Abstract. The Upper Blue Nile basin is one of the most data-scarce regions in developing countries, hence, the hydrological information required for informed decision making in water resources management is limited. The hydrological complexity of the basin, tied with the lack of hydrometeorological data, means that most hydrological studies in the region are either restricted to small subbasins where there are relatively better hydrometeorological data available, or at the whole basin scale but at very coarse time scales and spatial resolutions. In this study we develop a methodology that can improve the state-of-art by using the available, but sparse, hydrometeorological data and satellite products to obtain the estimates of all the components of the hydrological cycle (precipitation, evapotranspiration, discharge, and storage). To this scope, we use the JGrass-NewAge system and various remote sensing products. The satellite products SM2R-CCI is used for obtaining the rainfall inputs; SAF EUMETSAT for cloud cover fraction for proper net radiation estimation; GLEAM for comparison with estimated ET; and GRACE gravimetry data for comparison of the total water storage amounts available. Results are obtained at daily time-steps for the period 1994-2009 (16 years), and they can be used as a reference for any water resource development activities in the region. The overall long term mean budget analysis shows that precipitation of the basin is 1360 ± 230 mm per year. Evapotranspiration covers 56% of the yearly budget, runoff is 33%. Storage varies from minus 10% to plus 17% of the budget.

Key Words: Water budget, Upper Blue Nile, JGrass-NewAge system, Satellite data, evapotranspiration

1 Introduction

Freshwater is a scarce resource in many regions of the world: the problem continues to be aggravated by growing populations and significant increases in demand for agricultural and industrial purposes. The Nile River basin is one such region, with relatively arid climate because of high temperatures and solar radiation which foster rapid evapotranspiration. Most of the countries within the basin, such as Egypt, Sudan, Kenya, and Tanzania, receive insufficient fresh water (Pimentel et al., 2004). Exceptions to this are the small areas at the equators and the Upper Blue Nile basin in the Ethiopian highlands, which receives up to 2000 mm per year (Johnston and McCartney, 2010). Particularly, the Upper Blue Nile (hereafter UBN) basin is the main sources of water in the region. Also, it is probably one of the most hydro-climatologically and socio-politically complex basins in the world. The water resources management in the basin face many pressures and challenges: (1) as the principal contributor (i.e 85%) to the main Nile basin, UBN supports the lives of hundreds of millions of people living downstream, and it is referred

to as the "Water Tower" of northeast Africa; (2) locally, the basin is inhabited by 20 million people whose main livelihood is subsistence agriculture (Population Census Commission 2008); (3) topographically, the basin is very complex: it starts from mountains as high as 4,160 m a.s.l. and drains to lowlands of about 500 m a.s.l.; (4) the UBN is a part of trans-boundary river, hence its development and management require diplomatic discussions with many national governments; (5) many international and non-governmental organizations, each with different policies, legal regimes, and contrasting interests, are involved in the freshwater governance of the basin; (6) the Ethiopian government has started many water resource development projects, such as irrigation schemes and dams, among which the Grand Ethiopia Renaissance Dam (GERD), which, upon completion, will be one of the largest in Africa.

Tackling all these facts and challenges and developing better water resource development strategies is only possible by gathering quantitative information (Hall et al., 2014). Understanding the hydrological processes of UBN, therefore, is the basis for both the transboundary negotiations about sharing the water resources and for assessing the sustainability of farming systems in the region. In fact, because of the lack of hydrometeorological data and a proper modelling framework, the recent modelling efforts conducted within the basin have evident limitations in addressing these problems. Studies in the region are limited to small basins, particularly within the Lake Tana basin where there are relatively better hydrometeorological data (Rientjes et al., 2011; Uhlenbrook et al., 2010; Tekleab et al., 2011; Wale et al., 2009; Kebede et al., 2006; Bewket and Sterk, 2005; Steenhuis et al., 2009; Conway, 1997; Mishra et al., 2004; Mishra and Hata, 2006; Teferi et al., 2010), or at the whole basin scale, but in which case information on spatial variability is usually ignored (Kim et al., 2008; Kim and Kaluarachchi, 2009; Gebremicael et al., 2013; Tekleab et al., 2011). Other studies are limited to a specific hydrological process e.g. rainfall variability (Block and Rajagopalan, 2007; Abteu et al., 2009), time series and statistical analysis of in situ discharge/rainfall data (Teferi et al., 2010; Taye and Willems, 2011) or perform modelling at very low temporal resolutions (e.g. monthly) (Kim and Kaluarachchi, 2008; Tekleab et al., 2011). Spatially distributed information on all the components of the water budget does not exist and basin modelling approaches that are tailored to a single component do not provide an effective picture of the dynamics of the water resources within the basin.

To overcome data scarcity, large scale hydrological modelling can be supported by remote sensing (RS) products, which fill the data gaps in water balance dynamics estimation (Sheffield et al., 2012). For instance, a considerable number of researches has been carried out in the last two decades in developing satellite rainfall estimations procedures (Hong et al., 2006; Bellerby, 2007; Huffman et al., 2007; Kummerow et al., 1998; Joyce et al., 2004; Sorooshian et al., 2000; Brocca et al., 2014).

RS is also a viable option to fill the gaps for basin scale evapotranspiration estimation. Global satellite evapotranspiration products have been available by applying energy balance and empirical models to satellite derived surface radiation, meteorology and vegetation characteristics, and they are recognised to have a certain degree of reliability (e.g. Fisher et al., 2008; Mu et al., 2007; Sheffield et al., 2010).

Basin scale storage estimation is the most difficult task. Fortunately, the Gravity Recovery and Climate Experiment (GRACE) (Landerer and Swenson, 2012) came to fill this gap (e.g. Han et al., 2009; Muskett and Romanovsky, 2009; Rodell et al., 2007; Syed et al., 2008; Rodell et al., 2004). Guntner (2008), Ramillien et al. (2008) and Jiang et al. (2014) reviewed the use of GRACE data and positively recommended it for large scale water budget modeling. At the moment, satellite based retrievals

of discharge are not available as operational or research products, but, potentially it can be retrieved from satellite altimetry and multispectral sensors (e.g. Tarpanelli et al., 2015; Van Dijk et al., 2016). Moreover, the Surface Water Ocean Topography (SWOT, Durand et al. (2010)) mission, which is expected to be launched in 2020, will provide river elevation (with an accuracy of 10 cm), slope (with an accuracy of 1 cm/1 km) and width that can be used in estimating river discharge (Paiva et al., 2015; Pavelsky et al., 2014).

Notwithstanding the availability of these RS products at various (spatial and temporal) resolutions and accuracy, their use is clearly a new paradigm in water budget closure estimations (Sheffield et al., 2009; Andrew et al., 2014; Sahoo et al., 2011; Gao et al., 2010; Wang et al., 2014).

This study is an effort contributing to answering the quantitative issues related to the aforementioned problems and aims to resolve the water budget of the UBN basin using a new hydrological modelling framework (see section 3.1) and remote sensing data improving the estimates of previous studies. It obtains, at relatively small spatial scales and at daily time step, all the water budget components. It is also a methodological paper, in that it delineates various methodologies to overcome the data scarcity.

The paper is organized as follows: firstly, descriptions of the study area is given (section 2), then the methodologies for each water budget component and the model set-up are detailed in section 3. The results and discussions of each component and the water budget are presented in section 4. Finally, the conclusions of the study are given (section 5).

2 The Study Basin

The Upper Blue Nile (UBN) river originates at Lake Tana at Bahir Dar, flowing southeast through a series of cataracts. After about 150 km, the river enters to a deep canyon, and changes direction to the south. After flowing for another 120 km flow, the river again changes its direction to the west and northwest, towards the El Diem (Ethiopia-Sudan border). Many tributaries draining from many parts of the Ethiopian highlands join the main river along its course. The total distance of the river within Ethiopia is about 1000 km.

The UBN basin represents up to 60% of the Ethiopian highlands contribution to the Nile river flows, which is itself 85% of the total (Abu-Zeid and Biswas, 1996; Conway, 2000). The area of the river basin enclosed by a section at the Ethiopia-Sudan border is about 175,315 km² (figure 1), covering about 17% of the total area of the country. The large scale hydrological behaviour of the basin is described in a series of studies (Conway, 1997, 2000, 2005; Conway and Hulme, 1993). Specifically, its hydrological behaviour is characterized by high spatio-temporal variability. Since the UBN basin has the lion's share of the total Nile flow, it is the economic mainstay of downstream countries (i.e. Sudan and Egypt). Moreover, the Ethiopian highlands are highly populated and have high water demands of their own for irrigation and domestic uses.

The topographic distribution of the basin is shown in figure 1. The topography of UBN is very complex, with elevation ranging from 500 m in the lowlands at the Sudan border to 4160 m in the upper parts of the basin. Due to the topographic variations, the climate of the basin varies from cool (in the highlands) to hot (in the lowlands), with large variations in a limited elevation range. The hot season is from March to May, the wet season, with lower temperatures, is from June to September, while the dry season runs from October to February. There are three controlling mechanisms of rainfall in the UBN basin and

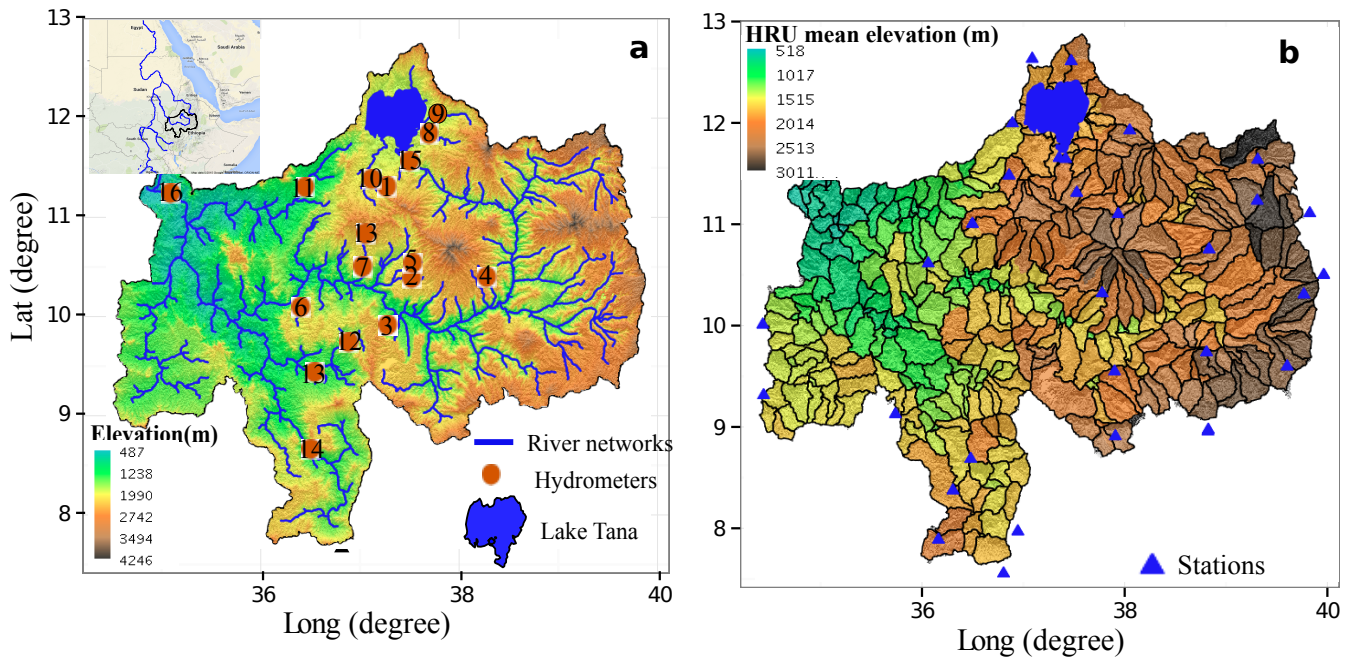

Figure 1. The Upper Blue Nile basin digital elevation map, along with the gauge stations (a); and subbasin partitions and meteorological stations used for simulation (b). Numbers inside the circles (figure a) designates the river gauging stations. The name of the basin referring to the numbers are provided in table 4.

in Ethiopia as whole (Seleshi and Zanke, 2004): the Intertropical Convergence Zone (ITCZ) that drives the monsoon rainfall during the wet season (Jun.-Sept.); the Saharan anticyclone that generates the dry and cool northeasterly winds in the dry season (Oct.-Feb.); and the Arabian highlands that produce thermal lows in the hot season (Mar.-May). Specifically studies have found that the interannual and seasonal variability of precipitation in the UBN basin is governed by the Southern Oscillation Index (SOI), the equatorial eastern Pacific sea level pressure, and the sea-surface temperature (SST) over the tropical eastern Pacific Ocean (Camberlin, 1997; Seleshi and Zanke, 2004). The mean annual rainfall and potential evapotranspiration of the UBN basin are estimated to be in the ranges of 1,200-1,600 mm and 1,000-1,800 mm, respectively (Conway, 1997, 2000), with high spatio-temporal variability. The annual temperature mean is 18.5° , with small seasonal variability.

3 Methodology

10 Water budget simulation is essential to the estimation of both water storage and water fluxes (rate of flow) for given, appropriate, control volumes and time periods. It is given by:

$$\frac{\partial S_k(t)}{\partial t} = J_k(t) + \sum_i^{m(k)} Q_{ki}(t) - ET_k(t) - Q_k(t) \quad (1)$$

where $J(t)$ is rainfall, and $ET(t)$ is actual evapotranspiration, $Q(t)$ is discharge, $Q_{ki}(t)$ is the discharge from the contributing streams. The index $k = 1, 2, 3, \dots$ is the control volume where the water budget is solved. In our case, the control volume is a portion of the basin (a subbasin) derived from topographic partitioning as described in section 3.1.

Table 1. JGrass-NewAge system components and respective references. The components in bold are the ones used in this study.

Role	Component Name	Description
Basin partitioning	GIS spatial toolbox and Horton Machine	A GIS spatial toolbox that uses DEM to extract basin, hillslopes, and channel links for NewAge-JGrass set-up (Formetta et al., 2014a; Abera et al., 2014).
Data interpolation	Kriging, Inverse Distance Weighting, and JAMI	Interpolates meteorological data from meteorological stations to points of interest according to a variety of kriging algorithms (Goovaerts, 2000; Haberlandt, 2007; Goovaerts, 1999; Schiemann et al., 2011), Inverse Distance Weighting (Goovaerts, 1997)
Energy balance	Shortwave radiation , Longwave radiation	Calculate shortwave and longwave radiation, respectively, from topographic and atmospheric data (Formetta et al., 2013, 2016).
Evapotranspiration	Penman-Monteith, Priestly-Taylor , Fao-Evapotranspiration	Estimates evapotranspiration using Penman-Monteith (Monteith et al., 1965), Priestly-Taylor (Priestley and Taylor, 1972), and Fao-Evapotranspiration (Allen et al., 1998) options
Runoff	ADIGE (Hymod)	Estimates runoff based on Hymod (Moore, 1985) algorithm (Formetta et al., 2011)
Snow melting	Snow melt	Modelling snow melting using three temperature and radiation based snow algorithms (Formetta et al., 2014b)
Optimization	Particle Swarm Optimization , DREAM, LUCA	Calibrate model parameters according to Particle Swarm Optimization (Kennedy and Eberhart, 1995), DREAM (Vrugt et al., 2009), LUCA (Hay et al., 2006) algorithms respectively.

3.1 JGrass-NewAge system set-up

- 5 UBN water budget is estimated using the JGrass-NewAge hydrological system. It is a set of modelling components, reported in table 1, that can be connected at runtime to create various modelling solutions. Each component is presented in details and tested against measured data in the corresponding papers cited in the table 1. Similar study using JGrass-NewAge system, but using mostly in-situ observations, has been conducted in Posina river basin (northeast Italy), and the model performance is assessed positively (Abera et al., submitted). Brief descriptions on the components used in this study are provided in the following sections. In this study, the shortwave solar radiation budget component (section 3.3), the evapotranspiration component (Priestley and Taylor, section 3.3), the Adige rainfall-runoff model (section 3.4), and all the components illustrated in figure 2 are used to estimate the various hydrological flows.

A necessary step for spatial hydrological modelling is the partitioning of the topographic information into an appropriate spatial scale. The SRTM 90 m X 90 m elevation data is used to generate the basin Geographic Information System (GIS) representation. The basin topographic representation in GIS, as detailed in (Formetta et al., 2014a; Abera et al., 2014; Formetta et al., 2011), is based on the Pfafstetter enumeration (Formetta et al., 2014a; Abera et al., 2014). The basin is subdivided in
5 Hydrologic Response Units (HRUs), where the model inputs (i.e. meteorological forcing data), and hydrological processes and outputs (i.e. evapotranspiration, discharge, shortwave solar radiation) are averaged (Formetta et al., 2014a). A routing scheme is applied to move the discharges from HRUs to the basin outlet through the channel network.

In this study, the UBN basin is divided into 402 subbasins (HRUs of mean area of $430 \pm 339 \text{ km}^2$) and channel links, as shown in figure 1b. This spatial partitioning may not be the finest scale possible, however, considering the size of the basin and
10 model input data resolutions, and the resolution of satellite products, it can be considered an acceptable scale to capture the spatial variability of the water budget.

3.2 Precipitation $J(t)$

The spatio-temporal precipitation input term of Eq. 1 ($J(t)$), is quantified with RS-based approaches. Currently, there are several satellite rainfall estimates (SREs) available for free at varying degrees of accuracy and reliability. Recently Abera et al. (2016)
15 compared five of them with high spatial and temporal resolutions over the same basin. It was shown that SM2R-CCI (Brocca et al., 2013, 2014) is one of the best products, particularly in capturing the total rainfall volume. A comparative analysis of the effects of different SREs on basin water budget components is an interesting area of research that can be extended from this study, however, here only SM2R-CCI is used for obtaining the precipitation input. The systematic error (bias) of SM2R-CCI is removed according to the ecdf matching techniques by Michelangeli et al. (2009) and Abera et al. (2016) by using
20 in-situ observations. The subbasin mean precipitation is estimated by averaging all the pixels RS corrected data within each subbasin. In accordance with the basin partition described in section 3.1, the 1994-2009 daily precipitation set is generated for 402 subbasins.

3.3 Evapotranspiration ET

Evapotranspiration estimation is crucial for agricultural and water resources management as it is an important flux within a
25 basin. The lack of in-situ data relating to ET impedes modelling efforts and makes it probably the most difficult task in water budget assessment. Here, ET is estimated according to the NewAge specific component. It provides estimates at any temporal and spatial resolution required by using the Priestley and Taylor (PT) Formula (Priestley and Taylor, 1972), which is one of the more common models used. PT is mainly based on net radiation, Rn , simplifying all the unknowns into the α_{PT} coefficient, as shown in Eq. 2.

$$30 \quad ET = \alpha_{PT} \frac{\Delta}{\Delta + \gamma} (Rn) \quad (2)$$

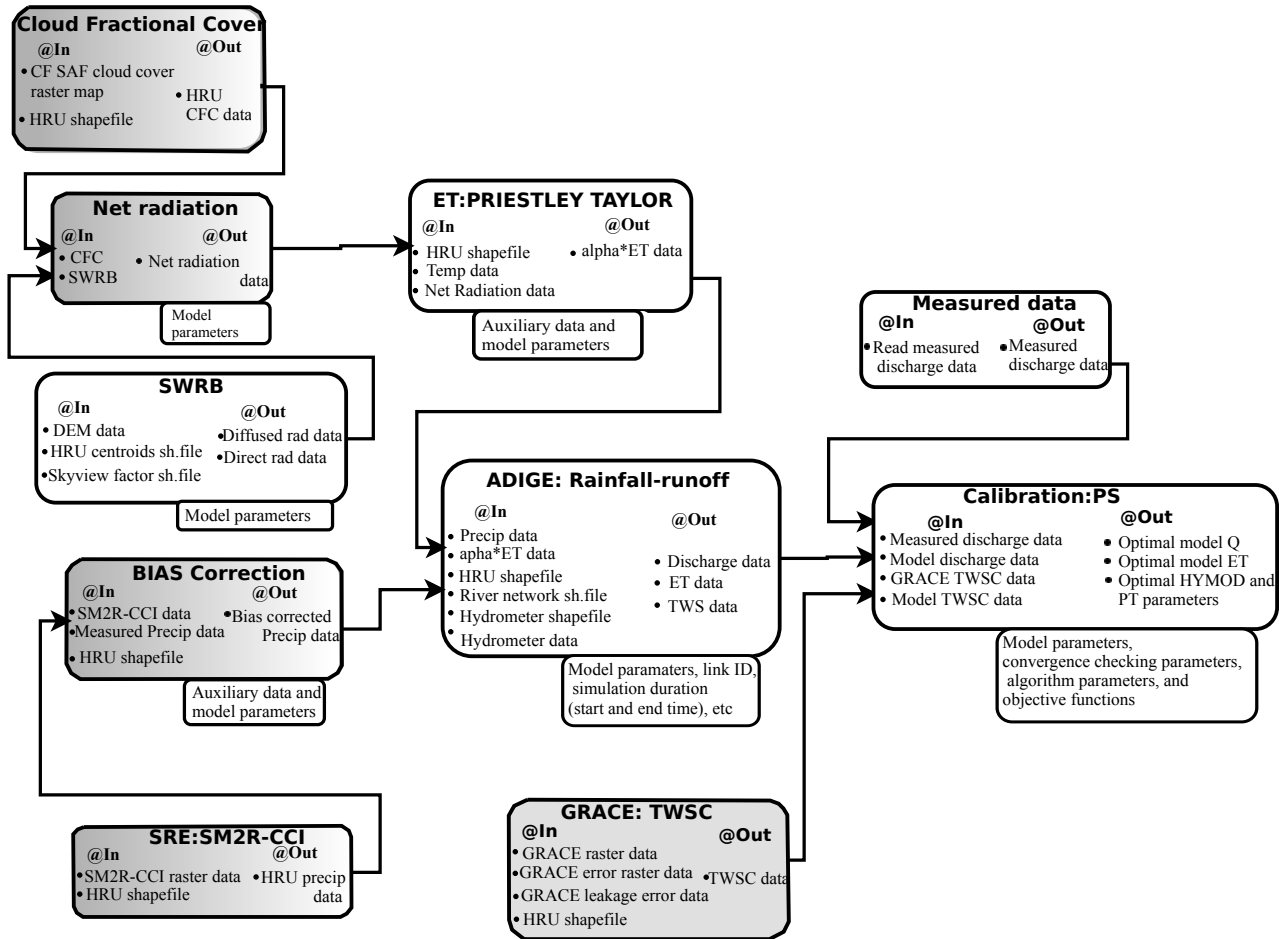

Figure 2. Workflow with a list of NewAge components (in white), and remote sensing data processing parts (shaded in grey, not yet included in JGrass-NewAGE and currently performed with R tools) used to derive the water budget of the UBN. It does not include the components used for the validation and verification processes.

Where Δ is the slope of the Clausius-Clapeyron relations and γ is the psychometric constant (Brutsaert, 2005). In this study, however, the actual evapotranspiration, ET is constrained not only by the atmospheric demands as in (Eq. 2), but it uses storage information which can be obtained from the ADIGE rainfall-runoff component of JGrass-NewAge. Hence, the ET equation is modified as (Abera et al., submitted):

$$5 \quad ET(t) = \alpha_{PT} \frac{S(t)}{S_{max}} \frac{\Delta}{\Delta + \gamma} (Rn) \quad (3)$$

where $S(t)$ is the groundwater storage, and S_{max} the maximum storage capacity for each HRU. The important unknown coefficient α_{PT} (Pejam et al., 2006; Assouline et al., 2016) and the S_{max} are calibrated within the rainfall-runoff model component, as explained below.

In this procedure, given that $S(t)$ is not measured, the assumption that there is null water storage difference after a long time, named Budyko's time, T_B , (Budyko, 1978), is required. So, here, what is searched is a time duration (T_B) such that the water storage assumes again the initial value (Abera et al., submitted). Once T_B is fixed, automatic calibration can be set to produce the set of parameters, including α_{PT} and S_{max} , for which, besides discharge is well reproduced, is also $S(T_B) = S(0)$. In this study, $T_B = 6$ years.

In equation 3, Rn is the main input modulating the atmospheric demand component of ET. To this scope, the NewAge shortwave radiation budget component, SWRB (Formetta et al., 2013), is used to return a value for each subbasin in clear sky conditions. Irradiance in clear sky conditions, however, is unsuitable for all sky condition since surface shortwave radiation is strongly affected by cloud cover and cloud type (Arking, 1991; Kjærsgaard et al., 2009). Therefore, the clear sky SWRB estimated using NewAge-SWRB is cut by using the cloud fractional cover (CFC) satellite data set (Karlsson et al., 2013), processed and provided by EUMETSAT Climate Monitoring Satellite Application Facility (CM SAF) project (Schulz et al., 2009). In this case net radiation is generated only from the shortwave radiation and the cloud cover data, as in the following formulation (Kim and Hogue, 2008):

$$Rn = (1 - CFC)R_S \quad (4)$$

Where R_S is the net shortwave radiation and Rn is the net radiation. The daily CFC data originates from polar orbiting satellites, version CDRV001, using a daily temporal resolution and a 0.25° spatial resolution from 1994 to 2009 (16 years). Satellite data are processed (Karlsson et al., 2013) to obtain the mean daily CFC for each subbasin. In comparison to CFC, the effects of surface albedo on Rn is minimal, particularly in highland areas with vegetation cover and no snow cover such as the UBN basin.

Once ET is estimated according to the methods described, it is useful to validate it with independently obtained ET estimates or data. In situ ET observations are not available for this basin, as is the case for most regions. Estimates of ET based on RS have been made by different algorithms (Norman et al., 1995; Mu et al., 2007; Jarmain, 2009; Fisher et al., 2008). In this study, the Global Land Evaporation Amsterdam Methodology (GLEAM) (Miralles et al., 2011a), a global, satellite-based, ET

data set is used. The performance of GLEAM is assessed positively in different studies (McCabe et al., 2016; Miralles et al., 2011b). Differently from the NewAge approach, GLEAM also considers dynamic vegetation information to cut PT-based potential ET to actual ET (Miralles et al., 2011a). GLEAM is available at 0.25° spatial resolution and daily temporal resolution. For comparison with NewAge ET, we estimated area weighted average GLEAM ET for each HRU polygon. The aim of the comparison is not for strict validation, but rather to assess the level of consistency between the two independent estimations. More details on GLEAM can be found in Miralles et al. (2011a, b) and McCabe et al. (2016). Comparison of the NewAge ET with MODIS standard ET product is also available in the supplementary material of the paper.

3.4 Discharge Q

For discharge estimation, the ADIGE rainfall-runoff component is used. It is based on the well-known HYMOD model (Moore, 1985) as runoff production component which also include the routing component, the artificial inflow-outflow management component. Detailed descriptions of HYMOD implementations in the NewAge model system are given at Formetta et al. (2011) and Abera et al. (submitted). The main inputs for the ADIGE model are $J(t)$ and $ET(t)$, as estimated in the previous sections. The NewAge Hymod component is applied to any HRU, in which the basin is subdivided and the total watershed discharge is the sum of the contribution of each HRU routed to the outlet. The ADIGE rainfall-runoff has five calibration parameters, and the calibration is performed using the particle swarm (PS) optimization. PS is a population-based stochastic optimization technique inspired by the social behaviour of flocking birds or fish schools (Kennedy and Eberhart, 1995). It is suited to obtaining a global optimal and less susceptible to getting trapped in local minima (Scheerlinck et al., 2009). The objective function used to estimate the optimal value of the parameter is the Kling-Gupta efficiency (KGE, Kling et al. (2012)). The KGE is preferred to the commonly-used Nash-Sutcliffe efficiency (NSE, Nash and Sutcliffe (1970)) because the NSE has been criticized for its overestimation of model skill for highly seasonal variables by underestimating flow variability (Schaeffli and Gupta, 2007; Gupta et al., 2009). For evaluation of the model performances, in addition to the KGE, two other goodness-of-fit (GOF) methods (percentage bias (PBIAS) and correlation coefficient) used in this study are described in Appendix A.

3.5 Total water storage change ds/dt

The ds/dt in Eq. 1 is the water contained in the ground, soil, snow and ice, lakes and rivers, and biomass. It is the total water storage (TWS) change, calculated as the residuals of the water budget fluxes for each control volume. In this paper, the ds/dt estimation at daily time steps is based on the interplay of all the other components as presented in Eq. 1. There is no way to estimate areal TWS from in situ observations. The new Gravity Recovery and Climate Experiment (GRACE) data (Landerer and Swenson, 2012) has a potential to estimate this component, but at very low spatial and temporal resolutions. At large scale, however, it can still be used for constraining and validating data to the modelling solutions. Here, the performance of our modelling approach to close the water budget, i.e. estimating storage following the characterization of all the terms, is assessed using the GRACE estimation at the basin scale. Monthly data is obtained from NASA's Jet Propulsion Laboratory (JPL) [ftp://podaac-ftp.jpl.nasa.gov/allData/tellus/L3/land mass/RL05](ftp://podaac-ftp.jpl.nasa.gov/allData/tellus/L3/land%20mass/RL05). The leakage errors and scaling factor (Landerer and Swenson, 2012) that are provided with the product are applied to improve the data before the comparison is made. The total

error of GRACE estimation is a combination of GRACE measurement and leakage errors (Billah et al., 2015). Based on the data of these two error types, the mean monthly error of GRACE in estimating total water storage change (TWSC) in the basin is about 8.2 mm. Since the other fluxes, for instance Q and ET , are modelled as functions of basin water storage, the good estimation of water storage by a model has inference to its reasonable computation of other fluxes as well (Döll et al., 2014).

5 3.6 Calibration and validation approach

The satellite precipitation data set (SM2R-CCI) is error corrected based on in situ observations. At the basin outlet (Ethiopia-Sudan Border), the ADIGE rainfall-runoff component (i.e. HYMOD model) is calibrated to fit the observed discharge during the six years of calibration period (1994-1999) at daily time steps. Based on the approach described in the ET estimation section, α_{PT} is calibrated by imposing that $S(t) = S(T_B)$ after $T_B = 6$ years. The value of six years is arbitrary but it was found to give good agreement with GRACE data (see below), so no other values were used. The simulation for each hydrological component is then verified using available in-situ or remote sensing data (Table 2), and three goodness-of-fit (KGE, PBIAS, r) are used as comparative indices (for detail information please see Appendix A), as follows:

- Discharge validation: Discharge simulation is validated for separate time-series data at the outlet at Ethiopian-Sudan border, where the model is calibrated. In addition, the simulation of NewAge at the internal links is validated where in situ data are available. The evaluations at the internal links provide an assessment of model estimation capacity at ungauged locations.
- ET validation: Once ET is estimated according to the procedures described above, GLEAM (Miralles et al., 2011a) is used as an independent data set to assess ET estimation. After GLEAM is aggregated for each subbasin, the GLEAM and the NewAge ET are compared and the goodness-of-fit (GOF) indexes are calculated, based on 16 years of data (1994-2009).
- ds/dt validation: The water storage change, ds/dt , estimated as residual of the water budget, is validated against the GRACE based data-set. The GRACE product was used to estimate the total water storage change for the the whole basin, since the error of GRACE increases if used at small scales. To harmonize and enable comparison between the model and the GRACE TWS data, it is necessary to do both time and spatial filtering. Following the GRACE TWS temporal resolution, the model ds/dt is aggregated at monthly time steps.

4 Results and Discussion

The results of the study are organized as follows: firstly, we present the results for 1) precipitation, 2) evapotranspiration, 3) discharge and 4) total water storage; secondly, the JGrass-NewAGE system is used to resolve the water budget closure at each subbasin, and the contribution of each term water budget term is further is analyzed.

Table 2. Short summary of the list of remote sensing products used in this study.

Satellite products	Spatial resolution	Temporal resolution	Reference	used as
SM2R-CCI	0.25	daily	Brocca et al. (2014, 2013); Abera et al. (2016)	input for Precipitation
GLEAM	0.25 degree	daily	Miralles et al. (2011a); McCabe et al. (2016)	verification for evapo- transpiration
MODIS ET (MOD16)	1-km	8-days	Mu et al. (2007, 2011)	verification for evapo- transpiration
GRACE TWS	1 degree	30-days	Landerer and Swenson (2012)	Verification for storage change
CM-SAF	0.25 degree	daily	Schulz et al. (2009)	input for evapotranspi- ration component

4.1 Precipitation J

The spatial distribution of mean, long-term, annual precipitation is presented in figure 3a. Generally, precipitation increases from the east (about 1000 mm/year) to the south and southwest (1800 mm/year). SM2R-CCI shows that the south and southwest parts of the basin receive higher precipitation than the east and northeast parts of the highlands. The rainiest subbasins are in the southern part of the basin. The precipitation data used correspond to a mean annual rainfall of about 1900 mm, while the mean annual precipitation reported for this region by Abteu et al. (2009) is about 2049 mm. The latter estimation, however, is from point gauge data, while this study is based on areal data. Generally, precipitation increases from the east (about 1000 mm/year) to the south and southwest (1800 mm/year). This spatial pattern is consistent with the results of Mellander et al. (2013) and Abteu et al. (2009). To understand the spatial distribution of the seasonal cycle, the quarterly percentage of total annual precipitation, calculated from 1994 to 2009 in daily estimations, is presented in figure 3 b. During the summer season (June, July and August), while the subbasins in the north and northeast receive about 65% of the annual precipitation (figure 3 b), the subbasins in the south receive about 40% of total precipitation.

4.2 Evapotranspiration ET

Based on the approach detailed in our methodology, the ET is estimated for each subbasin at daily time steps. Figure 4 a shows the comparisons of the ET time series from 1994-2002 (aggregated at daily, weekly, and monthly, from top to bottom) between NewAge and GLEAM. The Figure specifically refers to three selected subbasins representing different ranges of elevations and spatial locations. NewAge estimates have higher temporal variability in comparison to GLEAM. In the represented locations, GLEAM therefore accumulates a systematic growing difference in evapotranspired water volume, which could be not consistent with the estimated storage (see below).

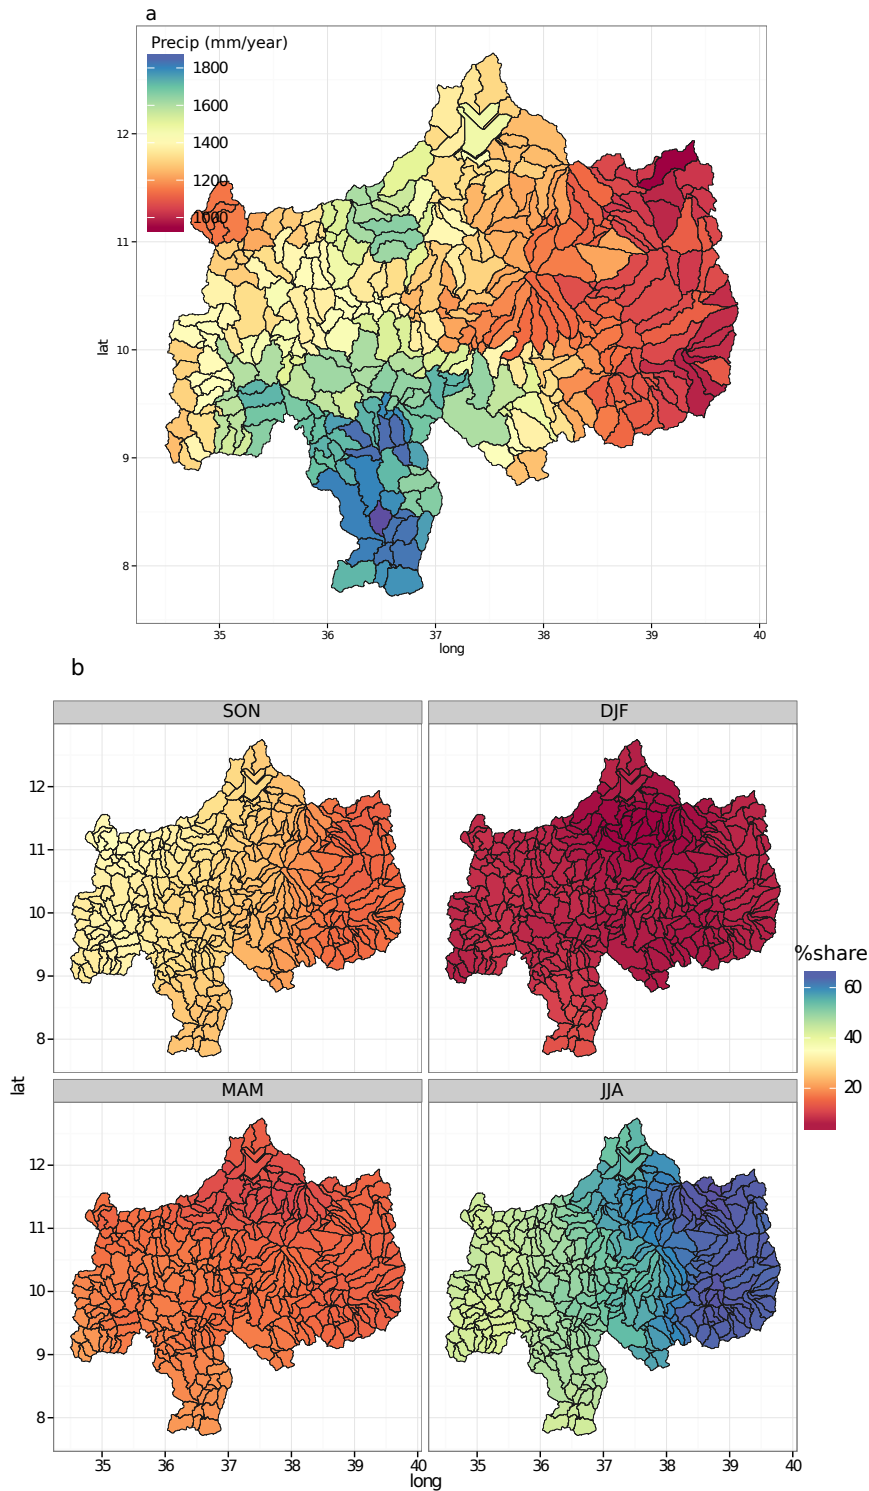

Figure 3. The spatial distribution of mean annual rainfall (a), and quarterly percentages share of the total rainfall (b) estimated from long term data (1994-2009): SON (September, October, and November), DJF (December, January, and February), MAM (March, April, and May), JJA (June, July and August). Note that high seasonality is observed in the eastern part of the basin.

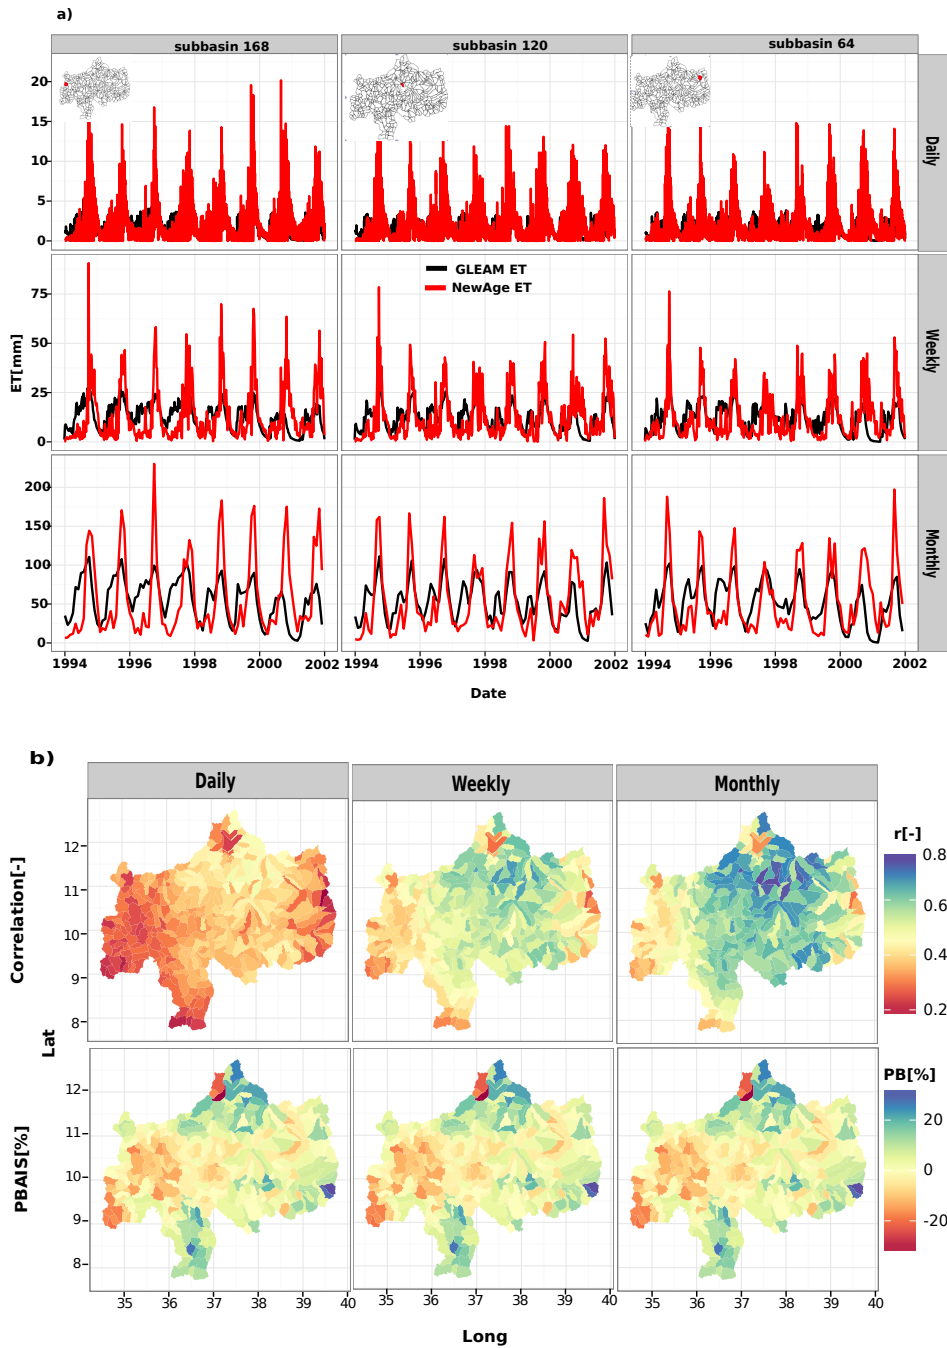

Figure 4. a: Time series ET estimation with NewAge and GLEAM for three subbasins: subbasin ID168, subbasin ID120, and subbasin ID64 at daily, weekly and monthly time steps. The locations of the subbasins are indicated on the maps at the top of each column of plots. b: spatial distribution of correlation coefficient and PBIAS between NewAge and GLEAM estimations at daily, weekly and monthly time steps.

The agreement/disagreement between the two *ET* estimations vary from subbasin to subbasin (figure 4). The spatial distribution correlation and PBIAS between the NewAge and GLEAM ET is presented in figure 4b. Spatially, the correlation between JGrass-NewAGE and GLEAM is higher in the eastern and central parts of the basin, while it tends to decrease systematically towards the west (i.e. to the lowlands, see figure 4b). The correlation between the two ET estimations increases when passing from daily to monthly time steps. The PBIAS between the two estimates ranges from -10% to 10%, with large numbers of subbasin being from -3% to 3%. Spatially, the comparison shows that GLEAM overestimates ET in the western parts of the basin (border to the Sudan) and underestimates ET in the northern parts of the basin (figure 4b). The overall basin correlation is 0.34 ± 0.07 (daily time step), 0.51 ± 0.08 (weekly time step), and 0.57 ± 0.10 (monthly time steps). Generally, except at daily time step, the two estimates have acceptable agreements (very low bias, and acceptable correlation). However, in comparison with the correlation (0.48 ± 0.15) and PBIAS ($14.5 \pm 18.9\%$) obtained between NewAge ET and MODIS ET Product (MOD16), as shown in the supplementary material, the correlation and PBIAS between NewAge ET and GLEAM ET is much better.

4.3 Discharge *Q*

The optimized parameters of the Adige model, obtained using automatic calibration procedure of NewAge, are given at table 3. At the basin outlet, the automatic calibration of the NewAge components provided very good values of the GOF indices (KGE=0.93, PBIAS = 2.2, $r = 0.94$). The performances, at the outlet remain high also during the validation period, having KGE=0.92, PBIAS = 2.4, and $r = 0.93$.

Model performances are also evaluated within the basin at the internal catchments outlets (table 4) where stage measurements are available. Figure 5 shows simulated hydrographs along with the observed discharges for some locations. The results show that the performances of the NewAge simulation are a little better than the performances reported by Mengistu and Sorteberg (2012), with slightly lower PBIAS value (PBIAS=8.2, $r=0.95$). Generally, the model predicts both the high flows and low flows well, with slight underestimation of peak flows (figure 5 a). This is likely due to the underestimation of SM2R-CCI precipitation data for high rainfall intensities (Abera et al., 2016). Additional source of error can also be caused by model inconsistency due to averaging out input data over large areas.

Table 3. Optimized parameters obtained from daily ADIGE simulation during the calibration period (1994-1999). The last parameter is for the ET component.

Parameters	value
$C_{max}[L]$	694.18
$B_{exp}[-]$	0.64
$\alpha_{Hymod}[-]$	0.61
$Rs[T]$	0.086
$Rq[T]$	0.394
$\alpha_{PT}[-]$	2.9

Table 4. The forecasting capacity of the NewAge Adige rainfall-runoff component at the internal sites, based on the optimized parameters calibrated at the outlet. The performance at the outlet (El Diem) is the model performance during validation period.

Hydrometer stations ID	River Name	Area (km ²)	KGE	PBIAS	r
1	Koga @ Merawi	244.00	0.67	-8.70	0.73
2	Jedeb @ Amanuel	305.00	0.38	40.80	0.53
3	Neshi @ Shambu	322.00	0.58	32.00	0.57
4	Suha @ Bichena	359.00	0.54	39.20	0.82
5	Temcha @ Dembecha	406.00	0.70	3.30	0.71
6	Gilgel Beles @ Mandura	675.00	0.68	11.40	0.70
7	Lower Fettam @ Galibed	757.00	0.67	-7.7	0.78
8	Gummera @ Bahir Dar	1394.00	0.19	-53.20	0.88
9	Ribb @ Addis Zemen	1592.00	0.81	12.00	0.86
10	Gelgel Abay @ Merawi	1664.00	0.81	12.00	0.93
11	Main Beles @ Bridge	3431.00	0.68	-1.70	0.74
12	Little Anger @ Gutin	3742.00	0.65	24.30	0.81
13	Great Anger @ Nekemt	4674.00	0.72	-14.10	0.82
14	Didessa @ Arjo	9981.00	0.55	19.60	0.81
15	Upper Blue Nile @ Bahir Dar	15321.00	0.26	5.10	0.60
16	Upper Blue Nile @ El Diem	174000.00	0.92	2.40	0.93

Regarding the internal sites discharge forecasting, we remark some representative results. The hydrograph comparison between the NewAge simulated discharge and the observed one of the Gelgel Beles river, enclosed at the bridge near to Mandura with an area of 675 km², is shown in figure 5 b. The performance of the uncalibrated NewAge at Geleleg Beles has a correlation coefficient of 0.70, PBIAS is 11.40% and the KGE value is 0.68 (table 4).

5 Simulation performances for the medium size basins, such as the Ribb river, enclosed at Addis Zemen (area=1592 km², KGE = 0.81, PBIAS = 12% and $r = 0.82$, figure 5 c), and Gilgel Abay river, enclosed at Merawi (area = 1664 km², KGE=0.81, PBIAS=12%, $r=0.93$), are very good. For the Ribb river, the NewAge simulation performance can be compared with SWAT Model performances by Setegn et al. (2008) ($r=0.74-0.76$). Even though SWAT was calibrated for this specific subbasin, the results of our study are much better. Similarly, without calibration for the Gilgel Abay river, the NewAge simulation performance is better than the results of Wase-Tana (Wosenie et al., 2014, PBIAS=34) and Flex_B (Fenicia et al., 2008, PBIAS=77.6) or comparable to SWAT (PBIAS=5).

10 To analyze the forecasting capacity of NewAge for the larger size basins, the performances at Angar river (area 4674 km²), Lake Tana (area 15321 km²), and Dedisa river basin (9981 km²) are reported. The simulation analysis at the Angar river enclosed near Nekemt (KGE = 0.72, PBIAS = -14.10%, and $r = 0.82$), Lake Tana (KGE = 0.26, PBIAS = 5.10, and $r =$
15 0.60), and Dedisa (KGE=0.55, PBIAS = 19.60, and $r = 0.81$) indicate that the performances are acceptable. The comparison

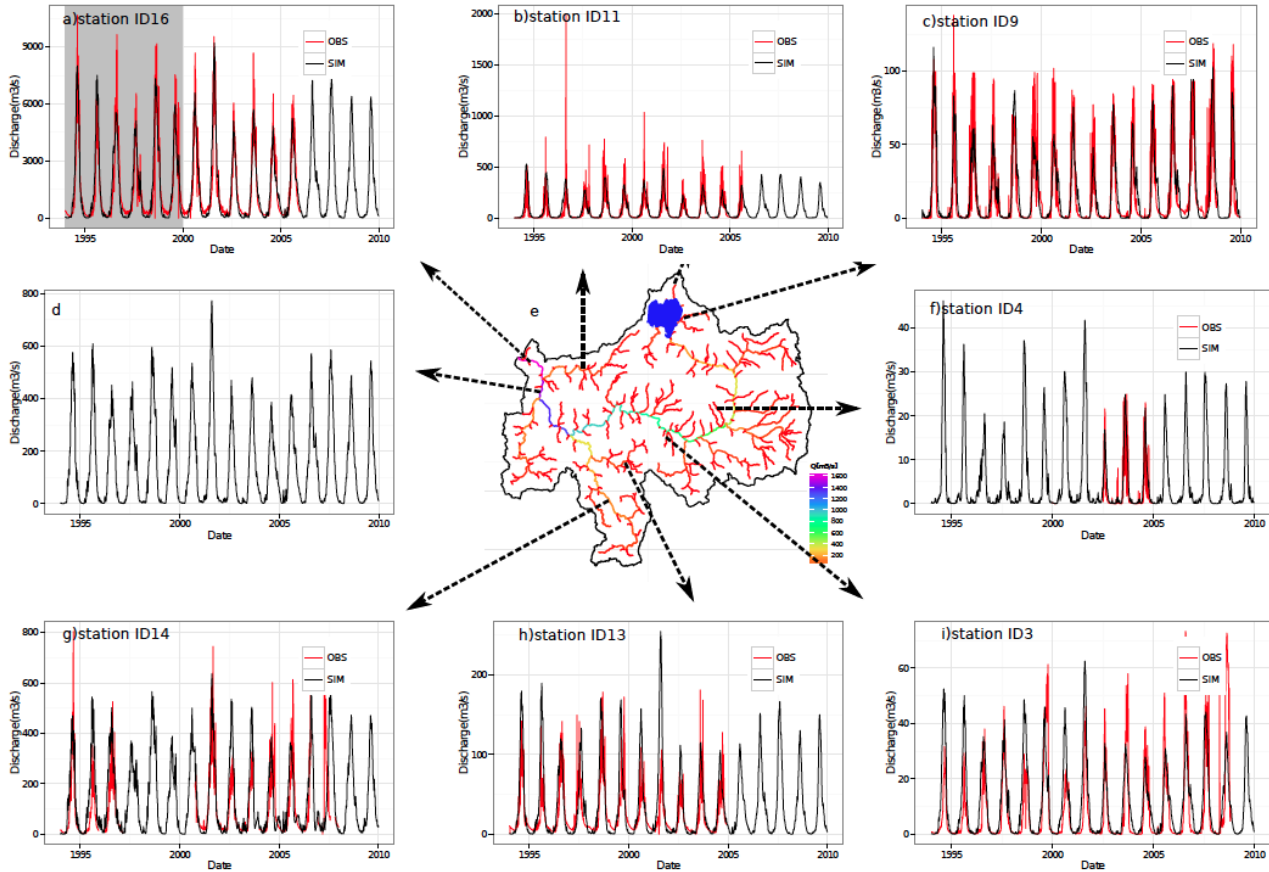

Figure 5. NewAge model forecasting validation at internal subbasins. The model calibrated and validated at El Diem (a) is used to estimate at each channel link and, where discharge measurements are available, they are verified: main Beles bridge (b), Ribb river enclosed at Addis Zemen (c), just simulation of the main Blue Nile before joining Beles river (d), Jedeb near Amanuel (f), Dedisa river basin enclosed near Arjo (g), Angar river basin enclosed near Nekemt (h), and Nesh near Shambu (i). Figure (e) shows the long term estimated daily discharge for all river links of the basin.

of simulated and observed discharges, as well as the locations of the Angar (basin brief description (Easton et al., 2010)) and Dedisa rivers are shown in figure 5, in plots h and g respectively.

For most subbasins, because of the good model performances (i.e. KGE is higher than 0.5 and PBIAS is within 20%), the estimated discharges are deemed adequate for forecasting and estimating water resource at locations where gauges are unavailable. The model is also able to reproduce discharge across the range of scales. For instance, the model performances at the Ethiopia-Sudan border (175 315 km²), Dedisa near Arjo (9981 km²), main Beles (3431 km²), and Temcha near Dembecha (406 km²) are also acceptable, except for Lake Tana, where the discharge is regulated (figure 5 and table 4). Sample simulations at all the channel links of the study basin at daily time step are provided in the supplementary material.

4.4 Total water storage change

NewAge simulated ds/dt for 16 years for each subbasin is calculated as a residual of the flux terms. The simulated ds/dt is represented and compared with the GRACE-based TWSC in Figure 6. The storage change shows high seasonality over the basin, with positive change in summer and negative change in winter. The change varies from -100 to +120 mm/month. The model ds/dt , aggregated at monthly time scale, is in accordance with the GRACE TWSC both in temporal pattern and amplitude. Over the whole basin a correlation coefficient of 0.84 is obtained. The good performances of the ds/dt component is certainly caused also by the ability of NewAge to well reproduce the other water fluxes. Due to the possible high leakage error introduced in GRACE TWSC at high spatial resolutions (Swenson and Wahr, 2006), statistical comparison at subbasin level is not performed. The spatial distribution of NewAge and GRACE ds/dt estimates can be found in the supplementary material.

4.5 Water budget closure

The water budget components (J, ET, Q, ds/dt) of 402 subbasin of the UBN are simulated for the period 1994-2009 at daily time steps. Figure 7 shows the long-term, monthly-mean, water budget closure derived from 1994-2009. The four months (January, April, July, and October) are selected to show the four seasons (Winter, Spring, Summer and Autumn). For all components, the mean seasonal variability is very high. Generally, the seasonal patterns of Q and ds/dt follow the J, showing the highest values in summer (i.e. July) and the lowest in winter (i.e. January). However, simulated ET shows distinct seasonal patterns with respect to the other components, the highest being during autumn (October), followed by winter (January). During the summer it is low, most likely due to high cloud cover.

The variability between the subbasins is also appreciable. Generally, all components tends to increase from the east to the southwest part of the basin, except for the summer season (July). During summer, on the other hand, the eastern part of the basin receives its highest rainfall, stores more water, and generates high runoff as well. In general the dominant budget component varies with months. For instance, in January ET is the dominant while in June and July ds/dt is more dominant. After the summer season, Q and ET are the dominant fluxes. A regression analysis based on the results for all subbasins and all years shows that, at short time scales such as at daily or monthly, the variability in ET is not due to variability in J ($R^2=0.01$). Conversely, at the yearly time scale, 78% of ET variance is explained by variability in J.

Figure 6. Comparison between basin-scale NewAge ds/dt and GRACE TWSC from 2004-2009 at monthly time steps.

The spatial variability of the long term mean annual water budget closure is shown in figure 8. The spatial variability of J and Q is higher than ds/dt and ET . The higher Q and ET in the southern and southwestern part of the basin are due to higher J . Similarly Q is lower in the eastern and northeastern part of the basin. Focusing on the percentage share of the output term (Q , ET , ds/dt) of total J (figure 8 c), ET dominates the water budget, followed by Q . It is noteworthy that the eastern subbasins with low ET still have percentage share of ET due to low amount of J received.

The long-term basin-average water budget components shows: 1360 ± 230 mm of J , followed by 740 ± 87 mm of ET , 454 ± 160 mm of Q and -4 ± 63 mm of ds/dt . While the spatial variability of the water budget is high, the annual variability is rather limited. Higher annual variability is observed for J , followed by Q . 2001 and 2006 are wet years, characterized by high J and Q . Conversely, 2002 and 2009 are dry years with 1167 mm and 1215 mm per year of precipitation. Details on the two dry years (2002, 2009) of the region can be read in Viste et al. (2013).

Figure 10 provides long term monthly mean estimates of water budget fluxes and storage. The basin scale mean budget is highly variable. The highest variability is mainly in J and S . During summer months, J , Q , and ds/dt shows high magnitude. ET is not highest in June, July and August, but, in October and December it is. The S accumulated in the summer season feeds the highest ET in autumn, and causes very high drops in S (figure 10).

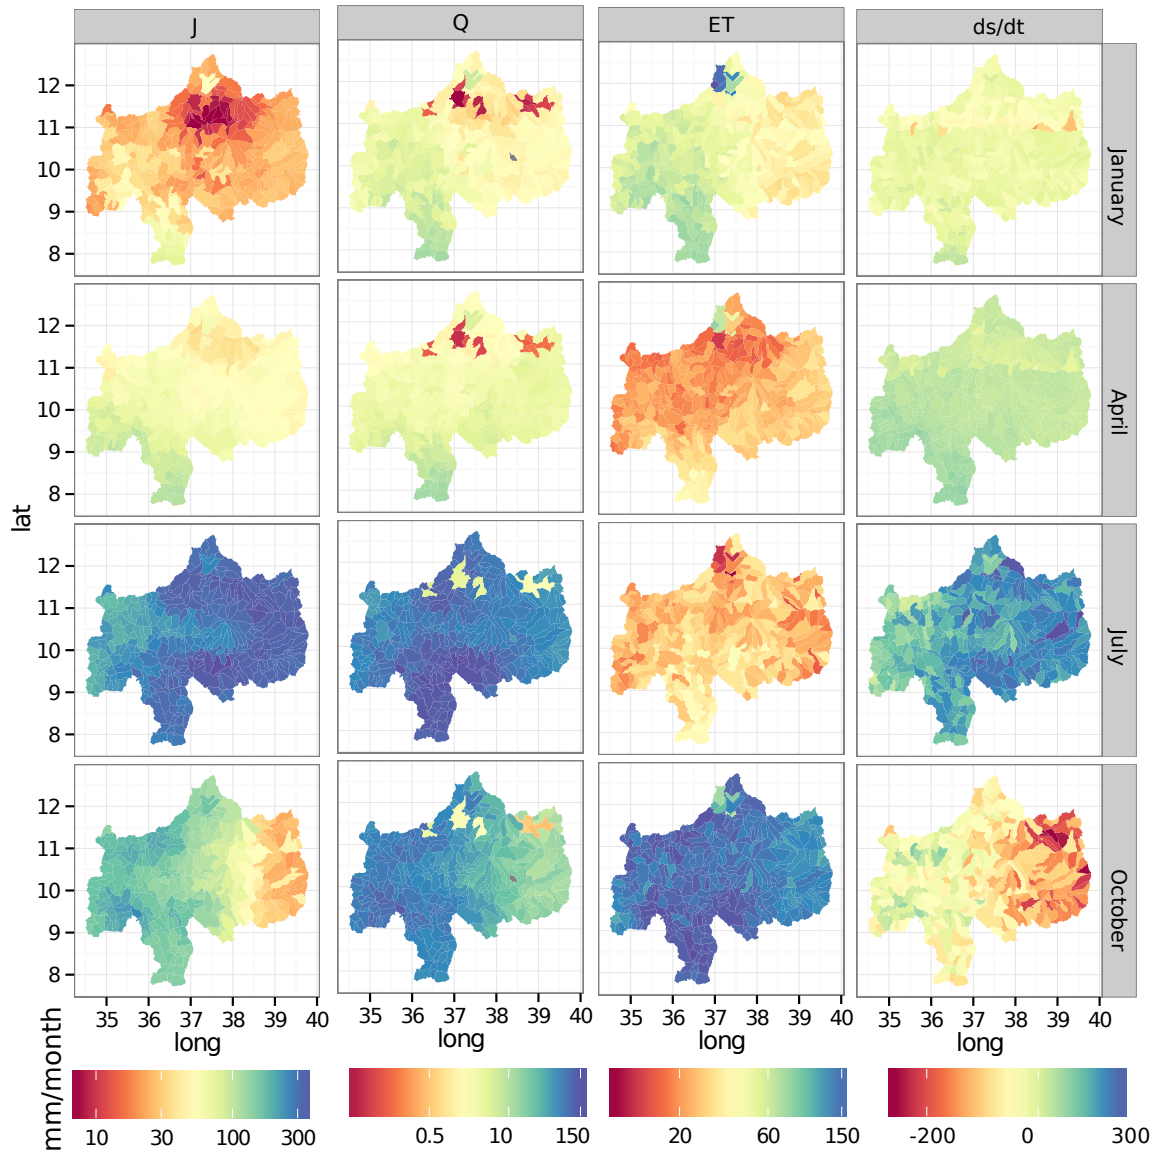

Figure 7. Spatial distribution of long term mean monthly water budget (January, April, July and October) in the UBN basin. For the sake of visibility, the legend is plotted separately and on logarithmic scale, except for the storage component.

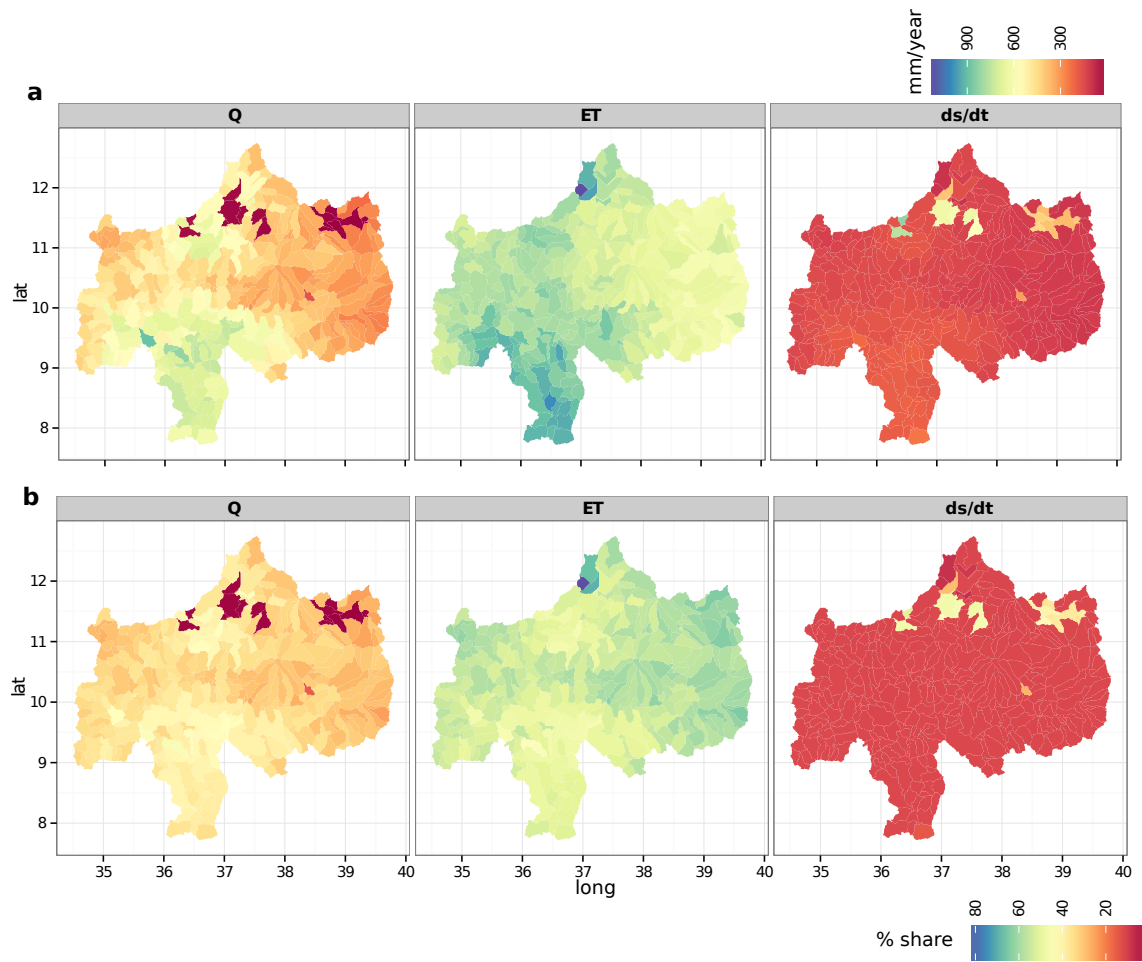

Figure 8. The spatial distributions of long term mean annual water budget closure: precipitation in mm (figure 3), the output terms (Q, ET, ds/dt) in mm (a), and the percentage share of the output term (Q, ET, ds/dt) of the total precipitation (b).

5 Conclusions

The goal of this study is to estimate the whole water budget and its spatial and temporal variability of the upper Blue Nile basin using the JGrass-NewAge hydrological system and remote sensing data. The study covered 16 years from 1994-2009. Different remote sensing data (SM2R-CCI, SAF EUMETSAT CFC, GLEAM, GRACE) are used to force and verify the modeling results.

5 The results can be summarized as follows:

- The basin scale annual precipitation over the basin is 1360 ± 230 mm, and highly variable spatially. The southern and southwestern parts of the basin receive the highest precipitation, which tend to decrease towards the eastern parts of the basin (figure 3).

Figure 9. Water budget components of the basin and its annual variabilities from 1994 to 2009. The relative share of each of the three components (Q, ET and ds/dt) of the total available water J is represented by the length of the bars (N.B. the total length of the bar minus the negative storage is J). The positive and negative storage of the years are shown by dark blue and light blue respectively).

- Generally, the interannual variability of ET is high, and tends to be higher in autumn and lower in summer. The average basin scale ET is about 740 ± 87 mm, and is the larger flux in water budget in the basin.
- The comparison of simulated ET with the satellite product GLEAM shows that GLEAM has low temporal variability. The correlation between GLEAM ET and NewAge ET increases from daily time steps to monthly time steps, and spatially it is higher in the east and central parts of the basin. Comparison with MODIS products was also performed (reported in supplementary material). MODIS actually shows even more large departure from JGrass-NewAge results. Both satellite products, however, seem to introduce a systematic bias which would not allow to close the budget.
- The NewAge ADIGE rainfall-runoff component is able to reproduce discharge very well at the outlet ($KGE = 0.92$). The long term annual runoff of the UBN basin is about 454 ± 160 mm. The verification results at the internal sites where measurements are available reveal that the model can be used for forecasting at ungauged locations with some success.
- The performances obtained are promising (figures 5 and 6, and table 4) and often greatly improve previous results.

Figure 10. Monthly mean Water budget components at basin scale and long term, based on estimates from 1994 to 2009. The relative shares of the three components (Q, ET and dS/dt) of the total available water J are shown .

The NewAge storage estimations and their space-time variability are effectively verified by the basin scale GRACE TWSC data which show high correlation and similar amplitude.

Despite the good results obtained, it is important to note that this study is limited by the lack of in-situ ET observation and low resolution GRACE data for confirmation of storage. To these regards, the results of this study would benefit from basin specific assessments of ET and ds/dt RS products based on ground measurements, as done in Abera et al. (2016) for precipitation.

Reproducibility

The forcing data used for NewAge simulation: SM2R-CCI is obtained from <http://hydrology.irpi.cnr.it/people/l.brocca>; the rain gauge precipitation and hydrometer discharge data were obtained from the National meteorological Agency and Ministry of Water and Energy of Ethiopia respectively, and it can be requested for research. The remote sensing data used for comparison: GLEAMS ET, MODIS ET and GRACE TWSC are freely available and can be downloaded at <http://www.gleam.eu>, <http://www.ntsg.umt.edu/project/mod16>, and <ftp://podaac-ftp.jpl.nasa.gov/allData/tellus/L3/landmass/RL05> respectively. Modelling components used for the simulations are available and documented through the Geoframe blog <http://geoframe.blogspot.com>. Additional data (i.e. GIS database, topographic information, input data and additional results) and other notes regarding the paper can be found at Zenodo DOI:10.5281/zenodo.264004

Acknowledgements. This research has been partially financed by the CLIMAWARE projects of University of Trento (<http://abouthydrology.blogspot.it/search/label/CLIMAWARE>) and by European Union FP7 Collaborative Project GLOBAQUA (Managing the effects of multiple stressors on aquatic ecosystems under water scarcity, grant no. 603629-ENV-2013.6.2.1). We would like to acknowledge the National meteorological Agency and Ministry of Water and Energy of Ethiopia for providing us the gauge rainfall and discharge data. We also thank the two anonymous reviewer for their work that helped to enhance the initial manuscript with their comments.

Appendix A: Model performance criteria

The model evaluation statistics used in the paper are the goodness-of-fit (GOF) indices. The following indexes are used as objective function and comparison of estimations.

1. PBIAS: is the measure of average tendency of estimated values to be large or smaller than their measured values. The value near to zero indicates high estimation, whereas the positive value indicates the overestimation and negative values indicate model underestimation (Moriassi et al., 2007; Gupta et al., 1999).

$$PBIAS = \frac{\sum_{i=1}^n (P_i - O_i)}{\sum_{i=1}^n O_i} 100 \quad (A1)$$

The PBIAS value ranges from -20 to 20% is considered good, and values between $\pm 20\%$ and $\pm 40\%$ and those greater than $\pm 40\%$ are considered satisfactory and unsatisfactory respectively (Stehr et al., 2008).

2. Kling-Gupta efficiency (KGE) is developed by Gupta et al. (2009) to provide a diagnostically interesting decomposition of the Nash-Sutcliffe efficiency (and hence MSE), which facilitates the analysis of the relative importance of its different components (correlation, bias and variability) in the context of hydrological modelling. Kling et al. (2012) proposed a revised version of this index. It is given by

5
$$KGE = 1 - ED \tag{A2}$$

$$ED = \sqrt{(r - 1)^2 + (vr - 1)^2 + (\beta - 1)^2} \tag{A3}$$

where ED is the Euclidian distance from the ideal point, β is the ratio between the mean simulated and mean observed flows, r is Pearson product-moment correlation coefficient, and v is the ratio between the observed (σ_o) and modelled (σ_s) standard deviations of the time series and takes account of the relative variability (Zambrano-Bigiarini, 2013). The
10 KGE ranges from infinity to a perfect estimation of 1, but a performance above 0.75 and 0.5 is considered as good and intermediate respectively (Thiemig et al., 2013).

3. Pearson correlation coefficient (r): please refer Moriasi et al. (2007). The correlation coefficient is best as much as it is close to 1.
