Authors‘ response to reviewers.

Reviewer #1 Accept as is (no corrections)

Reviewer #2 minor revisions

Comment #1: The introduction is excellent but long (9 paragraphs). There is a fair amount of theory/explanation that could potentially be moved to one of the sections describing the methods. I would invite the authors to at least consider this.

Response #1: We reviewed the Introduction. We included quite a lot on the modelling method because we neeed to to emphasize that this study used modelling techniques that are quite novel for the field. We therefore decided to leave the text covering multi-level models as it is. However, we moved the last sentence of the Introduction, which covers multi-model inference (and includes the Grueber et al 2011 reference), to the Method section, thus tightening the text and shortening it slightly.

Change #1: Last sentence of Introduction (P5 L10-13) deleted, and text added to Methods (P8 L19-20).

Comment #2: I would like to see a bit more discussion of the limitations of examining such large-scale spatiotemporal temperature patterns. The authors explain well the advantages of these scales (indeed this is a distinguishing characteristic of the paper), but what about the disadvantages (i.e. the paper limitations)? What is not captured by considering higher frequency patterns in time (e.g. heat waves and the role on ecosystems and other services)? Also, what is missed by not considering smaller scale spatial variability (i.e. thermal diversity or thermal refugia – see Kurylyk et al. 2015). Some of this ‘large-scale’ mindset influences the writing in places. For example, it is stated in P2, L28-30 that climate controls are most important, while hydrologic controls are of secondary importance. I would argue that order is (or at least can be) switched when it comes to thermal diversity.

Kurylyk BL, MacQuarrie KTB, Linnansaari T, Cunjak RA, Curry RA. 2015 Preserving, augmenting, and creating cold-water thermal refugia in rivers: concepts derived from research on the Miramichi River (Canada). Ecohydrology 8(6)

Response #2: The study is indeed focusing on larger spatio-temporal scales, which we make very explicit starting with the paper title (which includes such key words as “basin” and “seasonal”), and as the reviewer points out, with the introduction. However, we thought it would be useful to emphasize this even more clearly in the introduction and added a sentence stating that we did not focus on higher frequency temporal patterns or smaller spatial patterns.

Change #2: Sentence added (P2 L26-28).

Comment #3: The results and discussion sections have unnecessary mini introductions that should be deleted (e.g. P15, L27 – P16, L3)

Response #3: Agreed.

Change #3: Mini-introduction of sections 4 and 5 deleted.

Comment #4: The discussion around P18, L23 addresses the relationship between the climate variables (and the WT sensitivity to them) and the basin conditions. I might be more careful with some of the wording to be clear that the authors did not look at long term climate sensitivity but rather how the seasonal climate data influenced the water temperature. For example, it is stated: "Thus, water temperature in 24 impermeable basins appears to be more sensitive to climate than in permeable basins". The data in the paper do not support that this is true on a multi-decadal basis but rather just a seasonal basis. Climate implies long terms. Perhaps they should reword 'climate' as 'seasonal climate data' or something like this.
Response #4: We reviewed Discussion 5.2 and Conclusions sections, changing 'climate' for 'seasonal climate data' in four locations, which clarify that other uses of 'climate' nearby (eg within same paragraph or sub-section) has to be understood in that sense (ie not long-term multi-decadal climate).

Comment #5: Table 2 and related text: Is it possible that precipitation was more a statistical indicator of streamflow (and thus thermal inertia) rather than an indicator of surface advective input? This seems like it could be especially true in headwater streams

Response #5: In Table 2, aimed to relate the climate variables from CHESS to an actual physical process. So, with that perspective, precipitation would be an advective input indeed; we left Table 2 and associated text unchanged as a consequence. However, the reviewer makes the point that precipitation, as a predictor in the models, could be a proxy for the effect of increased streamflow and thermal inertia. We added this point in the Discussion.

Change #5: Text added (P17 L24-25).

Minor comments

P2, L20, the '(a)' is misplaced in this sentence causing the sentence to read awkwardly. **Done**

P4, L1, ‘rarely’ should be moved before ‘coordinated’ **Done**

P9, L7 typo (similar) **Done**

P9, L13, missing word(s) at end of sentence **Missing word (‘sites’) added at end of sentence**

P17, L1 should be ‘only partly causal’ **Done**

P18, L28 I don’t think ‘damper’ is the right word (or a word) **We checked and it is actually the right noun (something that dampens) but used as an adjective; we replaced it with ‘dampening’.**

Figure 1 caption should be slightly reworded. It is a bit confusing **Caption edited**

Abstract

Stream water temperature is a key control of many river processes (e.g. ecology, biogeochemistry, hydraulics) and services (e.g. power plant cooling, recreational use). Consequently, the effect of climate change and variability on stream temperature is a major scientific and practical concern. This paper aimed (1) to improve the understanding of large-scale spatial and temporal variability in climate–water temperature associations, and (2) to assess explicitly the influence of basin properties as modifiers of these relationships. A dataset was assembled including six distinct modelled climatic variables (air temperature, downward shortwave and longwave radiation, wind speed, specific humidity, and precipitation) and observed stream temperatures for the period 1984–2007 at 35 sites located on 21 rivers within 16 basins (Great Britain geographical extent); the study focused on broad spatio-temporal patterns hence was based on three-month averaged data (i.e. seasonal). A wide range of basin properties was derived. Five models were fitted (all seasons, winter, spring, summer, and autumn). Both site and national spatial scales were investigated at once by using multi-level modelling with linear multiple regressions. Model selection used Multi-Model Inference, which provides more robust models, based on sets of good models, rather than a single best model. Broad climate-water temperature associations common to all sites were obtained from the analysis of the fixed coefficients, while site-specific responses, i.e. random coefficients, were assessed against basin properties with ANOVA. All six climate predictors investigated play a role as a control of water temperature. Air temperature and shortwave radiation are important for all models/ seasons, while the other predictors are important for some models/

seasons only. The form and strength of the climate-stream temperature association vary depending on season and on water temperature. The dominating climate drivers and physical processes may change across seasons, and across the stream temperature range. The role of basin permeability, size, and elevation as modifiers of the climate-water temperature associations was confirmed; permeability has the primary influence, followed by size and elevation. Smaller, upland, and/or impermeable basins are the most influenced by atmospheric heat exchanges, while larger, lowland and permeable basins are least influenced. The study showed the importance of accounting properly for the spatial and temporal variability of climate-stream temperature associations and their modification by basin properties.

1 Introduction

River and stream water temperature (WT) is a key control of many river processes (e.g. ecology, biogeochemistry, hydraulics) and services (e.g. power plant cooling, recreational use); Webb et al. (2008). From the perspective of river ecology, WT's influence is both direct—e.g. organism growth rates (Imholt et al., 2013), predator-prey interactions (Boscarino et al., 2007), activity of poikilotherms, geographical distribution (Boisneau et al., 2008)—and indirect, e.g. water quality (chemical kinetics), nutrient consumption, food availability (Hannah and Garner, 2015).

Consequently, the effect of climate change and variability on stream temperature is a major scientific and practical concern (Garner et al., 2014). River thermal sensitivity to climate change and variability is controlled by complex drivers that need to be unravelled ~~(a)~~ to better understand (a) patterns of spatio-temporal variability and (b) the relative importance of different controls to inform water and land management, especially climate change mitigation and adaptations strategies (Hannah and Garner, 2015). There is a growing body of river temperature research but there is still limited understanding of large-scale spatial and temporal variability in climate–WT associations, and of the influence of basin properties as modifiers of these relationships (Garner et al., 2014). Due to the focus on large scales, this paper is not investigating higher frequency temporal patterns (eg heat waves) or smaller spatial variability (eg thermal diversity and refugia). This paper extends Laizé (2015).

River thermal regimes are complex because they involve many interacting drivers (Hannah et al., 2004, 2008). Caissie (2006) identified atmospheric conditions as the primary group of controls, with hydrology linked to basin physical properties (e.g. topography, geology) as secondary influencing factors.

The main climate variables (Fig. 1) which constitute an 'atmospheric conditions' group, can be identified by analysing the theoretical heat budget for a stream reach without tributary inflow, which may be expressed as (adapted from Hannah and Garner, 2015):

$$Q_n = Q^* + Q_h + Q_e + Q_{bhf} + Q_f + Q_a \qquad \text{Equation 1}$$

where Q_n is the total net heat exchange, Q^* the heat flux due to net radiation, Q_h the heat flux due to sensible transfer between air and water (sensible heat), Q_e the heat flux due to evaporation and condensation (latent heat), Q_{bhf} the heat flux to and from the river bed, Q_f the heat flux due to friction at the bed and banks, and Q_a the heat flux due to advective transfer by precipitation and groundwater.

The different components of Eq. (1) correspond to different processes, related to climatic and hydrological conditions. Q* corresponds to shortwave radiation (insolation from the sun) and longwave radiation (emitted towards the stream by clouds and overhanging surfaces such as vegetation, and reemitted back to space (lost) at water surface temperature). Q_h corresponds to convective energy exchanges between air and water (at the surface) causing heat loss or gain. Q_e represents heat loss by evaporation or gain by condensation. Q_{bhf} and Q_f do not relate directly to climate processes but rather local hydrological conditions. (Q_f can be assumed to be negligible in many systems; e.g. Hannah et al., 2008). Q_a corresponds to advective heat exchanges, e.g. inflow or outflow into the river reach, hyporheic exchange, groundwater. A direct, climatic component of Q_a is precipitation inputs, which is thought to have a limited contribution (Caissie, 2006).

These variables are not independent. Figure 1 features a schematic representation of the interactions between these variables. Downward short and long wave radiations increase WT but also air temperature, then there are exchanges between air and water, to influence sensible heating. Additionally, wind plays a significant role by increasing evaporative cooling and in modifying the air–water exchanges by increasing mixing (Hannah et al., 2008). The physical equations underpinning the role of wind can be found in Caissie et al. (2007).

A review of recent international water temperature research can be found in Hannah and Garner (2015). To date, most UK-focused studies (Table 1) tend to be either specific to a few monitoring sites, to have a limited geographical extent (i.e. focused with specific region of the country), and /or to consider few climate drivers. In addition, seasonality, which has huge ecological relevance with regards to phenology, is only explored formally in a small number of papers (e.g. Langan et al., 2001; Hrachowitz et al., 2010). A major difficulty is to pair WT and climate monitoring sites, as monitoring is rarely coordinated ~~rarely~~, then to identify time series with long enough common periods of record. For example, Garner et al. (2014) undertook a England and Wales scale study and matched water temperature monitoring sites with climate and hydrological monitoring sites for 38 temperature sites out of ~ 3,000 sites in the Environment Agency's Freshwater Temperature Archive (Orr et al., 2014). Garner et al. (2014) is one of the few studies internationally (eg Hrachowitz et al. (2010) in the UK; Isaak and Hubert (2001), Nelitz et al. (2007), or Isaak et al. (2010) in North America) to consider explicitly and empirically the role of a limited number of basin properties with regards to stream temperature.

In most of these studies, analyses are done on a site by site basis, which limits the extent to which broad patterns can be inferred (statistical results for a given site are only valid for that site); Caissie, 2006 emphasized this as a limitation when having to work across different spatial scales. In contrast, studies like Garner et al. (2014) group sites together using classification techniques to identify regional patterns. However, doing so causes a loss of information since data-points of all sites within a class are summarised and intra-class differences lost, and inferences at group level are not necessarily valid at site level. An alternative analytical/ statistical method, which can characterise broad patterns while preserving individual site information, should be investigated.

The following research gaps are identified (above): (a) climate–WT studies in the UK used a limited number of WT sites or climate explanatory variables (focus on air temperature links to WT) and /or are limited in geographical extent; (b) limited formal analysis of seasonality; (c) limited knowledge of role of basin properties as modifiers of climate–WT associations; and (d) need for alternative analysis method to optimise data utility.

Given this context, the aims of this study are (1) to improve the understanding of large-scale spatial and temporal variability in climate–WT associations, and (2) to assess explicitly the influence of basin properties as modifiers of these relationships. This paper resolves the issue of driving data availability by using a comprehensive and consistent set of modelled climate data (see Table 2 below). With a period of records of 1984–2007 (24 years), for a total of 35 sites located on 21 rivers within 16 basins (providing a Great Britain wide geographical extent) six distinct modelled climatic variables were taken within 1 km of the sites. The study focuses on broad spatio-temporal patterns; hence it is based on three-month averaged data (i.e. seasonal). Such a temporal scale limits issues of temporal auto-correlation often found in water temperature time series (Caissie, 2006). The study also investigates a wider range of basin properties than previous studies.

Innovatively, this paper investigates both site and national spatial scales at once. Multi-level (ML) modelling with linear multiple regressions is applied as an alternative to site-specific or to classification-based analyses because it allows pooling of all site data together while taking into account data structure (i.e. observations at site, sites within same basin) as well as not losing any information due to class-level data averaging (Zuur et al., 2009). With this modelling technique, it is possible to investigate both study aims (i.e. the broad climate-WT associations common to all sites, and the site-specific responses which may be related to basin properties) within the same analysis framework. ~~In addition, model selection used Multi-Model Inference (MMI), another state-of-the art technique, which provides more robust models based on sets of good models rather than selecting a single best model (Grueber et al., 2011).~~

2 Data

With regards to research Aim 1 of this paper, observed river temperature data were assembled with a view to maximise spatial and temporal coverage as much as practically possible. To address the issue of mismatching monitoring networks, climate variables were obtained from a modelled dataset. The paired climate–WT dataset used in this paper has been published online via an open-access data repository (Laizé and Bruna Meredith, 2015). With regards to Aim 2, a comprehensive and consistent set of basin properties were derived for all study sites.

2.1 Water temperature data

WT data (unit: ºC) were collated from various research projects run by the UK's Centre for Ecology and Hydrology (CEH). The period of record, temporal resolution, and recording method of the individual datasets vary. These datasets totalled 41 sites, of which 35 were retained after quality-control (e.g. removal of duplicates; see Fig. 2). As often the case, water temperature was not the main focus of these projects: fish for the River Frome (1 site, 1991-2009, 15-min logger; Welton et al., 1999), Great Ouse (1 site, 1989-1993, hourly logger), and Tadnoll (2 sites, 2005-2006, 15-min logger; Edwards et al., 2009) studies; impact of forestry on water quality for the Plynlimon catchment project (4 sites, 1984-2008, weekly manual recording; Neal et al., 2010); acidification monitoring for the UK Acid Water Monitoring Network (UKAWMN) project (10 sites, 1988-2008, monthly (not necessarily on same day) manual recoding; Evans et al., 2008); hydrological and biogeochemical processes for the LOwland CAtchment Research (LOCAR) project (17 sites, 2002-2011, 15-min logger; Wheater et al., 2006). Whether recording was done manually or with a logger, measures are instantaneous. Because these original projects were focused on natural rivers, the temperature data used herein may be considered as largely free from artificial influences (e.g. no industrial use for cooling or heated effluent discharges).

2.2 Climate data

The Climate Hydrology and Ecology research Support System (CHESS) dataset features six climate variables (Table 2). CHESS is the forcing dataset for the Joint UK Land Environment Simulator model (JULES; Best et al., 2011). CHESS is a UK-wide 1-km grid dataset derived by downscaling the UK Meteorological Office Rainfall and Evaporation Calculation System (MORECS) 40-km grids (Hough and Jones, 1997), except for precipitation that were derived from observed rain gauge data by using the natural neighbour interpolation method, which is a development of the Thiessen approach (Keller et al., 2006). For each 1-km cell, modelled daily time series of all variables are available for the period 1971–2007. The processes linked to AT, LWR, P, and SWR are given in the stream heat budget overview (see Introduction) and summarised in Table 2. Specific humidity (SH) gives a measure of evaporation potential (i.e. the more humidity, the less evaporation due to reduced vapour pressure gradients; e.g. Hannah et al., 2008). Wind speed (WS) captures the various effects of wind in increasing evaporation (cooling) and convective air-water exchanges (cooling or warming) Each CHESS cell was matched to the study temperature site(s) it contained.

2.3 Seasonal time series

Firstly, sub-daily water temperature data were averaged at a daily time step (Frome, Great Ouse, Tadnoll, LOCAR) while spot measurements (Plynlimon, UKAWMN) were assumed representative of the day on which they were taken, although it is worth keeping in mind that they are only representative of daylight conditions. Secondly, daily water temperature data were matched by date to the daily climate data. Thirdly, seasonal averages were computed from these daily data for all variables. Seasons were defined as: December–February (winter), March–May (spring), June–August (summer), and September–November (autumn). For winter, these seasonal data for year *y* were based on data from December of year *y*-1 to February of year *y* (e.g. for 1976, December 1975, January and February 1976). Lastly, five time series were derived from these data: one series per season at an annual time step (i.e. winter 2000, winter 2001, winter 2002, etc.), and one series with all seasons at a seasonal time step (i.e. autumn 2000, winter 2000, spring 2000, etc). These series and their related models are referred to as thereafter ‘autumn’, ‘winter’, ‘spring’, ‘summer’, and ‘all seasons’.

2.4 Basin properties

Basin properties were derived from the UK Flood Estimation Handbook (FEH), the UK ‘industry standard’ for flood regionalisation studies, which includes 19 basin descriptors (Bayliss, 1999). A subset of descriptors was used. First, the 19 catchment descriptors were derived for each site. Many basin properties co-vary, often substantially, and they are best interpreted as groups of properties (‘meta-properties’) rather than on their own. Descriptor specifications (Bayliss, 1999), pair plots, and correlation matrices were checked to identify likely groups of descriptors (for example, all FEH rainfall descriptors capturing basin wetness). Three groups were identifed, which relate to basin elevation, permeability (ie responsive impermeable v groundwater-fed basins), and size. These have been found to modify climate-hydrology associations in UK basins (eg Bower et al., 2004; Laizé and Hannah, 2010; Garner et al., 2014). Then, a test run of the basin property analysis outlined in Section 3.3 (ANOVA) was performed in order to check that all FEH descriptors from a given group of properties had consistent associations (positive or negative) with each model predictor (considering basin properties significantly associated with site-specific coefficients only), while one FEH descriptor was retained to represent each meta-property.

The following meta-properties and their corresponding FEH descriptors were thus selected for the final analysis:

- Elevation/wetness (‘elevation’ hereafter): as noted in Laizé and Hannah (2010), basin elevation and wetness are very strongly correlated in the UK; the meta-property ‘Elevation’ is represented by the ‘mean basin elevation above sea level‘ (m; FEH descriptor named ‘ALTBAR‘), and, for the winter model only, by the proportion of time basin soils are wet (%; FEH descriptor named ‘PROPWET‘), based on soil moisture time series classified as wet/dry days; highly correlated to rainfall); elevation is also related to air temperature;
- Size: basin area (km^2; ‘AREA‘) using its natural log; area is a proxy for discharge, thus for thermal capacity, and is also linked to elevation;

- Permeability: Base Flow Index from Hydrology of Soil Type (BFIHOST; dimensionless); ranging from 0 (less permeable basin) to 1 (more permeable); temperature regimes in groundwater-fed (permeable) basins are expected to be more influenced by groundwater inputs than in impermeable basins.

The 35 study sites are representative of a wide range of UK basin types in terms of the above properties: (1) upland/lowland (ALTBAR approximately within 20-700 m and PROPWET within 24-80%); (2) small and medium size (AREA ~0.5-415 km2); (3) impermeable/permeable (BFIHOST 0.24-0.92). In addition, the study sites feature combinations of all three meta-properties.

3 Methods

This section describes the analytical methods used. Firstly, as stated in the introduction, linear multiple regressions fitted with the Multi-level (ML) modelling technique was chosen as the core method because it allowed to analyse the multiple-site data in terms of both overall climate–WT associations (linked to research Aim 1) and site-specific responses (linked to research Aim 2; role of basins as modifiers of those associations). Although linear regressions are only approximating climate–WT associations (eg AT-WT associations are better described with logistic models; Mohseni et al., 1998), they were considered a sensible compromise. Secondly, with regards to overall climate-WT associations, ML model selection was done with Multi-Model Inference (MMI), a state-of-the-art technique that selects sets of good models rather than a single best model (Grueber et al., 2011), to yield more robust models than with standard single model selection, especially given the number of climate predictors used. Lastly, any relation between site-specific climate-WT responses and basin properties were tested formally using an analysis of variance (ANOVA).

The study work flow is summarised in Fig. 3: (a) WT observed data linked with (b) modelled climate variables, then (c) all converted to seasonal (three-month) average series used within (d) ML modelling / MMI framework producing (e) five output models (individual seasons and all seasons; Aim 1), and (f) sets of basin properties (Aim 2).

3.1 Multi-level modelling

To take into account the hierarchical nature of the water temperature dataset (e.g. data measured at the same site, sites located on the same river), ML modelling was used to build linear models with water temperature as the predicted variable, and the six climate variables as explanatory variables. When analysing multiple-site datasets, there are two common alternatives: (a) performing one regression for individual sites, or (b) one regression on all sites pooled together. On the one hand, site-specific regressions can make results highly uncertain (sites may have few data-points; fitting numerous regressions is more prone to identify spurious relationships, ie Type II errors). Thus, drawing out general patterns (e.g. variation between sites, effect of site characteristics) can be difficult. On the other hand, full pooling of sites ignores the clustering of samples within groups (eg measurements from a given site, or sites on the same river, may be more simila~~l~~r), which may hide important differences between groups and may cause problems with statistical inference (e.g. violation of the assumption of independence between samples, sites with large or small numbers of samples equally influencing the model outcome).

To overcome these issues, ML modelling can take into account the hierarchical structure in a dataset, ie the different 'levels' at which data can be grouped (eg data at sites, sites within basins, basins within countries), thus allowing for the pooling of data from multiple sites. A ML model has two components, which correspond to generic patterns (i.e. similar to a regression on fully-pooled data) and to level-specific patterns. The generic patterns, which are described by the explanatory variables as in a standard regression, are called the 'fixed component' or 'fixed effects' of the model. The unexplained variation between levels (eg patterns specific to a site) is termed the 'random component' or 'random effects'. The random component captures the fact that levels may respond differently to a given predictor. For example, stream temperature could be very responsive to climate at one site (high slope value) but unresponsive at another (low slope value). In some cases, levels may have the same response to predictors but may have differing averages, ie differing with regards to their intercepts (eg two sites with same temporal patterns but with one site systematically cooler than another due to local characteristics or recoding procedure); such ML models are commonly known as 'random intercept only'.

In our analyses, a three-level data structure was applied: individual observations (level 1) nested within monitoring sites (level 2) nested within river stretches (level 3). In addition, a time variable was included as a predictor to take into account any linear trend in the time series. To avoid instability issues when fitting models, the predictors were centred (i.e. predictor values minus their mean).

3.2 Model selection with multi-model inference

Following standard ML modelling practice (e.g. Zuur et al., 2009), the model selection was applied in two stages: (a) selection of the random component variables; (b) selection of the fixed component variables.

First, the random component selection was done as follows. With all predictors included in the fixed component, all combinations of predictors in the random component were fitted. The models were then ranked using Akaike's Information Criterion (AIC; Akaike, 1974). AIC is used to select models offering the best compromise between fit and predictor parsimony; a model with a lower AIC achieves a better rati of fit vs number of predictors. Note that a variation of AIC was used: AICc, which is AIC corrected for small-size datasets. Selection was done for the four seasonal series as well as the 'all season' series. In each case, the single combination of predictors giving the lowest AICc was retained as the random component.

Secondly, with the random component selected, the fixed component model selection followed the MMI approach, which selects sets of 'good' models rather a single 'best' one. Using a traditional model selection technique, like stepwise regression, the single model with the best (i.e. lowest) AICc would be selected. This presents two issues: (a) due to the algorithms underlying these types of selection techniques, some model formulations may end up not being tested thus causing a sub-optimal selection; (b) given models with similar AICc values have similarly good performance, it is not statistically correct to keep the lowest AICc model only as the best model and discard the others. MMI addresses these issues by selecting sets of good models. In practice, all possible combinations of predictors using from one to six of the climate variables described above were fitted. The resulting models were ranked based their AICc. All models within four points of the lowest AIC were selected (Zuur et al., 2009). Each set of models was then summarised as an 'average model' (predictor coefficients over all models in the set are averaged). Akaike weights (Burnham and Anderson, 2002) were then calculated; these are the re-scaled AICc scores of the models included in a MMI selection set. The weights, which add up to 1, give an indication of how important relatively to each others are the models within a MMI set. For example, results showed that the 'all seasons' model is based on two models with Akaike weights 0.74 and 0.26: the former model has more influence on the resulting average model than the latter.

The Akaike weights form the basis to calculate the Relative Importance (RI) of each predictor: RI is how one reports on the role of each explanatory variable in MMI.. For a given predictor, RI is calculated as the sum of the Akaike weights (re-scaled AICc) of the models in which that predictor is included. RI ranges from 0 (variable never included) to 1 (included in all models). For example, results showed that the 'all seasons' model is based on two models with Akaike weights 0.74 and 0.26; the explanatory variable P is only included in the latter model, hence its RI is 0.26, while the other five predictors are in both models and have a RI of 1 (see Table 3 below). With MMI, RI is analogous conceptually to predictor significance, assessed with p values,in standard regression Model. This is why p values are not calculated nor given in the Results section, but instead RI values for predictors are featured (a predictor with a higher RI is more significant). Grueber et al. (2011) cover the above points in details and give a very good example of such an application of MMI in a natural sciences context.

3.3 Analysis of basin property influence

For those explanatory variables that were included in the random effects (i.e. different sites can have different coefficients), any relation between site-specific coefficients and basin properties was investigated by using maps and scatter plots of coefficients against basin properties, and by applying ANOVA to confirm observed patterns. For each coefficient and basin property, ANOVA is comparing formally (a) a model assuming there is no difference in coefficient between sites against (b) a model assuming the coefficient is function of the basin property. A basin property is considered having significant influence on the WT–climate variable relationship when the ANOVA p value is <0.05. To quantify the influence of these properties, either alone or combined, linear regressions of the site-specific coefficients against these properties were fitted.

4 Results

~~The result section has three parts:~~

- ~~Selection and performance of the five models (all seasons, winter, spring, summer, autumn).~~
- ~~Analysis of the fixed component of the five ML models to inform on climate-WT associations (research Aim 1); results are split in three sub-sections (relative importance of the predictors, form and strength of predictor-WT associations, relative contributions of predictors to modelled WT).~~

- ~~Analysis of the random component of the five ML models to inform on site-specific climate-WT responses (for those predictors included as random effects), followed by ANOVA to assess the role of basins as modifiers of the climate WT associations. (research Aim 2).~~

4.1 Model selection and performance

As described above, selecting the five ML models was done in two stages. First, with all predictors included in the fixed component of the ML model, combinations of predictors as random effects were tested, and the combination yielding the lowest AICc was retained. As a result, the following variables were included as random effects (i.e. variables for which different sites have different coefficients): all seasons = AT and SWR; winter = SH; summer = P; autumn = SWR; no predictor was included for spring (random intercept only). Second, all combination of the predictors in the fixed components were tested with MMI. The number of models included in each final set as selected by MMI was: all seasons = 2; winter = 4; spring = 12; summer = 6; autumn = 14.

With ML models, standard R^2 are not appropriate; conditional R^2 (Nakagawa and Schielzeth, 2013), which are analogue to standard R^2 but designed for ML models, were calculated. Conditional R^2 were: 0.96 for both all seasons models; 0.88 for all four winter models; within 0.88-0.89 (mean 0.88) for the 12 spring models (mean 0.88); within 0.84-0.85 (mean 0.84) for the six summer models; within 0.88-0.89 (mean 0.88) for the 14 autumn models.

With MMI, each set of models is summarised as an 'average model', for which a given variable coefficient is its average value over all models in the set. The average model coefficients are presented in Table 3.. All average models have good fits consistent with conditional R^2 given above, and as evidenced by plots of modelled against observed water temperature data in Fig. 4. Thereafter, if unqualified, the term 'model' means the average model for a given set of selected models

4.2 Relative influence of climate drivers

4.2.1 Relative importance of the predictors

As explained above, within the MMI framework, the significance of a predictor is captured with its relative importance RI in the selected model sets (RI = 0, predictor never retained; RI

= 1, predictor retained in all models of set). Predictor RIs for all average models are given in Table 3. First, there is no predictor with a zero RI for any average model. This means that all predictors are used in all or part of the sets of selected individual models. Predictors can be ordered by decreasing importance: AT (RI=1 for all models); SWR (RI=1 for four models, and 0.64 for the summer one); WS (RI=1 for two models, and 0.33-0.68 for others); SH (RI=1 for two models, 0.34-0.53 for others); P (RI=1 for one model, 0.15-0.41 for others); LWR (RI=1 for one model, 0.13-0.25 for others).

Second, each model has its own set of most important predictors (with RI > 0.50 as a threshold, i.e. predictor included in half of the selected individual models): all seasons, all predictors except P; winter, AT, SWR, WS, and SH; spring, AT, SWR, and WS; summer, all predictors; autumn, AT and SWR.

4.2.2 Form and strength of associations between climate predictors and water temperature

The section focuses on the fixed effect coefficients of the predictors (i.e. coefficients valid for all sites). Predictors AT, SWR and SH have positive coefficients for all models (i.e. increases of these predictors are associated with a consistent warming effect on water temperature). Predictors LWR, WS, and P have positive or (mostly) negative coefficients (i.e. increases of these predictors are associated with warning or cooling, depending on season; Table 3).

The strength of the association varies with season. Comparing the absolute value of the seasonal coefficients for each variable (not between variables as they have different scales): AT, lowest in winter, highest in autumn; SWR, lowest in autumn, highest in winter; LWR, lowest in winter, highest in summer; WS, lowest in autumn, highest in summer; SH, lowest in autumn, highest in winter; P, lowest in summer, highest in autumn.

4.2.3 Relative predictor contributions

By definition, the predictors may have different units and orders of magnitude. Their coefficients cannot be compared directly to get an indication of their relative contribution to WT predictions. Instead, for each generic average model (see coefficients in Table 3), predicted WT values were generated for the whole period of record, then the percentage contributions of each predictor to these predicted WT values were calculated (ie a time series of predicted WT and of percentage contributions for the six predictors). Boxplots of the percentage contributions for the six predictors and the five models are featured on the left-hand side of Fig. 5 (for readability, outliers are not displayed). The thick black central line corresponds to the median percentage contribution. The shorter the boxes and whisker extents are, the more constant are predictor contributions to modelled WT, with longer extents representing more variation. While, the boxplots inform about contribution differences between models, plotting predictor contributions against modelled WT (right-hand side of Fig. 5) shows that the contribution variability, for a given model, is in many cases related to WT rather than random (i.e. some predictors are more or less influential depending on thermal conditions).

AT is the main contributor except in winter (second to SH); its median contribution is around 12% for winter, and 30-35% for the other models. In all cases, AT contribution increases as WT increases (AT has more influence at warmer WT).

SWR influence is quite constant for all models (medians ranging from +4.5% to 7.5%; up to a maximum of +15.8% in winter) except autumn, for which it is very limited (median +0.13%). Within each model, SWR contribution is fairly stable across the WT range but showing slightly more variability for colder WT.

LWR is the second contributor for the 'all seasons' and the summer models. Its contribution is negative except for spring, but in all cases, the contribution decreases as WT increases (i.e. LWR has more influence on colder WT).

WS has a negative contribution for all models except autumn. WS is most influential for colder WT (e.g. down to a minimum of -13.70% for all seasons model, -11.74% for summer); its contribution decreases as WT becomes warmer (e.g. around -1% for most models). WS contributions are more variable for colder WT (ie more scatter right-hand side plots; Fig. 5) than for warmer WT. For autumn, WS has limited influence, with its contribution ranging from +0.17% to +0.90%.

SH contribution is highest in winter (main contributor with median +27.20%) and for 'all seasons', but otherwise limited for the other seasons (medians ranging +2.10% to +7.23%). SH contributions are independent from WT.

P has limited influence with its contributions ranging from -1.13% (minimum, spring) to +0.22% (maximum, winter). Its contributions show very little variability and no pattern in relation to WT.

4.3 Role of basin properties

The site-specific coefficients were initially mapped against elevation and permeability to explore basin modification of the WT–climate relationship, and any pattern linked to easting/northing. While there was no clear easting/northing pattern, the maps showed potential associations between coefficients and basin properties.

Then, ANOVA was run on those descriptors to identify the ones significantly associated with the model site-specific coefficients. Associations between meta-properties/descriptors and site-specific coefficients are showed in Table 4. Note: no property was found to be associated with P coefficients in summer.

To quantify the influence of the properties, either alone, or combined, simple linear regressions of the site-specific coefficients were fitted and ranked with AICc following the MMI technique used above. Models are featured in Table 5. The best models are the ones with the lowest AICc (displayed in bold characters); while all models featured are within four AICc points, hence are considered equally good (Zuur et al., 2009). Depending on the site-specific coefficient, the R^2 range from 0.125 (autumn SWR) to 0.411 ('all seasons' AT). In each case, a single regression (on BFIHOST or ALTBAR) is the best model AICc-wise, although most of the multiple regressions are within 4 AICc points so equally valid models. In the UK context, these meta-properties are themselves not independent: (i) high upland basins are more often impermeablebecause permeable geology predominantly occurs in the UK lowlands; (ii) there are comparatively more larger basins at lower elevations. Results in Table 5 demonstrate this. For the 'all seasons' AT coefficient models, single regressions on BFIHOST, ln(AREA), and ALTBAR achieves a R^2 of 0.370, 0.284, and 0.127, respectively, but the multiple regressions with either two or all of them only achieve R^2 within 0.381–0.411. The comparatively small gain when adding several predictors is due to the three properties co-varying. Similar comments can be made on the other models.

5 Discussion

~~This section has two parts:~~

- ~~Discussion of the ML modelling fixed components (national-scale patterns of climate-WT associations; research Aim 1); this includes outcomes of MMI, physical interpretation of the models, and dependence between climate-WT association and season/temperature.~~

- ~~Discussion of the ML modelling random components (site-specific climate-WT responses to assess their modification by basin properties; research Aim 2); identified basin properties are first considered individually, then combined.~~

5.1 Influence of climate drivers

This section discusses results related to the fixed component of the ML models, which provide information on national-scale patterns (i.e. patterns valid for every sites used in the analysis). As explained above, these patterns would be analogue conceptually to those sought by using cluster analysis or fully-pooled regressions but without their shortcomings (e.g. loss of information, issues with dependent observations). The use of ML modelling adressed one of the limitation of empirical regression-based models, for which temperatures are predicted at specific sites only. Note: the four seasonal models are by definition related to the 'all seasons' model, since they are based on subsets of the same original dataset, so that seasonal patterns are not independent from the 'all seasons' patterns.

The six climate predictors investigated were identified as significant within the MMI framework (note: MMI applied to the selection of the fixed component part of the ML models only). Standard model selection techniques (e.g. stepwise) would have most likely excluded the predictors that are not retained in all models of the MMI selected model sets (i.e. predictors with lower RI values). In this regard, this study illustrated how MMI can be useful in picking the effect of secondary controls, otherwise masked by dominant primary drivers.

The models broadly make sense against known physical processes. In interpreting model results, it important to bear in mind that the aim of the study was to assess the relative empirical associations between WT and the set of climate drivers, therefore the models are not explicitly process-based. In addition, the climate variables are inter-related in some extent (e.g. P associated with more cloud cover, hence reduced SWR and greater SH), and the analysis is based on 3-month averaged data, which may cause some aspects of the physical processes to be lost by the averaging (e.g. distinction between variable like SWR, only contributing during daylight and others like LWR contributing continuously).

All models flag a close association between AT and WT. This finding is consistent with the literature: it is well documented that AT and WT are both influenced by similar climatic drivers (e.g. incoming radiation), and tend towards thermodynamic equilibrium (Caissie, 2006). Both variables consequently tend to co-vary positively, making AT a very useful predictor (as it has been widely demonstrated in the literature; e.g. Webb and Nobilis, 1997), although the association is only partly causal ~~only~~ (Johnson, 2003). SWR (insolation from sun) is physically a positive input of energy; and it is appropriately captured in the models with positive coefficients. In this study, LWR is the downward component of longwave radiation (see Table 2). From an energy budget perspective, LWR therefore corresponds to a positive flux toward the river water. Consequently, LWR contribution to WT should be positive. Results (Table 3 and Fig. 5) show this is not necessarily the case. LWR corresponds to radiation diffused by clouds, so co-varies positively with cloud cover (in addition, a pairwise plot of the study dataset shows that within a given season LWR inversely co-varies with SWR). Therefore, the negative WT-LWR associations would either be due to LWR acting as a proxy for processes driving colder water temperatures (e.g. cloud cover), or be a model artefact due to the LWR/SWR collinearity. SH represents the mass of water vapour in moist air. The rate of evaporation at the water surface is directly proportional to the SH gradient (the more humid the air, the lower the evaporation rate). All models give a positive association between SH and WT. As SH increases, the evaporation rate decreases, and consequently, cooling due energy loss as latent heat decreases as well. WS has a cooling effect by increasing evaporation at the water surface, which would be captured by a negative contribution to WT. In addition, WS plays a significant role in air–water energy exchanges by increasing mixing, which would manifest as increased cooling or warming depending on the AT-WT gradient. For all models but autumn, WS has an overall negative contribution (cooling). For the autumn model, the variable RI and its percentage contribution are both low, so the positive association has to be considered with caution. P have positive or negative coefficients depending on model. When rainfall occurs, its temperature may be higher or lower than that of the river depending on season. In addition, P can also act as a proxy for cloud cover, thus for reduced SWR and increased LWR; in some cases it might also capture the effect of increased streamflow and thermal inertia. P has limited importance and percentage contribution in all the models, which is probably due to precipitations being event-based whereas other variables are continuous (e.g. AT).

The form and strength of the climate-WT association vary depending on season and on WT range, as showed by the variability in predictor coefficients and contributions. This most likely captures that the dominating climate drivers and physical processes (e.g. evaporation/condensation, radiative fluxes; see energy budget above) may change from one season to another, or within the same season, from colder to warmer weather conditions. As a consequence, the impact of short (e.g. seasonal climatic drought) and long term climate variability or change, and of mitigation schemes (e.g. increasing riparian tree shading) on stream temperature may not be uniform across time (e.g. higher long-term temperature increases in winter and spring; Langan et al., 2001).

Probably because AT performs very well as a predictor (e.g. Webb and Nobilis, 1997), most empirical models have been based on single AT-WT regressions (Caissie, 2006) with very few using other climate predictors (e.g. AT and solar radiation; Jeppesen and Iversen, 1987). The present study demonstrated the potential of several other climate variables to contribute explanatory power (even if they are weaker predictors than AT), which can be beneficial when trying to tease out the relative influences of the various interconnected processes controlling water temperature regimes.~~,~~ Although this was not the primary objective of the study, the models could be used to generate seasonal water temperatures for the whole spatial and temporal extent of the CHESS datasets (whole country, 1971–2007 period of records), for example allowing to investigate broader geographical pattern, or the impact of extreme events like drought.

5.2 Role of basin properties

The analysis of the random component of the models (i.e. site-specific) identified permeability, elevation, and basin size as the main modifiers of the climate-WT response (note: unlike for the fixed component, the random predictors were selected using standard AIC, i.e. there is only one random component formulation for each of the five models). The use of ML modelling addressed the limitations of empirical regression-based models to work across different spatial scales (see above; Caissie, 2006). The basin properties are first reviewed individually, then together to assess how their respective influences may combine within a basin (i.e. are all influences cumulating, or one property dominating?)

For all models and for all predictors (all seasons AT, autumn SWR, winter SH), the more (less) permeable the basin, the lower (higher) the coefficients. Thus, water temperature in impermeable basins appears to be more sensitive to seasonal climate data than in permeable basins. Indeed, in permeable basins, the temperature regime is comparatively more influenced by the groundwater input to the river; groundwater temperature tends to have more inertia and to have a dampening~~r~~ effect on river WT (groundwater warmer than river in winter, cooler in summer) - see for example, Webb and Zhang (1999), Hannah et al. (2004), Caissie, 2006, Kelleher et al. (2012). This pattern is consistent with Garner et al. (2014), which used different temperature monitoring sites and basin properties to investigate air–water temperature associations only.

With regard to basin size, –with the ‘all seasons’ model, WT in smaller basins is more sensitive to AT but less sensitive to SWR than in larger basins. With the autumn model, WT in smaller basins is more sensitive to SWR. With the winter model, WT in smaller basins is more sensitive to SH.

Although, there are seemingly contradictory patterns for SWR, this can be explained by the modelling. Where studies typically use only one variable to represent the whole climate (e.g. AT, Garner et al., 2014), several climate predictors are considered herein. As noted in the Introduction, AT and SWR co-vary in some extent. In the ‘all seasons’ model, AT and SWR were both selected to capture the between-site variability of the climate-WT response, while in the autumn model, only SWR was retained. As a consequence, in the autumn model, SWR represents climate control, most probably capturing part of the WT variability explained by AT when both variables are included as in the ‘all seasons’ model. Overall, WT is more sensitive to seasonal climate data in smaller basins. Then, the inclusion of both AT and SWR in ‘all seasons’ allows to refine the assessment of river thermal sensitivity beyond climate as a whole, to different types of energy processes: smaller streams are more sensitive to air-water heat exchanges but less sensitive to radiative fluxes than larger streams. One can hypothesize that smaller streams have a lower volume of water to heat up than larger streams but also are likely to experience greater relative shading by riparian trees than wider rivers downstream.

This finding, at first, looks partly inconsistent with Garner et al. (2014), who concluded that larger basins were more sensitive to climate than smaller ones, because (i) headwater stream being located at the start of the network have less time than larger streams to reach equilibrium with AT further downstream, and (ii) headwater streams are more likely to be shaded (riparian woodlands, topography). However, Garner et al. (2014) was based on cluster analysis; small basins were included in one cluster only, which also included permeable basins. As a consequence, it is likely that permeability and size influences were in some extent confounded. In contrast, the sites used in this paper cover all combinations of size/permeability basin types. Secondly, as noted by Kelleher et al. (2012), within the small stream type, one needs to distinguish between shaded (i.e. due to with riparian woodland or topography) and exposed streams, with shaded streams behaving more like permeable streams. Only basin-wide land cover information was available for 29 out of 35 sites: 27

basins are under 20% woodland. While one cannot exclude woodland being concentrated on the riparian corridor of each site, it is sensible to assume the 35 sites have a mix of shaded and exposed streams. Although it would explain the pattern with ‘all seasons’ SWR (more shading, less incoming sun), the shaded headwater argument has to be considered inconclusive in relation to the wider climate controls.

With regard to basin elevation, results can be summarised as follows: (i) ‘all seasons’ model, WT in higher elevation basins is more sensitive to AT but less sensitive to SWR; (ii) winter model, WT in higher elevation basins is more sensitive to SH. These patterns can be explained partly by elevation, partly by the fact that permeability, size and elevation are not strictly independent in the UK. As noted above, elevation and rainfall co-vary greatly in the UK, so that upland basins are wetter than lowland basins, hence associated with greater precipitation (i.e. with more cloud cover and consequently, less influenced by SWR). In terms of basin types, the study sites have no upland permeable basins (the UK geology is such that this type hardly occurs in any case), plus high elevation basins tend to be smaller basins. The patterns observed with elevation, which are consistent with those for permeability and size, are most likely partly reflecting the upland basins are also largely impermeable and smaller.

Although each property has been statistically identified as having an influence, the latter point leads to investigating how these influences may combine. The regression models of site-specific coefficients against permeability, size, and elevation presented in Table 5 provide some quantification of the influence of basin properties, both on their own, and combined. In each case, the best model uses a single basin property, although the retention of other properties in the MMI sets confirms the role of all three. In three cases out of four (‘all seasons’ AT, autumn SWR, winter SH), permeability (BFIHOST) is dominant. Therefore, the patterns described above would be primarily set by basin permeability, then by size and elevation. At one end of the spectrum, small, upland, and/or impermeable basins are the most exposed to atmospheric heat exchanges, at the other end, large, lowland, and permeable basins are the least exposed.

6 Conclusions

By focusing on a nation-wide set of water temperature sites and extensive climate dataset, this study addressed some of the limits of previous UK papers (limited number of WT sites, climate predictors, and /or geographical extent); it also investigated formally seasonal patterns, and, by using a wide range of basin descriptors, improved knowledge of the role of basin properties as modifiers of climate–WT associations.

With regards to the need to explore alternative modelling techniques to maximise data utility, ML modelling allowed to model climate-WT responses both at site and at national scales, thereby adressing the limitation of empirical regression-based models compared to deterministic models (Caissie, 2006). While the present ML models took into account discrepancies in temperature sampling (eg data from sites with 15-min recording may show different patterns from sites with weekly data), the effect of these discrepancies were not investigated explicitly, and would merit further research. In addition, the model selection based on the MMI approach permitted to investigate climate variables that would been most likely excluded by standard selection techniques, and identify their influence as secondary controls.

In relation to research Aim 1 (improved understanding of large-scale climate–WT associations), the modelling exercise showed that all of the six climate predictors investigated in this study play a role as a control of water temperature. AT and SWR are important for all models/ seasons, while LWR, SH, and WS are important for some models/ seasons only. The form and strength of the seasonal climate data-stream temperature association vary depending on season and on water temperature. The dominating climate drivers and physical processes may change across seasons, and across the stream temperature range. The impact of climate variability or change, whether short or long term (e.g. seasonal supra-seasonal, or inter-annual climatic drought, long-term air temperature increase~~es~~), and the benefit of mitigation measures (e.g. increasing shading) on stream temperatures need to be assessed accordingly. While this study focused on wider spatial paterns, it is noteworthy that stream temperature could also be influenced by micro-climate effects (as far as metadata could be scrutinised, the study sites were free of such effects), future research could investigate how micro-climate and climate data spatial resolution may influence the models.

In relation to research Aim 2 (assessing influence of basin properties as modifiers of climate-WT associations), the study confirmed the role of basin permeability, size, and elevation as modifiers of the climate-WT associations. The primary modifier is basin permeability, then size and elevation. Smaller, upland, and/or impermeable basins are the ones most influenced by atmospheric heat exchanges, while the larger, lowland and permeable basins are least influenced (note: some basin types occur less frequently or hardly in the UK, e.g. upland permeable). This means that, in addition to seasons and temperature range, the impact of seasonal climate data on stream temperatures and the benefits of mitigation schemes may vary with location. This study shows the importance of accounting properly for the spatial and temporal variability of climate-stream temperature associations and their modification by basin properties.

Data availability

The dataset used in this paper is available from the NERC EIDC open-access data repository (Laizé and Bruna Meredith, 2015).

Acknowledgements

The authors would like to thanks CEH colleagues for their help with (a) sourcing the water temperature datasets, Mike Bowes, Francois Edwards, Ned Hewitt, Mike Hutchins, and Gareth Old; and (b) retrieving the CHESS data, Eleanor Blyth, Douglas Clark, and Richard Ellis. The authors acknowledge financial support from the Natural Environment Research Council (NERC) through its National Capability funding to the Centre for Ecology and Hydrology, and its PhD funding to the first author. Some of the material in this paper was taken from the first author's PhD thesis.

Table 1. Climate–water temperature studies carried out in the UK.

Reference	Number of Sites	Number of Basins	Location	Number of Climatic Variables	Length of Study Period
Wilby *et al.* (2014)	36	2	central England	1	2 years
Garner *et al.* (2014)	38	38	England & Wales	1	18 years
Broadmeadow *et al.* (2011)	10	2	south England	3	3 years
Brown *et al.* (2010)	6	1	north England	2	2 years
Hrachowitz *et al.* (2010)	25	1	northeast Scotland	0	2 years
Hannah *et al.* (2008)	2	1	northeast Scotland	7*	2 years
Malcolm *et al.* (2004)	6	1	northeast Scotland	1	3 years
Hannah *et al.* (2004)	1	1	northeast Scotland	9*	6 months
Webb *et al.* (2003)	4	1	southwest England	1	5 years
Langan *et al.* (2001)	1	1	northeast Scotland	1	30 years
Webb and Zhang (1999)	2	2	South England	5	2 seasons
Evans *et al.* (1998)	1	1	west England	9*	17 days
Crisp (1997)	5	1	northwest Wales	1	3 years
Webb and Zhang (1997)	11	1	southwest England	4	2 seasons

* includes different measurements of related climatic variables

Table 2. CHESS data.

Climate Variable	Abbreviation	Units	Process
Air temperature	AT	^{o}K	Convective energy exchanges at water surface; energy loss or gain
Long wave radiation	LWR	W m^{-2}	Downward energy bounced back by clouds; energy gain
Specific humidity	SH	kg kg^{-1}	Air moisture content; higher humidity reduces evaporation rate; energy loss (evaporation) or gain (condensation)
Precipitation	P	kg $m^{-2}d^{-1}$ (mm d^{-1})	Advective exchanges; energy loss or gain
Short wave radiation	SWR	W m^{-2}	Downward direct energy (i.e. insolation); energy gain
Wind speed	WS	m s^{-1}	Increases evaporation (energy loss) and convective exchanges (air mixing; energy loss or gain)

Table 3. Generic response for the five average models.

	all seasons		winter		spring		summer		autumn	
	Coef.	*RI*	Coef.	*RI*	Coef.	*RI*	Coef.	*RI*	Coef.	*RI*
AT	0.5824	*1.00*	0.3955	*1.00*	0.6815	*1.00*	0.4969	*1.00*	0.6860	*1.00*
SWR	0.0055	*1.00*	0.0193	*1.00*	0.0073	*1.00*	0.0049	*0.64*	0.0003	*1.00*
LWR	-0.0149	*1.00*	0.0001	*0.13*	0.0020	*0.18*	-0.0126	*0.52*	-0.0013	*0.25*
WS	-0.1348	*1.00*	-0.0685	*0.68*	-0.0774	*0.63*	-0.3028	*1.00*	0.0181	*0.33*
SH	0.4664	*1.00*	0.6658	*1.00*	0.0772	*0.34*	0.1542	*0.53*	0.0507	*0.37*
P	0.0003	*0.26*	0.0007	*0.15*	-0.0041	*0.38*	-0.0004	*1.00*	-0.0045	*0.41*

Table 4. Basin descriptors significantly related to site-specific model coefficients (ANOVA; $p \leq 0.05$).

Model	Predictor	Basin Meta-property	FEH Descriptor	Type of Association
all seasons	AT	Elevation	ALTBAR	Positive
		Permeability	BFIHOST	Negative
		Size	AREA*	Negative
all seasons	SWR	Elevation	ALTBAR	Negative
		Size	AREA	Positive
autumn	SWR	Permeability	BFIHOST	Negative
		Size	AREA*	Negative
winter	SH	Elevation	PROPWET	Positive
		Permeability	BFIHOST	Negative
		Size	AREA*	Negative

*tested on natural log

Table 5. Linear regressions of site-specific coefficients as function of basin properties (models ordered by increasing AICc; best model in bold characters, all other models are within four AICc points of best model hence selected via MMI).

WT Model	Coefficient	Linear Regression	R^2	AICc
all seasons	AT	**BFIHOST**	**0.370**	**-31.3**
		BFIHOST+ALTBAR	0.403	-30.1
		BFIHOST+ln(AREA)	0.381	-29.3
		BFIHOST+ln(AREA)+ALTBAR	0.411	-28.3
all seasons	SWR	**ALTBAR**	**0.177**	**-277.5**
		ALTBAR+ln(AREA)	0.183	-275.2
		ln(AREA)	0.089	-274.0
autumn	SWR	**BFIHOST**	**0.125**	**-223.1**
		ln(AREA)	0.115	-222.6
		BFIHOST+ln(AREA)	0.136	-220.9
winter	SH	**BFIHOST**	**0.192**	**48.7**
		ln(AREA)	0.162	50.0
		BFIHOST+ln(AREA)	0.203	50.8
		BFIHOST+PROPWET	0.192	51.3
		PROPWET	0.123	51.6
		PROPWET+ln(AREA)	0.178	51.9

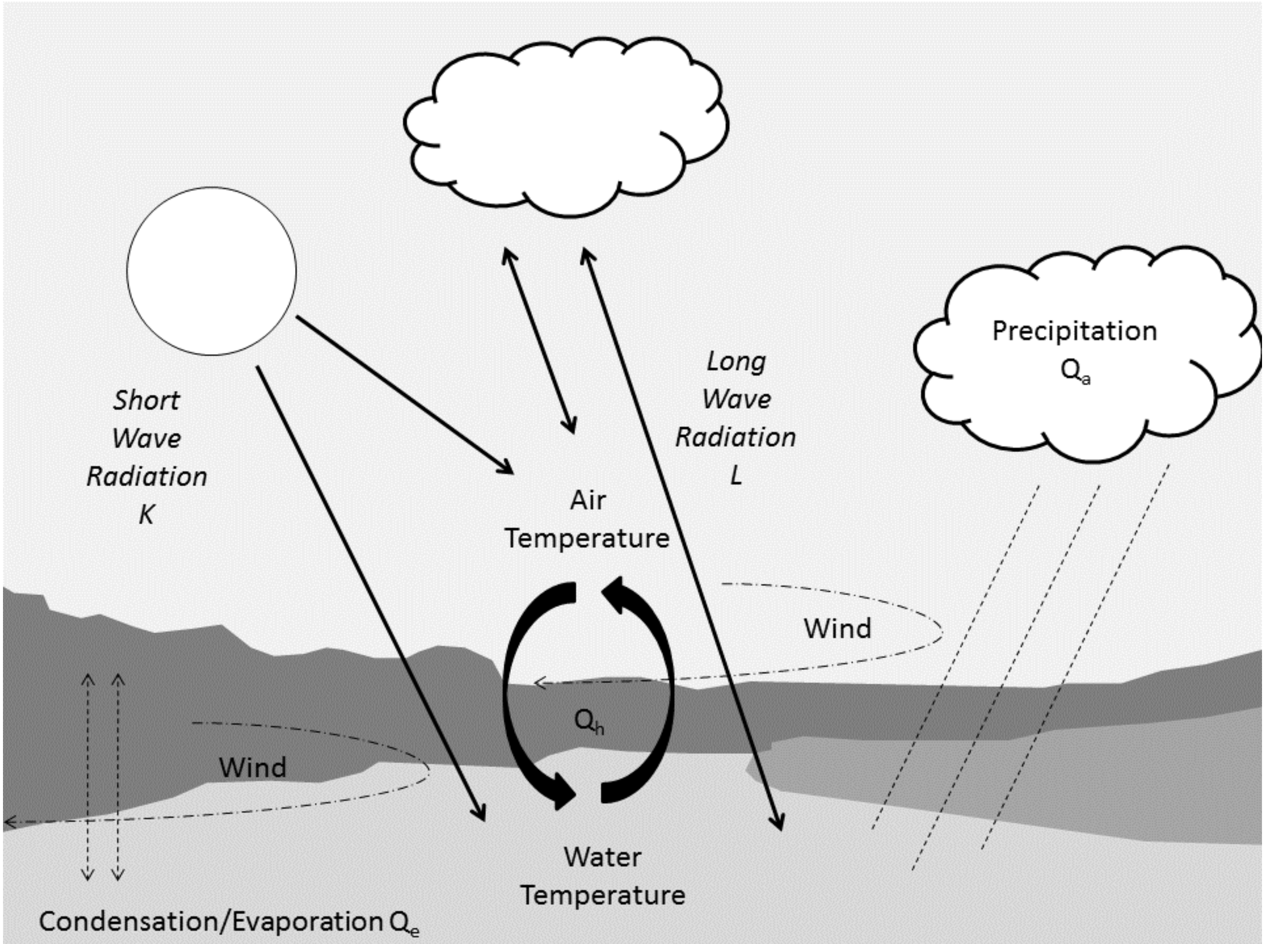

Figure 1. Multiple interdependent climate controls of water temperature; ~~Q* is~~ the sum of K and L corresponds to Q* (heat flux due to net radiation)~~;~~; Q_a corresponds to advective heat exchanges, which include precipitation (direct climatic component) and ~~also~~ smaller ~~advective~~ fluxes due to inflow/outflow into river, hyporheic exchange, or groundwater (not shown on figure); [adapted from Caissie (2006) and Hannah et al. (2008)].

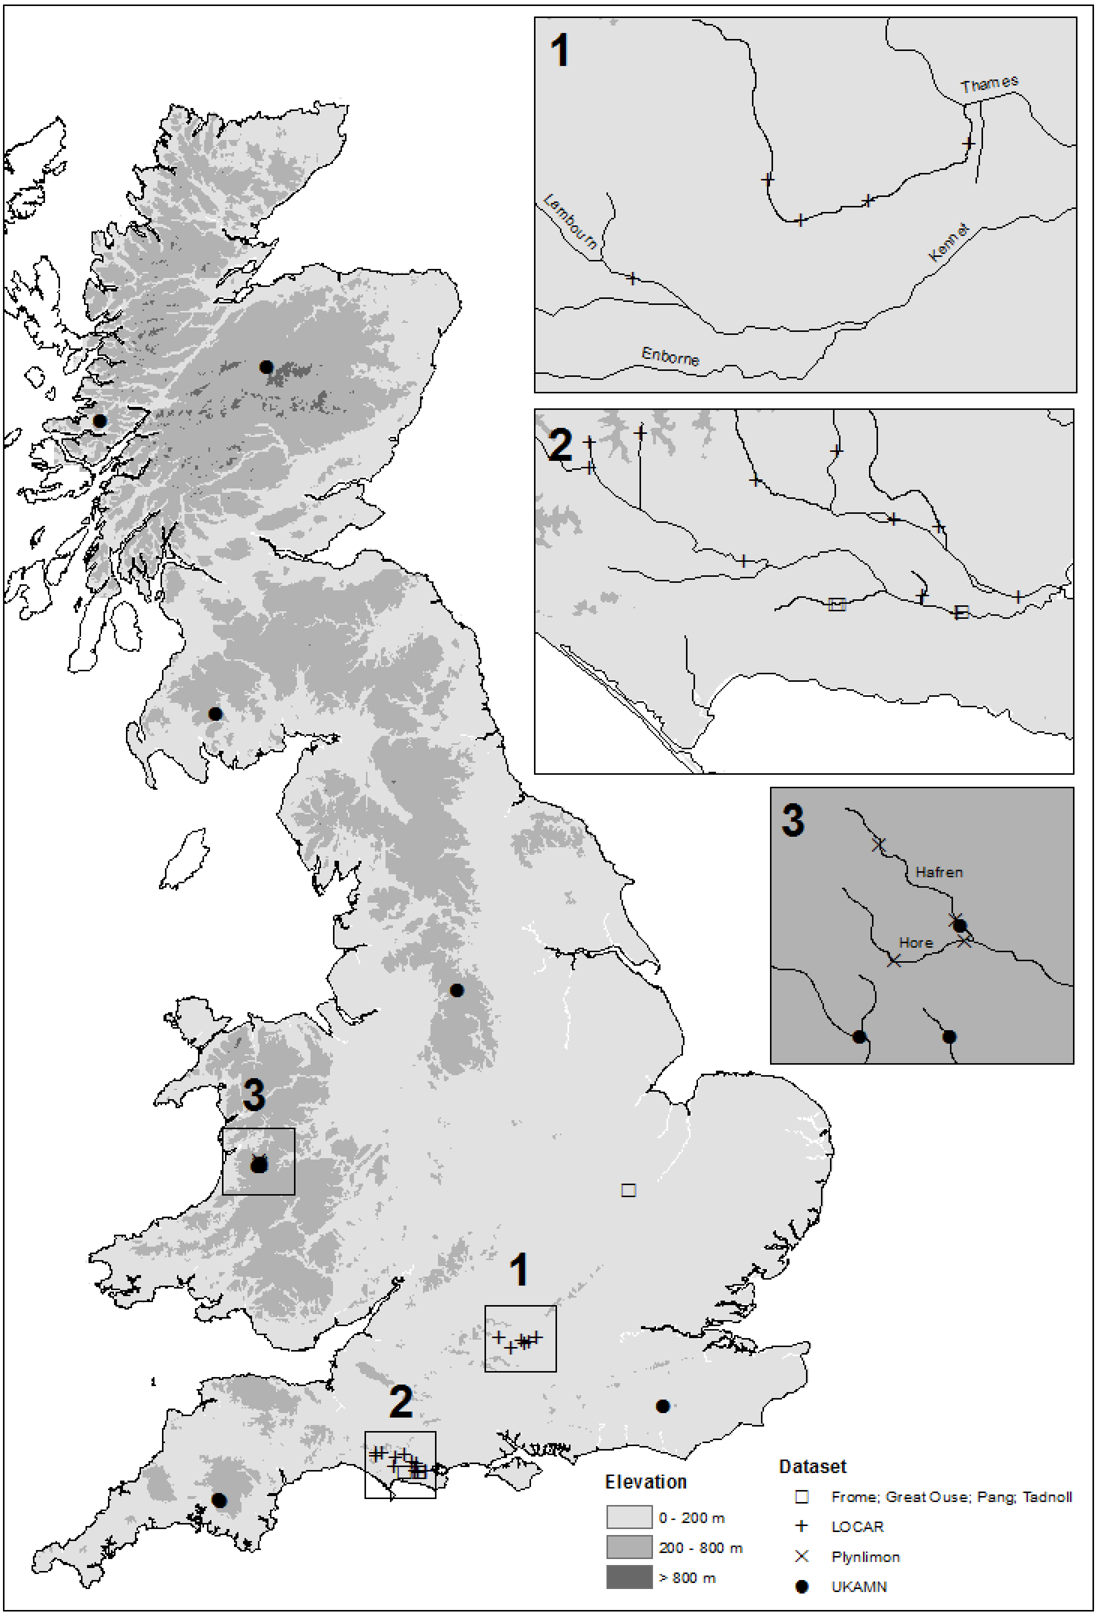

Figure 2. Location map of the study sites.

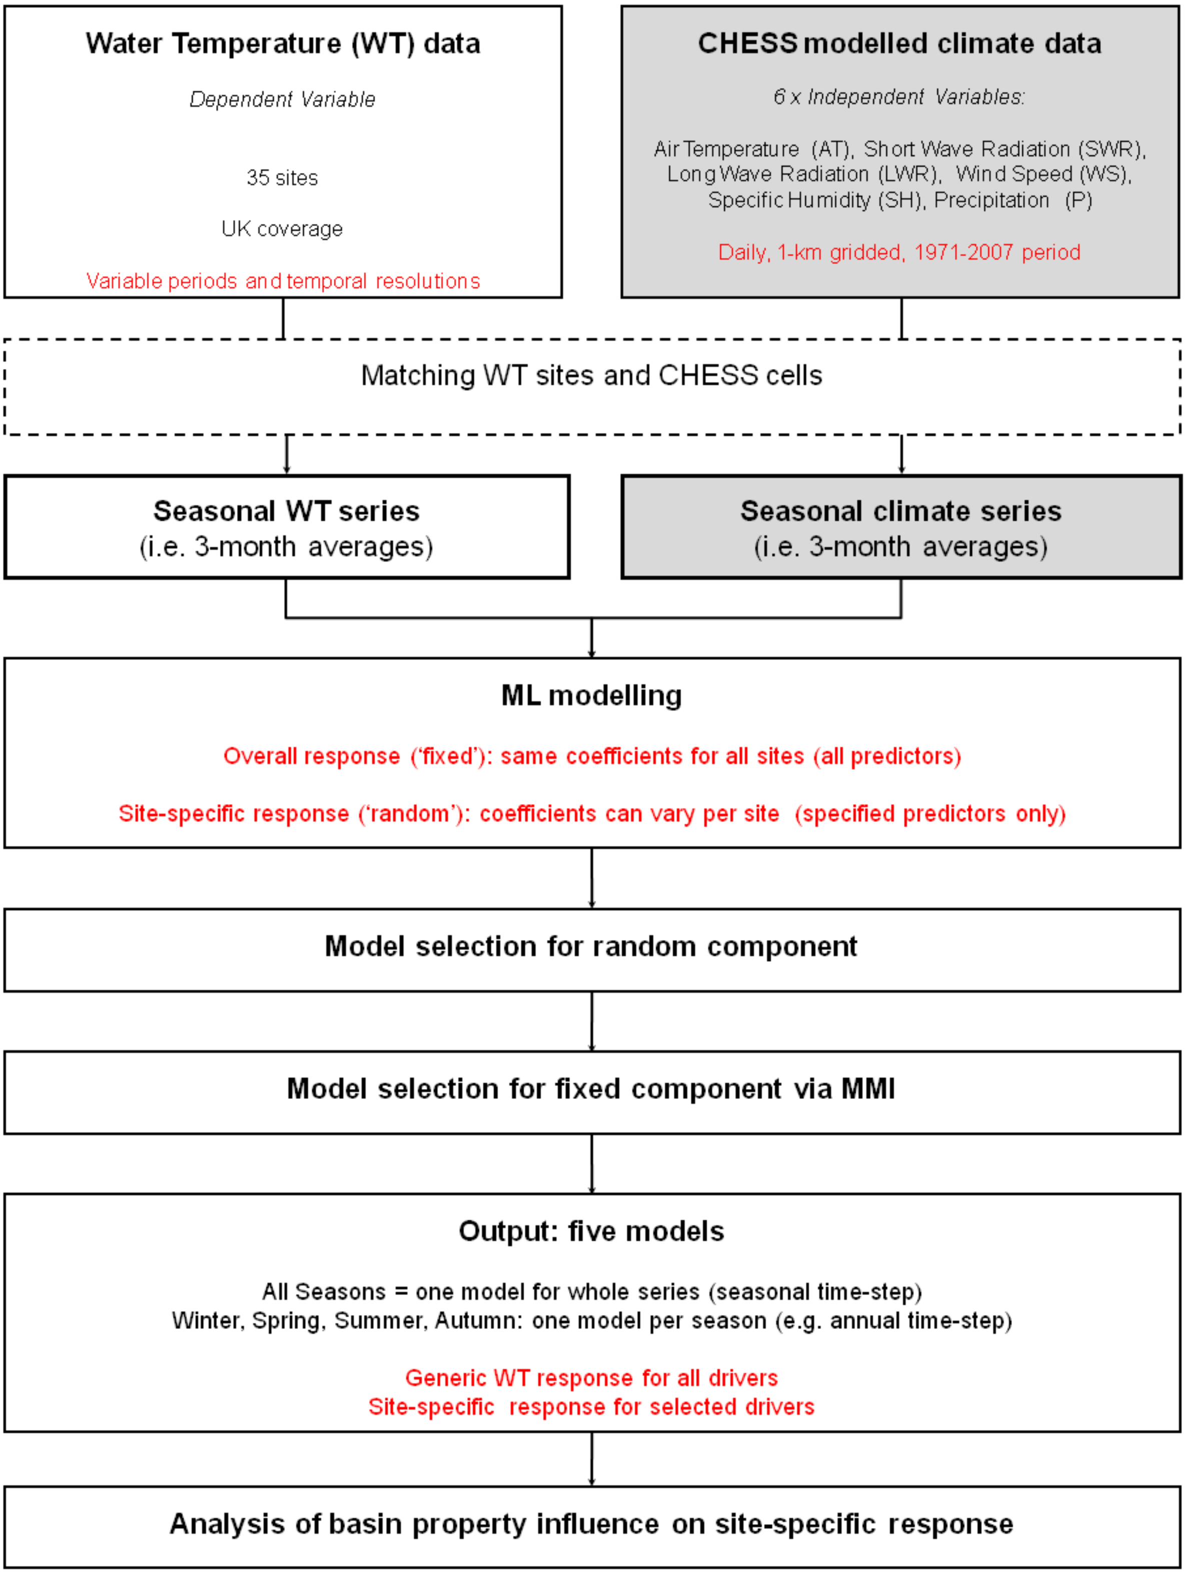

Figure 3. Study flow chart.

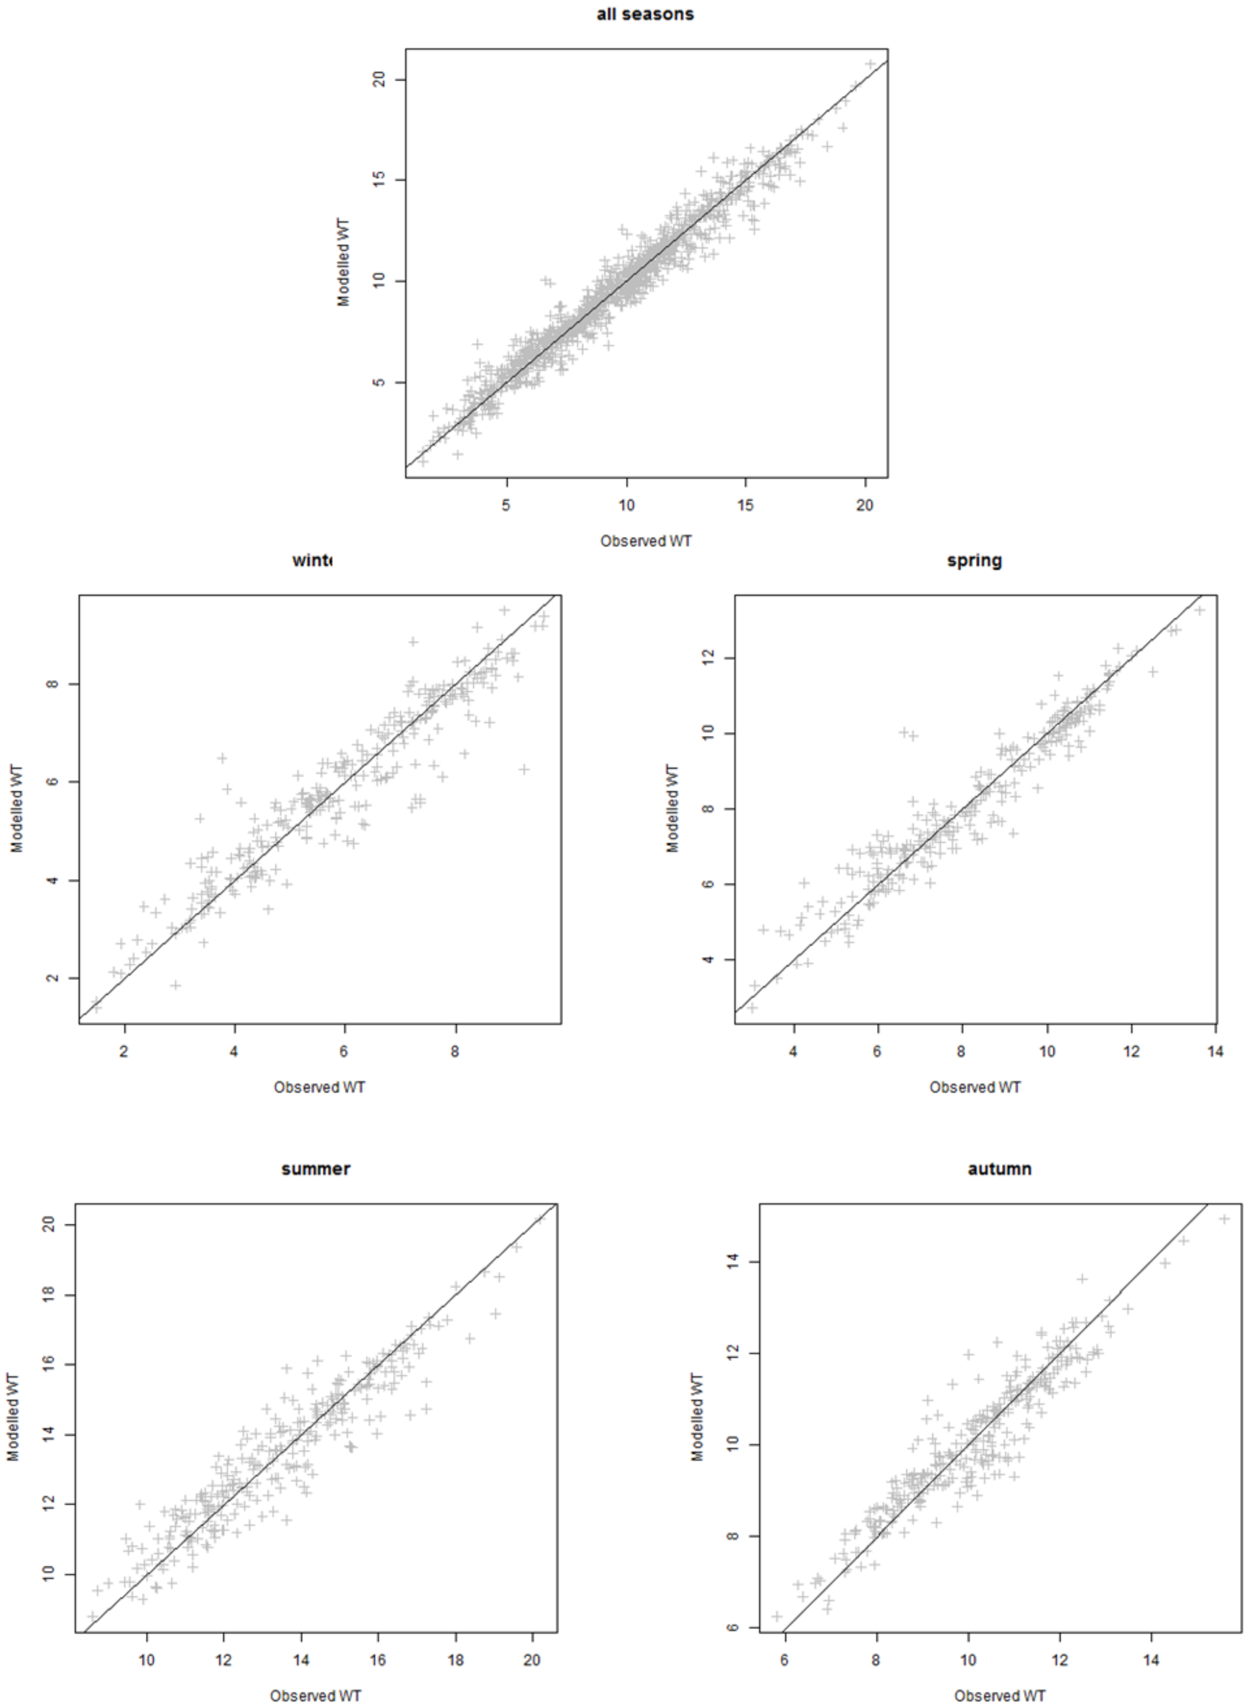

Figure 4. Plots of observed and modelled water temperature for the five models.

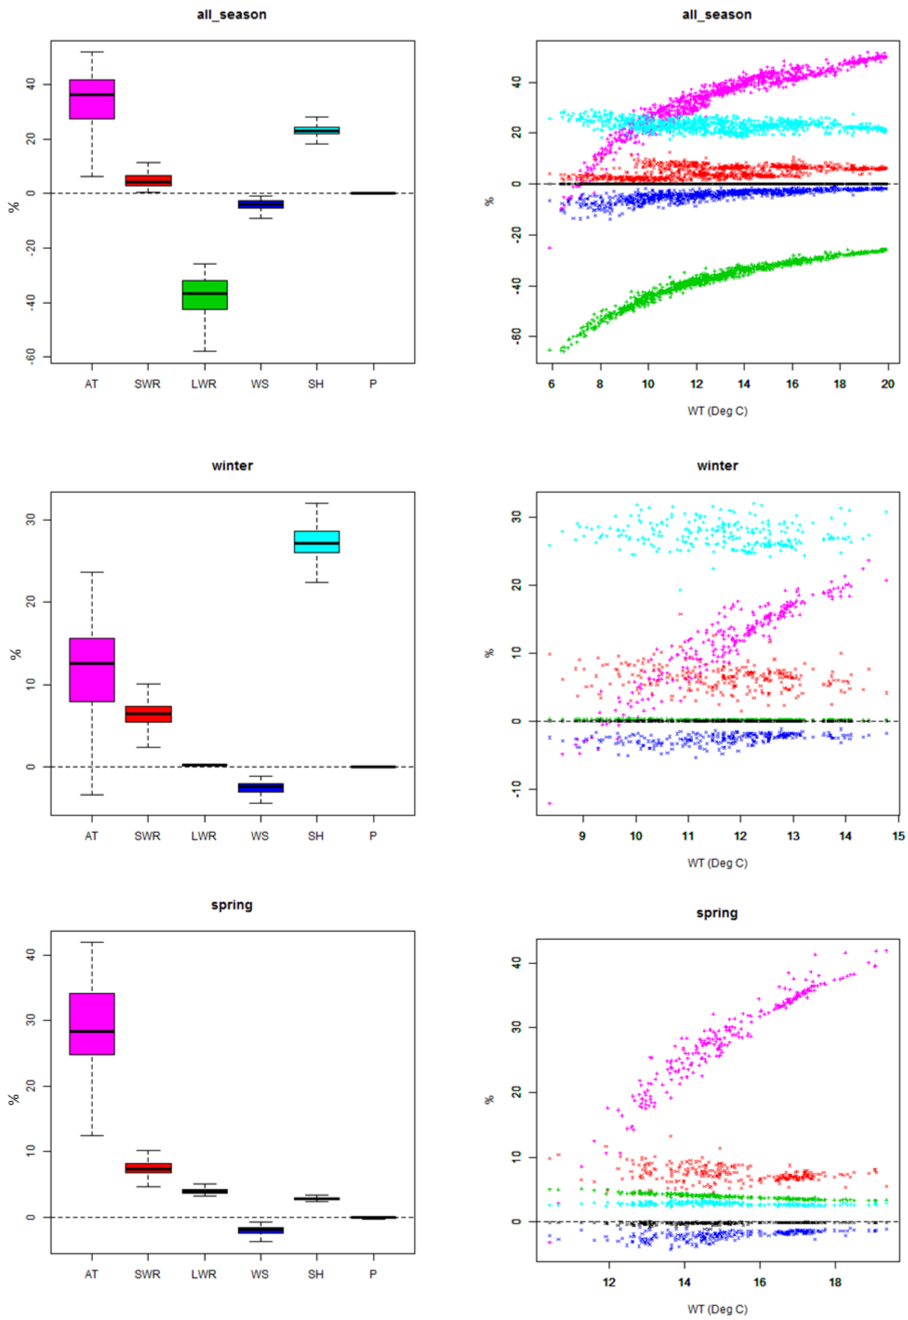

Figure 5a. Contributions of climate predictors to modelled WT (all seasons, winter, and spring): left-hand side, boxplots of percentage contributions of climate predictors to modelled WT values for all data-points (except outliers); right-hand side, scatter plots of percentage contributions of climate predictors to modelled WT values against modelled WT values for all data-points; colour-coding for all plots: magenta, AT; red, SWR; green, LWR; dark blue, WS; cyan, SH; black, P.

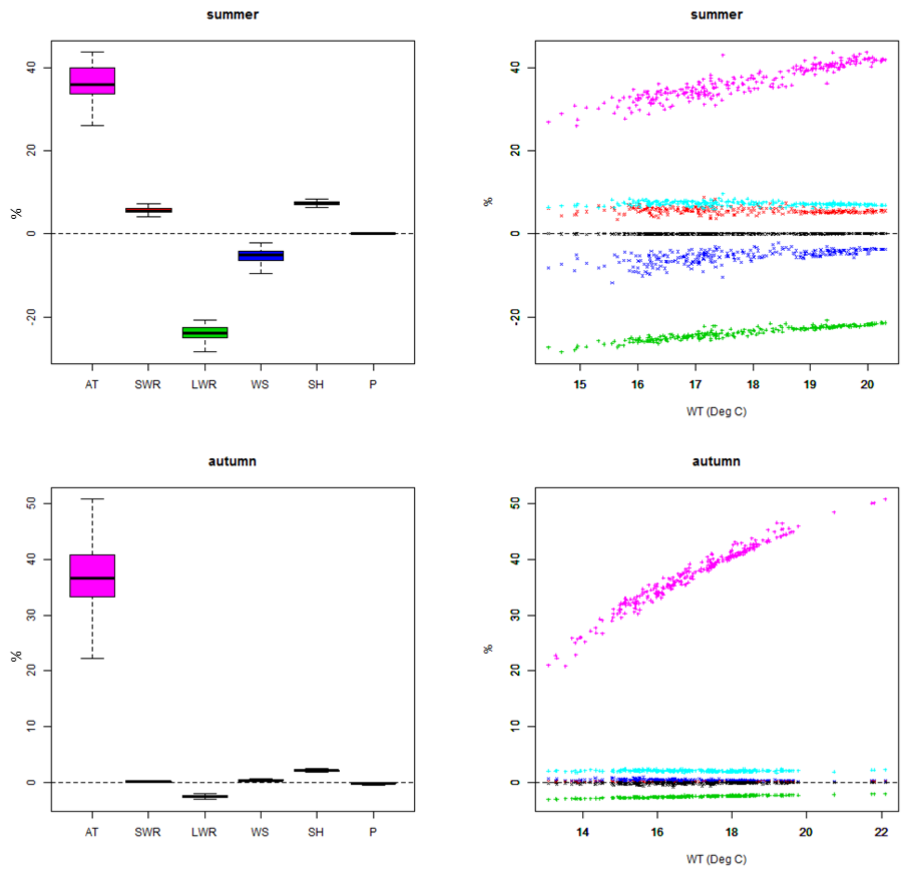

Figure 5b. Contributions of climate predictors to modelled WT (summer and autumn): left-hand side, boxplots of percentage contributions of climate predictors to modelled WT values for all data-points (except outliers); right-hand side, scatter plots of percentage contributions of climate predictors to modelled WT values against modelled WT values for all data-points; colour-coding for all plots: magenta, AT; red, SWR; green, LWR; dark blue, WS; cyan, SH; black, P.
