacity of the moraine. Many studies account for the moraine stability using a ratio of the
23 moraine width-to-height (Table 2), which is subject to large errors if a global DEM is used
24 (Fujita et al., 2008). Fujita et al. (2013) developed a surrogate parameter known as the steep
25 lakefront area (SLA) using remotely sensed data that is not as susceptible to the uncertainty
26 associated with global DEMs. The SLA is the average slope between the lake and any point
27 within 1000 m of the moraine, which is similar in concept to the mean slope of the moraine
28 based on a 100 m buffer that was used by Wang et al. (2011). The slope of any point within
29 1000 m of the moraine is meant to capture the steepest slope between the lake and the base of the

1 terminal moraine. Fujita et al. (2013) examined moraines that had previously failed and
2 determined that lakes with a SLA less than 10° were not susceptible to fail.

3 This study uses the SLA with a threshold of 10° to determine if the hydrostatic pressure may
4 cause the moraine to self-destruct. NDWI delineations of the lake area are used to identify the
5 pixels for the SLA calculation. The elevation of these lake pixels was set equal to the average
6 elevation of the glacial lake from the GDEM based on the year 2000 delineation. Furthermore,
7 the SLA was only computed for the main body of the lake, i.e., the SLA was not computed from
8 melt ponds on the damming moraines of the lakes. Initial results of the SLA reported very high
9 values of the SLA due to the elevation changes between adjacent pixels in the GDEM. These
10 values are not representative of the slope of the moraine or the hydrostatic pressure on the
11 moraine, so a 100 m buffer around the lake was used such that the SLA would be accurately
12 captured.

13 **4.1.4 Buried Ice**

14 The other main cause of failure associated with “self-destruction” is the melting of ice within a
15 lake’s terminal moraine since a disintegrating ice-core can undermine the structural integrity of
16 the moraine (Richardson and Reynolds, 2000). This can have large implications for the
17 hydrostatic pressure, piping/seepage, and reducing the height of the freeboard associated with the
18 terminal moraine (Emmer and Cochachin, 2013). The importance of accounting for ice-cored
19 moraines is apparent from previous studies (Table 2), but requires detailed information regarding
20 the terminal moraine that is typically not available from remotely sensed data. Bolch et al.
21 (2011) used permafrost as a surrogate parameter to suggest the potential of an ice-cored moraine.
22 A similar approach was assessed in this study using permafrost maps (Gruber, 2012); however, a
23 comparison between lakes with known ice cores and the permafrost maps revealed no correlation.
24 McKillop and Clague (2007) assessed the presence of an ice core according to the shape of the
25 moraine using aerial imagery by assuming that a moraine with a rounded surface with arcuate
26 ridges had an ice core, that a disproportionately large terminal moraine in front of a glacier was
27 potentially ice-cored, and a narrow, sharp-crested moraine with an angular cross-section was ice-
28 free. Unfortunately, this approach is highly subjective and appears to fail for glacial lakes with
29 ice cores in Nepal. For example, Tsho Rolpa has a narrow terminal and lateral moraine that

1 would suggest its moraine is ice free; however, it is known to have an ice core (Yamada, 1998;
2 Richardson and Reynolds, 2000; ICIMOD, 2011).

3 In the field a common approach to determine if a moraine is ice-cored is by observing ice cliffs
4 or karst topography (Yamada, 1998; Richardson and Reynolds, 2000; ICIMOD, 2011). Another
5 common way is to witness changes in the outlet channel over time, which has been observed at
6 Imja Tsho (Watanabe, 1994), Tsho Rolpa (Yamada, 1998), and Thulagi Tsho (ICIMOD, 2011).
7 This study takes a similar approach using satellite imagery and Google Earth to identify the
8 presence of any water on the moraine or any changes in the outlet. If water is present on the
9 moraine or any changes in the outlet are observed, the moraine is assumed to have an ice core.
10 During the analysis, a combination of Google Earth and satellite imagery was found to help
11 differentiate between shadows and water, but it is recommended to err on the side of caution
12 when one is unsure. Unfortunately, the lack of clear thresholds for identifying water on the
13 moraine or changes in the outlet adds a small amount of subjectiveness to this study. However,
14 as this was the most effective and least subjective approach for identifying the presence of buried
15 ice in the moraine, it was used for the remote assessment.

16 **4.1.5 GLOF Modeling**

17 Flood models play a crucial role in a glacial lake hazard assessment as they identify areas at risk,
18 which allows one to determine the downstream impact. Westoby et al. (2014) provides a
19 thorough overview of the various types of floods and types of models that may be used to
20 reconstruct a GLOF. In short, if the flood entrains enough sediment from the moraine and
21 channel downstream, the flood may transform into a debris flow, which increases the momentum
22 of the flood thereby increasing the GLOF's extent and potential damage. The models used to
23 reconstruct these debris flows or GLOFs range from simple computationally inexpensive GIS-
24 based methods to computationally expensive, physically based numerical models. The GIS-
25 based methods typically rely solely on the geometry of the downstream channel from a DEM.
26 Numerical models have been used to resolve the flow of a GLOF in one or two dimensions. The
27 benefit of two-dimensional models is their ability to capture more complex features and flow
28 characteristics, e.g., multi-directional flows or super-elevation of flow around a channel bed
29 (Westoby et al., 2014). The selection of a particular model or method typically depends on data
30 availability and the desired model complexity.

1 This study explored the use of two computationally inexpensive flood models: the Modified
2 Single Flow direction (MSF) model developed by Huggel et al. (2003) and the Monte Carlo
3 Least Cost Path (MC-LCP) model developed by Watson et al. (2015). The MSF model is a
4 standard flow direction model that “allows the flow to divert from the steepest descent direction
5 up to 45° on both sides” (Huggel et al., 2003). The model requires a sink-filled DEM, a starting
6 point in the form of a polygon, and a set threshold to stop the model based on the average angle
7 between the starting point and the downstream flood. The MC-LCP model uses a Monte Carlo
8 simulation to vary the DEM as a function of its uncertainty, while identifying the potential flow
9 path for each simulation using a least cost analysis.

10 The lack of data related to previous GLOFs makes it difficult to assess the performance of
11 different models. Watson et al. (2015) used the 1985 GLOF at Dig Tsho to compare the
12 performance of the MSF and MC-LCP models to the actual flood extents. These models used
13 the GDEM resampled to 15 m and were found to perform reasonably well, although the MC-
14 LCP model had a larger inundation area and fewer artefacts. Watson et al. (2015) also observed
15 that in high relief Himalayan catchments, the requirements for an artificially filled DEM by the
16 MSF model created large linear inundation artefacts, whereas the MC-LCP model displayed
17 improved flow routing and hence is more appropriate for assessing first-order socio-economic
18 impacts of a potential GLOF. It is important to note that the GDEM reflects the post-GLOF
19 terrain, which was severely altered by the GLOF (Vuichard and Zimmermann, 1987). Ideally, a
20 pre-GLOF DEM would be used for model validation so modeled flood extents would not be
21 affected by scouring and deposition in the main channel. Furthermore, the comparison reveals
22 multiple areas where the MC-LCP model does not capture the actual flood extent, which would
23 be highly problematic for a hazard assessment if these areas were populated.

24 As both the MSF and MC-LCP models have no physical basis, model selection was determined
25 by the one that yielded the most reasonable, conservative estimate of inundation areas when
26 compared to a two-dimensional debris-flow model, FLO-2D, from Imja Tsho (Somos-
27 Valenzuela et al., 2015). Figure 3 shows the flood extent for the FLO-2D, MSF, and MC-LCP
28 models along with the performance of the MC-LCP model for various DEMs (GDEM and
29 SRTM) and resolutions (resampled to 15 or 30 m). The comparison revealed the MSF model
30 (Figure 3B) and the MC-LCP model resampled to a 15 m resolution for the SRTM DEM (Figure

1 3C) and the GDEM (Figure 3D) severely underestimated the flood extent. On the other hand, the
2 MC-LCP model with the 90 m SRTM DEM yielded too conservative of an estimate (Figure 3G).
3 The 30 m results for both the SRTM DEM (Figure 3E) and GDEM (Figure 3F) agreed well with
4 the FLO2D results (Figure 3A); however, a more detailed analysis revealed the GDEM tracked
5 the main channel better. Therefore, the MC-LCP model with the 30m GDEM was used in this
6 study to model the potential GLOFs from each lake. The GLOF from each lake was routed to
7 the confluence of the Sun Kosi for seven of the eight glacial lakes, and approximately 60 km
8 downstream for Thulagi Tsho based on the assumption that beyond this distance the downstream
9 effects are minimal as the river is able to absorb the flood's energy (Vuichard and Zimmermann,
10 1987).

11 **4.1.6 Downstream Impact**

12 Buildings and agricultural land use data were extracted from the inundation extent of each MC-
13 LCP GLOF scenario to provide a first-pass assessment of socio-economic implications.
14 Buildings were downloaded from OpenStreetMap and validated in Google Earth, which also was
15 used to add to the dataset where required using the most recent imagery. Areas of agricultural
16 land were manually digitized in Google Earth and included all visibly managed land, i.e., land
17 that appeared cleared, walled, farmed, or grazed, and would likely have detrimental socio-
18 economic implications of flooded. The potential downstream impact was broken down into three
19 classes: high, medium, and low. High impact is defined as the potential loss of life with no
20 warning (lodges/buildings) and/or costly projects (e.g., hydropower). Medium impact is defined
21 as any damage that is disruptive, which is meant to include damage to agricultural lands, bridges,
22 trails, etc. Lastly, low impact is defined as having no impact on humans, infrastructure, or other
23 projects. For the purpose of this study, buildings are assumed to have permanent occupants
24 whose lives would be threatened in the event of a GLOF. Agricultural lands are considered to be
25 a medium impact as their occupancy changes temporally depending on the season and in the
26 event that people are in the fields they may be able to hear and/or see an upstream flood and have
27 an opportunity to move to safe ground. The definition of costly projects or infrastructure is fairly
28 subjective, but is meant to refer to any hydropower system or similar project since the loss of a
29 mature hydropower system can effect multiple generations and jeopardize the economic
30 development of the country (Richardson and Reynolds, 2000).

1 **4.2 Risk classification and management actions**

2 The hazard elements described above are crucial for determining if a glacial lake is susceptible to
3 a dynamic or a self-destructive failure. Figure 4 shows the workflow that is used to determine if
4 the lake is susceptible to failure and how the cause of failures translates into the hazard
5 associated with the lake. The most dangerous situation is a glacial lake that is susceptible to both
6 dynamic and self-destructive failures, which would classify the lake as a very high hazard.
7 Susceptibility is defined as a hazard greater than low, i.e., a lake that is considered a medium
8 hazard for dynamic failure and medium hazard for self-destructive failure is still classified as
9 very high hazard. The other scenario that classifies a lake as very high is a lake with a buried ice
10 core that is susceptible to a snow/ice avalanche as the ice core may alter the height of the
11 moraine over time and/or the erosion and breach of the moraine. A lake that is susceptible to
12 avalanches, but does not have an ice core was classified as high hazard. Snow/ice avalanches
13 were given the highest hazard classification since they are the most frequent cause of failure in
14 the Himalaya (Emmer and Cochachin, 2013). Additionally, any lake with a buried ice core that
15 is susceptible to a rockfall, upstream GLOF, or has a steep SLA is classified as high hazard.
16 These hazard ratings are meant to reflect self-destructive failures being the second most common
17 cause of GLOFs followed by mass movement entering the lake from rock or liquid water
18 (Emmer and Cochachin, 2013). As temperatures continue to increase, thereby promoting the
19 formation of more glacial lakes and altering slope stability due to changes in permafrost, there is
20 a possibility that failures from rockfalls and/or upstream GLOFs may become more common as
21 they are in Cordillera Blanca. A lake that does not have an ice core, but is susceptible to a
22 rockfall, upstream GLOF, or has a steep SLA is considered to be medium hazard.

23 The risk of a GLOF is a function of a glacial lake's hazard and its potential downstream impact
24 (Figure 5). Very high risk lakes are defined as any lake where the downstream impact is high,
25 i.e., lives or costly projects are threatened, and the hazard of the lake is very high. High risk is
26 defined as a lake that has a high downstream impact and a high hazard or a medium downstream
27 impact with a high or very high hazard. Medium risk refers to lakes that have a high or medium
28 downstream impact, but are only a medium hazard, or a lake that has a low downstream impact,
29 but is a high or very high hazard. Lastly, low risk refers to the remaining lakes that are less of a
30 threat to downstream communities and not a high hazard. It is important to note that any site that

1 is at risk of a dynamic or self-destructive failure is valuable from an academic perspective as
2 they may help improve the current state of knowledge of GLOF hazards.

3

4 **5 Results & Discussion of Remote Hazard Assessment**

5 The remote hazard assessment builds off of existing knowledge of glacial lakes in Nepal while
6 integrating new approaches to develop a holistic understanding of their hazard and risks. The
7 mass movement trajectories mark the first time these potential triggers have been modeled at a
8 larger scale, which provides valuable information on the potential for mass to enter a lake in
9 addition to identifying the locations of these avalanche and rockfall prone areas that should be
10 further investigated. The stability of a moraine utilizes a previously developed approach, i.e., the
11 SLA (Fujita et al., 2013), in combination with predictions of the presence of buried ice from
12 satellite imagery such that self-destructive failures may be integrated into the hazard framework
13 with the dynamic failures. Similarly, the downstream impacts use a previously developed GLOF
14 model, i.e., MC-LCP approach (Watson et al., 2015), to obtain a conservative estimate of
15 potentially inundated areas downstream. For three of the eight glacial lakes considered in this
16 study, this is the first time their potential GLOFs have been modeled. Furthermore, this study
17 combined lake expansion rates from satellite imagery with ice thickness estimates to model the
18 evolution of these glacial lakes to determine how their hazard may vary over the next 50 years.

19 Table 4 provides a brief summary of the hazard parameters for each glacial lake. The potential
20 for avalanches and rockfalls should not be surprising as these glacial lakes have developed on
21 avalanche-fed debris-covered glaciers, so their surrounding slopes are commonly unstable.
22 Three of the eight glacial lakes are threatened by a potential upstream GLOF, which makes it
23 important to assess the hazards associated with these upstream lakes as well. The SLA varies
24 between 4.9° at Lower Barun Tsho up to 18.8° for Chamlang North Tsho. Buried ice is predicted
25 to be present in the moraines of five of these lakes, but only two of these glacial lakes have a
26 SLA above the 10° threshold thereby classifying these lakes as a high risk of self-destruction.

27 The hazard of these eight glacial lakes varies from low to very high with five of the eight lakes
28 currently being very high hazard (Table 5). Four of the lakes classified as very high hazard are
29 susceptible to both dynamic and self-destructive failures. Specifically, Chamlang South Tsho
30 and Tsho Rolpa are both very high hazard for dynamic failure and high hazard for self-

1 destructive failure. The MC-LCP GLOF modeling revealed potential to damage buildings and
2 large swathes of agricultural lands for all eight glacial lakes, so the downstream impact was high
3 for all the lakes. The amount of buildings, agricultural land, and bridges affected varied greatly,
4 which was partly due to differences in the distance the GLOF was allowed to propagate
5 downstream, but also due to the amount of development below each glacial lake. Therefore, the
6 inundated buildings per km² and percentage of agricultural land affected are beneficial for
7 comparing the impacts of different glacial lakes. Tsho Rolpa had the highest amount of affected
8 buildings (56.8 buildings km⁻²) and agricultural land (16.0%) followed closely behind by Thulagi
9 Tsho (49.7 buildings km⁻² and 13.1%, respectively). Chamlang North Tsho, Chamlang South
10 Tsho, and Lumding Tsho had the smallest amounts of inundated buildings and agricultural land
11 affected; however, a GLOF from these lakes could potentially impact on the order of 200
12 buildings, 2.5 km² of agricultural land, and 15 bridges, which is still cause for considerable
13 concern. Based on these hazard classifications and downstream impacts, the risk for each glacial
14 lake ranged from medium to very high. These high and very high risk classifications should not
15 be surprising as all the lakes investigated in this study (with the exception of Dig Tsho) were
16 previously deemed hazardous or in need of further investigation (ICIMOD, 2011; Byers et al.,
17 2013).

18 Figure 6 shows that Lower Barun Tsho, Imja Tsho, and Lumding Tsho continue to expand
19 rapidly, while Tsho Rolpa and Thulagi Tsho have stagnated in recent years. The other lakes
20 (Chamlang North Tsho, Chamlang South Tsho, and Dig Tsho) have already detached from their
21 glaciers and lack the ability to expand. These expansion estimates combined with the mass
22 movement trajectories reveal that Imja Tsho is susceptible to a dynamic failure in the next 10 –
23 20 years (Table 4). These results have important implications on the hazard and risk associated
24 with Imja Tsho as they indicate that in 10 – 20 years Imja Tsho may be a very high hazard and
25 very high risk (Table 5). Additionally, the expansion of Lower Barun Tsho and Lumding Tsho
26 makes them susceptible to potential avalanches located further upstream; however, this does not
27 alter their hazard ratings as they are presently at risk as well.

28 **5.1 Imja Tsho**

29 Imja Tsho is one of the most well studied glacial lakes in Nepal, yet the remote hazard
30 assessment still yields new relevant insight. The mass movement trajectories (Figure 7A,B)

1 show that the lake is currently not at risk of a dynamic failure. These trajectories are
2 conservative estimates of avalanche and rockfall runout and for a worst-case scenario they
3 remain at least 800 m and 400 m from the calving front, respectively. The ice thickness behind
4 the calving front is greater than 200 m thick (Somos-Valenzuela et al., 2014; Frey et al., 2014),
5 which allows the lake to continue to expand (Figure 7D). A detailed analysis of the growth of
6 Imja Tsho (Figure 6) shows the lake is expanding at an average rate of $0.034 \pm 0.003 \text{ km}^2 \text{ yr}^{-1}$.
7 Based on these expansion rates and the ice thickness estimates, the lake may be at risk of a
8 rockfall entering the lake in 10 years and an avalanche entering the lake in 20 years.

9 Fortunately, at the present moment the lake is unlikely to have a self-destructive failure as its
10 SLA is fairly gentle at 6.8° . The melt ponds on the moraine (Figure 7C) suggest the presence of
11 buried ice, which has been confirmed in the field (Hambrey et al., 2008). The ice-cored moraine
12 is currently not a large concern as its gentle slope does not produce hydrostatic pressure that
13 endangers the lake. However, satellite imagery reveals the outlet lakes have been changing
14 rapidly, which is important to monitor as these changes may alter the hydrostatic pressure on the
15 moraine (Fujita et al., 2013). If the outlet lakes on the terminal moraine are considered to be part
16 of the lake, the SLA changes to 11.0° and Imja Tsho would currently be a high hazard and high
17 risk. Therefore, monitoring the development of the outlet lakes and their influence on the
18 hydrostatic pressure should be a top priority. The MC-LCP model (Figure 7E,F) shows that 539
19 buildings and 2.7 km^2 of agricultural land are at risk (Table 6), which corresponds to a high
20 downstream impact.

21 Imja Tsho is currently classified as medium risk due to its low hazard and high downstream
22 impact. These high downstream impacts highlight the importance of running hydrodynamic
23 models with high resolution imagery to improve the mapping of inundated areas and inform the
24 local communities (Somos-Valenzuela et al., 2014). The expansion model reveals that if Imja
25 Tsho continues to grow at its current pace it will be a very high risk in the next 10 – 20 years.
26 Since the expansion is highly concerning, one important area of future work should be measuring
27 the ice thickness upglacier of Imja-Lhotse Shar Glacier using geophysical techniques such that
28 the potential future extent of Imja Tsho may be accurately quantified. Additionally, efforts
29 should focus on modeling the GLOF process chain, i.e., mass movement entering the lake, the
30 wave propagation, the possible breach of the moraine due to the overtopping, and the

1 downstream impacts due to the future risk. The ice-cored moraine has already been well
2 characterized (Hambrey et al., 2008), but is critical to avoid during any lake lowering activities
3 such that a breach is not initiated. Furthermore, while self-destructive failure is not an
4 immediate concern, repeat bathymetric studies on the outlet lakes would provide valuable
5 information regarding the evolution of the moraine to understand how the hydrostatic pressures
6 may change over time. Based on this remote assessment, the current risk mitigation actions to
7 lower the level of the lake, ideally by 20 m (Somos-Valenzuela et al., 2015), are well justified
8 and hopefully will serve as a good example of how to mitigate the risk of a glacial lake before it
9 becomes highly hazardous.

10 **5.2 Lumding Tsho**

11 Lumding Tsho was classified as a high priority for further investigation (ICIMOD, 2011), but
12 has received very little attention beyond an analysis of its expansion (Bajracharya and Mool,
13 2009) and SLA (Fujita et al., 2013). The remote assessment confirms that Lumding Tsho is a
14 very high hazard as it is susceptible to both dynamic and self-destructive failures. The mass
15 movement trajectories reveal the lake is susceptible to avalanches and rockfalls from the
16 southern side slope (Figure S5A,B). Furthermore, the lake is susceptible to a GLOF from
17 Lumding Tsho Teng located 600 m upstream of Lumding Tsho. Lumding Tsho Teng (27°47.4'
18 N, 86°37.3' E, 5141 m a.s.l.) has an area of 0.34 km² and is susceptible to a large avalanche from
19 its northeastern slope in addition to potential rockfalls from its surrounding slopes. Lumding
20 Teng Tsho also has a SLA of 31.7° indicating its moraine is highly unstable. These
21 measurements on Lumding Teng Tsho indicate the lake is a very high hazard, so an upstream
22 GLOF should be a great concern for Lumding Tsho.

23 Lumding Tsho also has a SLA (10.5°) that exceeds the stable threshold indicating the lake is
24 susceptible to a self-destructive failure. Fortunately, the lack of ponds and apparently stable
25 outlet channel on the terminal moraine indicate the moraine is unlikely to be ice-cored (Figure
26 S5C). Detailed analysis of the growth of Lumding Tsho reveals the lake is growing at an
27 average rate of $0.023 \pm 0.002 \text{ km}^2 \text{ yr}^{-1}$ (Figure 6). The lake expansion model estimates the lake
28 may continue to grow 500 m upglacier (Figure S5D), which would make it susceptible to large
29 avalanches (assumed 50 m depth) from Lumding glacier that currently do not reach the lake.
30 Therefore, the lake is likely to become more hazardous in the future as its proximity to more

1 avalanche prone areas increases, but its hazard classification does not change as it was already
2 classified as a very high hazard. The MC-LCP GLOF model (Figure S5E,F) reveals 184
3 buildings and 2.0 km² of agricultural land are at risk (Table 6). This downstream impact is the
4 smallest of those considered in this study, but still shows there is considerable risk to livelihoods
5 downstream thereby classifying Lumding Tsho as very high risk.

6 An initial rapid reconnaissance was undertaken from 20 – 24 October 2015 to assess the hazards
7 associated with Lumding Tsho as directed by the management action framework (Figure 5). The
8 short field campaign consisted of a bathymetric study, streamflow measurements of the outlet,
9 and visual inspection of the terminal moraine and surrounding slopes. The bathymetric survey
10 was conducted over two days using an inflatable kayak and a Garmin echoMAP 54dv to measure
11 4768 points of lake depth. The shoreline was delineated using the NDWI methods as previously
12 reported. The shoreline was converted into point measurements that were used in conjunction
13 with the bathymetric survey to interpolate depth throughout the lake using the Topo to Raster
14 tool in ArcGIS (Somos-Valenzuela et al., 2014). The lake was found to have an average depth of
15 51 m, a maximum depth of 114 m, and a total volume of 57.7 x 10⁶ m³ (Figure 8).

16 Streamflow from the outlet of the lake was measured to be 8.4 m³ s⁻¹ in the afternoon of 23
17 October using a Pygmy Current Meter with an AquaCalc Pro Plus computer (Rickly
18 Hydrological Company). Inspection of the terminal moraine revealed the outlet was the only
19 source of water exiting the lake, i.e., there was no apparent seepage through the terminal moraine.
20 Additionally, no ponds or karst-like features were present on the terminal moraine, which further
21 indicated that the moraine was relatively stable. In contrast to the SLA, the terminal moraine
22 appeared to be relatively gentle and fairly wide (Figure 9C). A detailed analysis of the SLA
23 calculations reveals that 1 km downstream of Lumding Tsho is a large waterfall. If the distance
24 from the lake used to compute the SLA was changed from 1 km to 950 m, then the SLA changes
25 to 9.8°, which would change the hazard of a potential self-destructive failure from medium to
26 low. The waterfall is important to consider as this drop in elevation would generate a significant
27 amount of energy that could exacerbate a GLOF downstream. Therefore, a physically-based
28 flood model that can account for this acquisition of energy would be valuable for improving
29 estimates of the potential downstream impacts.

1 Visual inspection of the side slopes revealed the slopes were very steep and likely lacked the
2 ability to generate a large rockfall (Figure 9A,B). On the southern slope there was one large
3 boulder that could be a potential concern (highlighted in Figure 9B), but its limited elevation
4 above the lake level would likely cause only a small surge wave. The snow and ice above the
5 southern side slopes was also very steep and no hanging glaciers were apparent. A more detailed
6 assessment of the stability of the side slopes would be invaluable in improving the likelihood of a
7 rockfall or avalanche. Specifically, the three hanging glaciers located behind the calving front
8 (Figure 5.9A) are potential hazards as the lake grows. Physically-based mass movement models
9 would generate important information regarding the size and trajectories of these slopes failures.
10 Unfortunately, due to time constraints, a detailed analysis of Lumding Teng Tsho, the upstream
11 glacial lake, was unable to be conducted. Similar knowledge of the stability of the slopes
12 surrounding Lumding Teng Tsho would inform the likelihood of an upstream GLOF. A
13 bathymetric study on Lumding Teng Tsho and an assessment of the stability of its moraine
14 should also be a high priority. In the event of a GLOF, the northern lateral moraine of Lumding
15 Tsho may protect the lake from the upstream flood. A physically-based GLOF model that
16 accounts for erosion would yield insight into the potential breach of the lateral moraine and
17 subsequent GLOF from Lumding Tsho. Based on the rapid field reconnaissance, the hazard
18 associated with Lumding Tsho can be reduced from very high to high due to the apparent
19 stability of the moraine. However, more detailed analyses of slope stability around Lumding
20 Tsho and Lumding Teng Tsho in addition to modeling the potential GLOFs from both of these
21 lakes should be a top priority.

22 **5.3 Chamlang North Tsho**

23 Chamlang North Tsho has already reached its fullest extent, so its proximity to hazards is not
24 going to change over time (Figure S1D). The southern and eastern slopes reveal the lake is very
25 susceptible to rockfalls and avalanches to the extent that any rockfall or avalanche will enter the
26 lake (Figure S1A,B). This potential for a dynamic failure is exacerbated by its steep terminal
27 moraine, which has a SLA of 18.8°. This SLA is the highest among the eight glacial lakes
28 investigated in this study and much greater than the stability threshold of 10°. Fortunately, no
29 melt ponds were observed on the moraine and the outlet appears to be stable from satellite
30 imagery indicating an ice-cored moraine is unlikely (Figure S1C). Nonetheless, the combination

1 of the steep terminal moraine and the likelihood of mass movement entering the lake give
2 Chamlang North Tsho a classification of very high hazard. The MC-LCP GLOF model (Figure
3 S1E,F) reveals that 244 buildings and 2.5 km² of agricultural land are at risk (Table 6) causing
4 Chamlang North Tsho to be a very high risk.

5 Based on the remote assessment, the most important area of future investigation should be
6 modeling the GLOF process chain. The avalanche prone slopes were observed by Byers et al.
7 (2013), who identified four overhanging glaciers on Chamlang North Tsho's southern slopes.
8 The use of high resolution imagery may help quantify the size of a potential avalanche. Byers et
9 al. (2013) modeled a potential GLOF using the GDEM with the U.S. Army Corps of Engineers'
10 Hydrologic Engineering Center River Analysis System (HEC-RAS). The ensuing flood model
11 provides an improved estimate compared to the MC-LCP model, which estimates the water level
12 will rise by 9 m at Bung; however, the downstream impacts were not detailed due to the lack of
13 high resolution imagery. The acquisition of high resolution DEMs for this region and/or cross
14 sections at critical locations should be a high priority. This high resolution DEM should be used
15 with two-dimensional flood models to more accurately estimate the downstream impacts.
16 Additionally, a geotechnical survey including sedimentological sampling of the moraine should
17 be performed such that erosion can be properly accounted for in breach scenarios (Westoby et al.,
18 2015) and the stability of the moraine with respect to the current hydrostatic pressures may be
19 quantified. Lastly, a bathymetric survey of Chamlang North Tsho is needed for the high
20 resolution physically-based GLOF modeling.

21 **5.4 Chamlang South Tsho**

22 Chamlang South Tsho has very similar hazard characteristics to Chamlang North Tsho.
23 Chamlang South Tsho is no longer expanding as it has already reached its fullest extent (Figure
24 6). Mass movement trajectories also show that the lake is surrounded by unstable slopes such
25 that any rockfall or avalanche will enter the lake (Figure S2A,B). The SLA exceeds the stability
26 threshold with a value of 10.5° indicating that the moraine is unstable. Additionally, satellite
27 imagery reveals the presence of melt ponds on the moraine thereby suggesting the moraine is
28 ice-cored (Figure S2C), which has been verified from the differencing of multi-temporal high
29 resolution DEMs (Sawagaki et al., 2012; Lamsal et al., 2016). Therefore, the steep ice-cored
30 moraine is considered to be a high risk to self-destruct. The combination of self-destructive

1 failure and the potential for a dynamic failure classifies this glacial lake as a very high hazard.
2 The MC-LCP GLOF model (Figure S2E,F) also reveals 228 buildings and 2.5 km² of
3 agricultural land are at risk (Table 6), so Chamlang South Tsho is considered to be a very high
4 risk.

5 The remote assessment of mass movement entering the lake from the surrounding slopes was
6 verified by field observations (Byers et al., 2013) and satellite imagery (Lamsal et al., 2016).
7 Sawagaki et al. (2012) also performed a bathymetric survey on the lake in 2009 and estimated
8 the total volume to be $35.6 \times 10^6 \text{ m}^3$. These detailed field measurements and observations are
9 highly valuable for verifying the remote assessment and furthering the current state of
10 knowledge with regard to the lake; however, these observations have led to two drastically
11 different conclusions from Byers et al. (2013) and Lamsal et al. (2016) regarding the danger of
12 the lake. Byers et al. (2013) concluded the lake was safe from any dynamic failure based on the
13 assumption that any mass movement-generated wave would be dampened and repelled by the
14 length and surficial roughness of the terminal moraine. In direct contrast, Lamsal et al. (2016)
15 stated a large surge wave could easily overtop the ice-cored moraine as it is only 4 – 18 m higher
16 than the lake level, but no calculations were performed to support this assessment. Furthermore,
17 Lamsal et al. (2016) measured the steep slope of the distal face of the terminal moraine, the low
18 elevation of the toe of the terminal moraine, and observed seepage through the terminal moraine,
19 which led them to conclude the lake was dangerous.

20 These conflicting studies, which had access to the same data and had similar on-site observations,
21 highlight the need to take an objective approach towards understanding the risks associated with
22 a glacial lake. The main priority with respect to Chamlang South Tsho should be modeling the
23 entire GLOF process chain. This objective analysis would clarify the conflicting views on the
24 potential for a dynamic failure. As a first-pass approach, the methods used by Heller and Hager
25 (2009) were applied to estimate the impulse wave height using one of the avalanche volumes and
26 tracks from the mass movement modeling. The modeled avalanche was $8.1 \times 10^4 \text{ m}^3$ (assumed
27 10 m thickness) located 800 m east of Chamlang South Tsho at an elevation of 5650 m a.s.l. The
28 avalanche density was assumed to be 500 kg m^3 and the avalanche was assumed to expand from
29 its initial width of 90 m to the width of the lake at the location where the avalanche enters the
30 lake (300 m). Based on these assumptions, the avalanche would generate a 20.5 m wave, which
31 would likely easily overtop the ice-cored moraine. This simplified approach highlights the

1 importance of using high resolution satellite imagery to determine the potential sizes of
2 avalanches in conjunction with physically-based models to more accurately model the avalanche,
3 the wave propagation, and any potential overtopping and/or breaching that may occur.

4 Additionally, the potential for a self-destructive failure needs to be explored in further detail as
5 the remote assessment suggests the lake is unstable, which is supported by the SLA calculations
6 in Fujita et al. (2013) and the observations and measurements from Lamsal et al. (2016). A
7 chemical analysis of the seepage would lend insight as to the source of the water, i.e., whether
8 the water is the melting of the ice core or lake water. Geophysical surveys of the terminal
9 moraine should be used to determine the spatial extent and depth of the ice core and geotechnical
10 surveys of the composition of the debris would be valuable for assessing the stability of the
11 moraine in detail. Lastly, Lamsal et al. (2016) highlighted the potential downstream impact and
12 Byers et al. (2013) noted that a GLOF from Chamlang South Tsho is a concern for these
13 communities, so improved modeling using a physically-based GLOF model should be a top
14 priority. The combination of these modeling efforts and field measurements would definitively
15 determine the hazard of the lake and the threat to downstream communities.

16 **5.5 Dig Tsho**

17 Dig Tsho is a prime example of why glacial lakes should not be prioritized based on the size of
18 the lake. In 1985, Dig Tsho was only 0.5 km² with a maximum depth of 18 m, yet its GLOF had
19 devastating impacts downstream (Vuichard and Zimmermann, 1987). The breach of its moraine
20 reduced the lake to its present size of 0.4 km² (Figure 6). The remote assessment shows that Dig
21 Tsho is still very susceptible to another dynamic failure (Figure S3A,B) as any mass movement
22 from the surrounding slopes is likely to enter the glacial lake. Fortunately, its previously
23 breached moraine appears to be very stable as its SLA is 8.9° and an ice-core is unlikely (Figure
24 S3C). Based on the potential for another dynamic failure, Dig Tsho is classified as a high hazard.
25 The MC-LCP model (Figure S3E,F) shows that 519 buildings and 2.8 km² are at risk from a
26 GLOF (Table 6), thereby classifying Dig Tsho as a high risk based on the remote assessment.

27 Field investigations should assess the current bathymetry of the lake to determine the amount of
28 water that could be displaced by a GLOF. Most likely the maximum depth greatly diminished
29 after the GLOF in conjunction with the reduction in the area of the lake, so the potential GLOF
30 discharge would be smaller than the 1985 GLOF. A 1-D GLOF model that has been applied to

1 other glacial lakes in Nepal (Byers et al., 2013; Khanal et al., 2015) would be beneficial in
2 determining how the downstream impacts have changed based on the new bathymetry.

3 **5.6 Lower Barun Tsho**

4 Lower Barun Tsho has received little attention despite being considered one of the most
5 dangerous glacial lakes in Nepal (ICIMOD, 2011). In this regard, the remote assessment yields
6 valuable information regarding its hazards and can be used to guide future investigations of the
7 lake. The mass movement trajectories show the lake is very susceptible to rockfalls and
8 avalanches from its southern slope (Figure S4A,B). Figure 6 also reveals that Lower Barun Tsho
9 has had the most rapid expansion rate of the eight lakes studied with an average growth of 0.054
10 $\pm 0.006 \text{ km}^2 \text{ yr}^{-1}$. The expansion of Lower Barun Tsho places it at further risk of avalanches and
11 rockfalls located upglacier such that the lake will only be more susceptible to a dynamic failure
12 in the future (Figure S4D). There also exists a smaller glacial lake located 4.5 km north of
13 Lower Barun Tsho called Seto Pohkari ($27^{\circ}50'$ N, $87^{\circ}5'$ E, 4842 m a.s.l.). The MC-LCP model
14 of Seto Pohkari shows that Lower Barun Tsho is at risk of this potential upstream GLOF. Seto
15 Pohkari has an area of 0.41 km^2 and is considered to be a high hazard as the avalanche and
16 rockfall trajectories reveal the lake is susceptible to mass movement entering the lake from its
17 surrounding slopes. Fortunately, the moraine of Seto Pohkari appears to be stable with no melt
18 ponds and a gentle SLA of 4.0° . Similarly, Lower Barun Tsho has a gentle SLA of 4.9°
19 indicating the lake is not susceptible to a self-destructive failure. However, satellite imagery
20 reveals there are apparent ponds on the terminal moraine of Lower Barun Tsho (Figure S4C) and
21 there appear to be changes in its outlet suggesting that Lower Barun Tsho likely has an ice cored
22 moraine. The combination of the ice cored moraine and the lake's susceptibility to a dynamic
23 failure classify the lake as a very high hazard. The MC-LCP model (Figure S4E,F) also reveals
24 that in the event of a GLOF 640 buildings, 5.9 km^2 of agricultural land, and potential
25 hydropower projects (WECS and NEA, 2015) would be at risk (Table 6). Therefore, Lower
26 Barun Tsho is classified as a very high risk.

27 Similar to Lumding Tsho, Lower Barun Tsho should be a main priority of future field campaigns
28 in Nepal as the lake is a very high risk, but has received little attention. Field campaigns should
29 focus on investigating the potential of mass movement entering the lake from the southern slopes
30 of Lower Barun Tsho. This investigation should be coordinated with physically-based modeling

1 efforts of the GLOF process chain to determine how mass movement entering the lake will
2 propagate across the lake and potentially breach the moraine. While the lake is unlikely to fail
3 due to the hydrostatic pressures, a sedimentological survey of the composition of the moraine
4 would greatly improve modeling a potential breach. Geophysical techniques should also be
5 performed on the moraine to determine the presence and spatial extent of the potential ice core as
6 this may have large implications on the breach of the GLOF. The expansion of Lower Barun
7 Tsho is a large concern as it only increases its susceptibility to rockfall and avalanche prone
8 areas upglacier; therefore, geophysical techniques should be used on Barun Glacier to determine
9 the maximum potential extent of the glacial lake. Additionally, bathymetric surveys should be
10 performed on Lower Barun Tsho to aid modeling efforts of the GLOF process chain. Seto
11 Pohkari also requires attention with regard to its bathymetry and modeling the process chain for
12 avalanches and rockfalls from its surrounding slopes. Similar to Lumding Tsho, the northern
13 lateral moraine of Lower Barun Tsho may protect the lake from the upstream GLOF. Therefore,
14 a physically-based flood model for both Lower Barun Tsho and Seto Pohkari would greatly
15 improve the understanding of the risk faced by downstream communities.

16 **5.7 Thulagi Tsho**

17 Thulagi Tsho is one of the three glacial lakes where field campaigns were performed to
18 investigate the hazard of a GLOF by ICIMOD (2011). The results from the remote assessment
19 yield valuable information that may be used to supplement these initial field campaigns. Mass
20 movement trajectories reveal the lake is susceptible to rockfalls from both side slopes, but is not
21 susceptible to avalanches (Figure S6A,B). Figure 6 shows that the lake growth has stalled since
22 2010. The lake expansion model reveals the bed elevation of the glacier behind the calving front
23 is greater than the lake level indicating that the lake may have reached its maximum spatial
24 extent (Figure S6D). An assessment of the terminal moraine shows there are ponds on the
25 terminal moraine and the outlet channel has changed in the last 15 years, which suggests the
26 moraine is ice-cored. Fortunately, the SLA of 7.1° reveals the terminal moraine is apparently
27 stable. This finding is in direct contrast to Fujita et al. (2013), which estimated a potential flood
28 volume for Thulagi Tsho of 0.6 million m^3 indicating the SLA was greater than the 10° threshold.
29 These differences are likely due to the 100 m buffer, the exclusion of the melt ponds, and/or
30 potential differences in the lake delineations and DEMs used in this study. Based on this

1 analysis, the lake is a high hazard due to the chance of a dynamic failure in conjunction with the
2 ice-cored moraine. The MC-LCP GLOF model (Figure S6E,F) reveals 754 buildings, 2.0 km² of
3 agricultural land, and planned hydropower projects (ICIMOD, 2011) are at risk (Table 6). These
4 downstream impacts were among the most severe of the glacial lakes in this study as shown by
5 the second highest buildings per km² and percentage of agricultural land. The combination of
6 these high downstream impacts and high hazard classify Thulagi Tsho as a high risk.

7 As previously mentioned, the results of the remote assessment provide valuable information to
8 supplement the work performed by ICIMOD (2011) and the one dimensional GLOF modeling
9 performed by Khanal et al. (2015). Specifically, the lake expansion model shows that Thulagi
10 Tsho appears to have reached its maximum extent, which should be confirmed with a
11 geophysical survey measuring ice thickness behind the calving front. Additionally, the mass
12 movement trajectories are the first time any slope stability has been modeled at this site. These
13 trajectories reveal the lake's vulnerability to mass movement entering the lake and should be the
14 focus of future modeling efforts at this lake. High resolution satellite imagery and field
15 inspection should be used to determine the potential size of any rockfall such that these estimates
16 may be applied to a physically-based mass movement model. These mass movement models
17 could be used in conjunction with the bathymetric survey by ICIMOD (2011) to model the wave
18 propagation and breach of the moraine. A sedimentological survey to accompany the
19 geophysical investigations performed by ICIMOD (2011) would allow the moraine stability and
20 breach parameters to be quantified with greater accuracy. Furthermore, Khanal et al. (2015) also
21 found the downstream impacts from a GLOF were very high; therefore, a two-dimensional
22 physically-based model should build off these results to more accurately quantify the risks and
23 vulnerable areas, which may be used to inform the downstream communities.

24 **5.8 Tsho Rolpa**

25 Tsho Rolpa is arguably the most well-studied glacial lake in Nepal and currently the only glacial
26 lake that has been remediated (Richardson and Reynolds, 2000). Richardson and Reynolds
27 (2000) thoroughly discuss the hazards associated with the glacial lake. Nonetheless, the remote
28 assessment yields valuable insight into the future development of the lake and potential
29 vulnerabilities that may guide future work that should be performed on the lake. Similar to
30 Thulagi Tsho, the lake expansion model shows that Tsho Rolpa appears to have reached its

1 maximum extent (Figure S7D), which explains why the lake area has been relatively constant
2 over the last decade. A geophysical survey behind the calving front would be beneficial to
3 support this finding. If the model is correct, this has large implications on the hazard of the lake
4 as this will limit the magnitude of future avalanches entering the lake, i.e., Richardson and
5 Reynolds (2000) found that the magnitude of avalanches was increasing as the lake grew. The
6 mass movement trajectories show that the lake is susceptible to avalanches from its northern
7 slope (Figure S7A) and rockfalls from its surrounding side slopes (Figure S7B). The avalanche
8 activity has been a major concern for Tsho Rolpa, so the logical next step is to use physically-
9 based models to model the GLOF process chain and determine how vulnerable the lake is to
10 these threats. Satellite imagery from the last decade also reveals changes in the islands near the
11 terminal moraine, which suggest the presence of an ice core (Figure S7C). The ice core has been
12 confirmed and well documented (ICIMOD, 2011). Additionally, the SLA of 17.5° is the second
13 highest of any of the glacial lakes in this study and Fujita et al. (2013) found Tsho Rolpa had the
14 highest potential flood volume of the lakes in their study. The combination of the ice core, the
15 high SLA, and the potential for mass movement to enter the lake confirm the previous
16 assessments that Tsho Rolpa is a very high hazard.

17 Additionally, there are three glacial lakes located upstream that are threats to Tsho Rolpa. The
18 first upstream glacial lake, Tsho Rolpa Upper 1 (27°50.7' N, 86°27.8' E, 4968 m a.s.l.), is
19 located 1.5 km southeast of Tsho Rolpa and has an area of 0.12 km². The hazard assessment
20 reveals this upstream glacial lake is susceptible to ice avalanches, rockfalls, and has a SLA of
21 13.0°, thereby classifying Tsho Rolpa Upper 1 as a high hazard. The MC-LCP model reveals a
22 GLOF has the potential to enter Tsho Rolpa; however, this would require the upstream GLOF to
23 overtop and/or erode the southern lateral moraine of Tsho Rolpa. Similar to Lumding Tsho and
24 Lower Barun Tsho, flood modeling that incorporates erosion would help determine if this lake is
25 a credible threat to Tsho Rolpa. The second glacial lake located upstream of Tsho Rolpa, Tsho
26 Rolpa Upper 2 (27°50.1' N, 86°29.0' E, 4858 m a.s.l.) has an area of 0.03 km² and is only
27 susceptible to potential rockfalls. It also has a SLA of 10.1° thereby classifying the lake as a
28 medium hazard. The third glacial lake, Tsho Rolpa Upper 3 (27°51.4' N, 86°30.0' E, 5316 m
29 a.s.l.) has an area of 0.02 km² and is also only susceptible to potential rockfalls. This lake has a
30 greater SLA of 20.2°, which also classifies it as a medium hazard. However, while Tsho Rolpa

1 Upper 1 is much larger and appears to be a greater hazard than the other two upstream glacial
2 lakes, the MC-LCP GLOFs reveal a GLOF from Tsho Rolpa Upper 2 or 3 would flow onto
3 Trakarding Glacier and directly enter Tsho Rolpa. Therefore, the hazard associated with these
4 glacial lakes should be further investigated.

5 The MC-LCP GLOF model of Tsho Rolpa (Figure S7E,F) shows that 2787 buildings, 7.8 km² of
6 agricultural land, and 35 bridges would be at risk (Table 6). These impacts are both the highest
7 number of buildings per km² affected and the highest percentage of agricultural land affected,
8 which classified the risk associated with Tsho Rolpa as very high. Khanal et al. (2015) used a
9 one-dimensional model, which confirmed the severe consequences downstream and highlights
10 the importance of applying a two-dimensional model to create accurate hazard maps for the
11 communities. This assessment is in agreement with other studies that Tsho Rolpa is still a high
12 risk despite the fact that the lake was lowered by 3-4 m. Those risk-mitigation efforts serve as a
13 good example that lowering the level of these lakes is possible, but also highlights the need to
14 lower the lake 15 – 20 m further (Reynolds, 1999). A detailed analysis of the changes in the
15 GLOF as a function of the lowered lake level would be a valuable resource to determine the
16 exact amount the lake should be lowered.

17

18 **6 Conclusions**

19 The remote assessment integrates the key hazard parameters in an objective manner that is
20 repeatable and relies solely on globally available remotely sensed data. This study investigated
21 eight glacial lakes in Nepal that are widely considered to be highly hazardous and was found to
22 yield valuable insight with respect to each lake regardless of the amount of previous attention the
23 lake had received. For Lumding Tsho and Lower Barun Tsho, this was the first time these lakes
24 have been holistically studied since they were listed as a high priority of further investigation.
25 For other glacial lakes that have already been studied extensively, e.g., Tsho Rolpa and Imja
26 Tsho, the remote assessment yielded valuable information regarding their future expansions.
27 This study is the first of its kind to incorporate detailed modeling of lake growth into a hazard
28 assessment. For Imja Tsho this is particularly valuable as the assessment is able to identify
29 future hazardous conditions before they occur and hopefully shows the benefit of implementing
30 risk-mitigation strategies prior to the lake becoming highly hazardous.

1 The remote assessment is meant to be a simple tool for understanding the hazards and is meant to
2 guide the focus of future modeling efforts and field campaigns. The difficulty associated with
3 conducting fieldwork in these areas and the scarcity of site-specific field data required to
4 adequately model the risk at each site, as discussed in this study, highlights the need for
5 coordinated efforts amongst institutions and local agencies to address these knowledge gaps.
6 This collaborative effort is crucial when one considers the variety of expertise that is required to
7 conduct these field campaigns and effectively model the GLOF scenarios. Furthermore, despite
8 the methods in this study only being applied to eight glacial lakes, the framework was developed
9 such that future work may apply the remote assessment to all the glacial lakes in Nepal. In this
10 manner, a holistic and objective understanding of the current and future state of GLOF hazards
11 may be developed.

5

- 1 Table 1. Previous qualitative hazard assessments applied to eight glacial lakes in Nepal.
2 Fractions are the amount of hazard parameters identified out of the total number of parameters
3 used by each method. Details shown in Tables S.1 – S.3.

Lake	O'Connor et al. (2001)	Costa and Schuster (1988)	Wang et al. (2008)	Arithmetic Mean
Chamlang North Tsho	2/2	3/4	6/8	0.83
Chamlang South Tsho	2/2	3/4	6/8	0.83
Dig Tsho	2/2	2/4	5/8	0.71
Imja Tsho	1/2	2/4	5/8	0.54
Lower Barun Tsho	2/2	3/4	5/8	0.79
Lumding Tsho	2/2	2/4	6/8	0.75
Thulagi Tsho	1/2	2/4	5/8	0.54
Tsho Rolpa	2/2	3/4	6/8	0.83

4
5

- 6 Table 2. Previous semi-quantitative and quantitative hazard assessments applied to eight glacial
7 lakes in Nepal. Values and thresholds for classifications are specific to each study. Fractions are
8 the amount of scenarios for each lake that are considered to be highly dangerous. Details shown
9 in Tables S.4 – S.6.

Lake	Semi-Quantitative		Quantitative			
	Bolch et al. (2011a)		Wang et al. (2011)		Emmer and Vilímek (2014)	
Chamlang North Tsho	0.45	Medium	0.85	Very High	2/5	High
Chamlang South Tsho	0.57	Medium	0.84	Very High	1/5	High
Dig Tsho	0.41	Medium	0.72	High	2/5	High
Imja Tsho	0.63	High	0.49	Low	1/5	High
Lower Barun Tsho	0.89	High	0.51	Medium	3/5	High
Lumding Tsho	0.79	High	0.61	Medium	4/5	High
Thulagi Tsho	0.71	High	0.51	Medium	1/5	High
Tsho Rolpa	0.89	High	0.60	Medium	4/5	High

10
11

1 Table 3. Most frequently used parameters associated with previous studies (adapted from Emmer
 2 and Vilímek, 2013)

Hazard Parameter	Number of Studies
<i>Stability of Moraine</i>	
Moraine width-to-height ratio	9
Buried ice in moraine	8
Piping/seepage through moraine	7
Dam freeboard	6
Dam Type	5
Steepness of moraine	5
<i>Potential Triggering Events</i>	
Mass movement into lake	11
Distance b/w lake and glacier	8
Glacier snout steepness	6
Seismic activity	3
Extreme temp/precip	3
<i>Downstream Impact</i>	
GLOF Model	6
Lake area and/or volume	5

3
 4
 5 Table 4. Summary of the hazard parameters for the studied glacial lakes.

Lake	Snow/ice avalanche	Rockfall	GLOF upstream	SLA (°)	Ice-cored moraine	Future change to hazards
Chamlang North Tsho	Yes	Yes	No	18.8	No	-
Chamlang South Tsho	Yes	Yes	No	10.5	Yes ¹	-
Dig Tsho	Yes	Yes	No	8.9	No	-
Imja Tsho	No	No	No	6.8	Yes ^{1,2}	Yes (10-20 yrs)
Lower Barun Tsho	Yes	Yes	Yes	4.9	Yes ^{1,2}	Yes (10-20 yrs)
Lumding Tsho	Yes	Yes	Yes	10.3	No	Yes (10-20 yrs)
Thulagi Tsho	No	Yes	No	7.1	Yes ^{1,2}	No change
Tsho Rolpa	Yes	Yes	Yes	17.5	Yes ²	No change

6 ¹ponds appear to be on the moraine; ²changes in the outlet area identified
 7

1 Table 5. Summary of hazard, downstream impact, and risk for each glacial lake.

Lake	Hazard			Downstream Impact	Overall Risk
	Dynamic	Self-Destructive	Overall		
Chamlang North Tsho	High	Medium	Very High	High	Very High
Chamlang South Tsho	Very High	High	Very High	High	Very High
Dig Tsho	High	Low	High	High	High
Imja Tsho	Low*	Low	Low	High	Medium*
Lower Barun Tsho	Very High	Low	Very High	High	Very High
Lumding Tsho	High	Medium	Very High	High	Very High
Thulagi Tsho	High	Low	High	High	High
Tsho Rolpa	Very High	High	Very High	High	Very High

2 *Future hazard and risk is very high

4 Table 6. Details of downstream impacts from MC-LCP GLOF models for each glacial lake.

Lake	Total Area	Buildings		Agricultural Land		Bridges	Hydropower
	(km ²)	(total)	(# km ⁻²)	(km ²)	(%)	(total)	Systems
Chamlang North Tsho	28.2	244	8.7	2.5	8.8	14	-
Chamlang South Tsho	27.1	228	8.4	2.5	9.1	14	-
Dig Tsho	30.2	519	17.2	2.8	9.2	23	-
Imja Tsho	32.9	539	16.4	2.7	8.1	28	-
Lower Barun Tsho	45.8	640	14.0	5.9	12.8	20	Yes
Lumding Tsho	25.5	184	7.2	2.4	9.2	16	-
Thulagi Tsho	15.2	754	49.7	2.0	13.1	20	Yes
Tsho Rolpa	49.0	2787	56.8	7.8	16.0	35	-
