Abstract. The transition zone between land and water is difficult to map with conventional geophysical systems due to shallow water depth and often challenging environmental conditions. The emerging technology of airborne topobathymetric Light Detection and Ranging (LiDAR) is capable of providing both topographic and bathymetric elevation information, using only a single green laser, resulting in a seamless coverage of the land-water transition zone. However, there is no transparent and reproducible method for processing green topobathymetric LiDAR data into a Digital Elevation Model (DEM). The general processing steps involve data filtering, water surface detection and refraction correction. Specifically, the procedure of water surface detection and modelling, solely using green laser LiDAR data, has not previously been described in detail for tidal environments. The aim of this study was to fill this gap of knowledge by developing a step-by-step procedure for making a Digital Water Surface Model (DWSM) using the green laser LiDAR data. The detailed description of the processing procedure augments its reliability, makes it user friendly and repeatable. A DEM was obtained from the processed topobathymetric LiDAR data collected in spring 2014 from the Knudedyb tidal inlet system in the Danish Wadden Sea. The vertical accuracy of the LiDAR data is determined to ± 8 cm at a 95% confidence level, and the horizontal accuracy is determined as the mean error to ± 10 cm. The LiDAR technique is found capable of detecting features with a size of less than 1 m^2 . The derived high resolution DEM was applied for detection and classification of geomorphometric and morphological features within the natural environment of the study area. Initially, the Bathymetric Positioning Index (BPI) and the slope of the DEM were used to make a continuous classification of the geomorphometry. Subsequently, stage (or elevation in relation to tidal range) and a combination of statistical neighbourhood analyses (moving average and standard deviation) with varying window sizes, combined with the DEM slope were used to classify the study area into six specific types of morphological features (i.e. subtidal channel, intertidal

1 flat, intertidal creek, linear bar, swash bar and beach dune). The developed classification method is
2 adapted and applied to a specific case, but it can also be implemented in other cases and environments.

3 **1 Introduction**

4 The coastal zone is under pressure from human exploitation in many and various ways. Many large cities
5 are located near the coast, and they grow gradually with the increase in worldwide population and
6 urbanization. Many industrial activities take place in close vicinity to the coast, e.g. fishery, construction,
7 maintenance dredging for safety of navigation, and mining for raw materials. The coastal zone also
8 provides the setting for many recreational and touristic activities, such as sailing, swimming, hiking,
9 diving and surfing. In addition to human exploitation, climate change also poses a future threat with a
10 predicted rising sea level and increasing storm intensity and frequency, expected to cause erosion and
11 flooding in the coastal zone (Mousavi et al., 2011). All these pressures and different interests underpin the
12 societal need for high resolution mapping, monitoring, and sustainable management in the coastal zone.

13 Historically, the transition zones between land and water have been difficult or even impossible to map
14 and investigate in high spatial resolution due to the difficulties in collecting data in these challenging,
15 high-energy environments. The airborne near-infrared (NIR) Light Detection and Ranging (LiDAR) is a
16 technique often used for measuring high-resolution topography, however, NIR laser is incapable of
17 measuring bathymetry due to the absorption and reflection of the laser light at the water surface.
18 Traditionally, high-resolution bathymetry is measured with a multibeam echosounder (MBES) system
19 mounted on a vessel, but it does not cover the bathymetry in the shallow water due to the vessel draft
20 limitation.

21 NIR LiDAR and MBES are applied in different environments; however, the data are very similar and the
22 processed high-resolution topography/bathymetry is often captured, visualised and analysed in a Digital
23 Elevation Model (DEM). The processed DEM may be applied for various purposes, e.g. for
24 geomorphological mapping. Previous studies classifying morphology in either terrestrial or marine
25 environments have been performed numerous times (Al-Hamdani et al., 2008; Cavalli and Marchi, 2008;
26 Hogg et al., 2016; Höfle and Rutzinger, 2011; Ismail et al., 2015; Kaskela et al., 2012; Lecours et al.,
27 2016; Sacchetti et al., 2011). These classification studies generally focus on either the marine or the
28 terrestrial environment and do not cover the fine-scale morphology in the shallow water, due to the
29 challenging environmental conditions. To overcome this impediment a new generation of airborne green
30 topobathymetric LiDAR that enables high resolution measurements of both topography and shallow
31 bathymetry has been introduced (Guenther, 1985; Jensen, 2009; Pe'eri and Long, 2011). The potential of
32 merging morphological classifications of marine and terrestrial environments enables a holistic approach
33 for managing the coastal zone.

34 The raw topobathymetric LiDAR measurements are spatially visualized as points in a point cloud, with
35 each point containing information of its location and elevation. The point cloud must be piped through a
36 series of steps before it can be visualised as a DEM. Most of the processing steps required to process raw

1 topobathymetric LiDAR data into a DEM are similar to the processing steps of topographic LiDAR data
2 (Huising and Gomes Pereira, 1998). However, additional processing steps are required for
3 topobathymetric LiDAR data due to the refraction of the laser beam at the water surface. All submerged
4 LiDAR points have to be corrected for refraction; therefore, the water depth must be known for each
5 point. This sets a requirement for making a Digital Water Surface Model (DWSM), before the refraction
6 correction can be performed.

7 Often the water surface is detected and modelled from simultaneous collection of green and NIR LiDAR
8 measurements, where the green laser reflects from the seabed and the NIR laser reflects from the air-
9 water interface, and the NIR laser data are then used to detect and model the water surface (Allouis et al.,
10 2010; Collin et al., 2008; Guenther, 2007; Parker and Sinclair, 2012). The use of NIR LiDAR data for
11 water surface detection has been applied in several studies. For instance, Hofle et al. (2009) proposed a
12 method for mapping water surfaces based on the geometrical and intensity information from NIR LiDAR
13 data. Su and Gibeau (2009) classified water points from NIR LiDAR based on point density, intensity
14 and elevation. They identified the shoreline based on the large sudden decrease in NIR LiDAR intensity
15 values when going from land to water. Brzank et al. (2008) used the same three variables (point density,
16 intensity and elevation) in a supervised fuzzy classification to detect the water surface in a section of the
17 Wadden Sea. Another study in the Wadden Sea by Schmidt et al. (2012) used a range of geometric
18 characteristics as well as intensity values to classify water points from NIR LiDAR data.

19 The capability of NIR LiDAR data for detecting the water surface is thus well documented. However,
20 deriving all the information from a single green LiDAR dataset would be a more effective solution for
21 water surface and seabed detection, with respect to the financial expenses and for the difficulties of
22 storing and handling often very large amounts of data. However, there is no definitive method for making
23 a DWSM from green topobathymetric LiDAR data. For this purpose, the Austrian LiDAR company
24 RIEGL have developed a software, *RiHYDRO* (RIEGL, 2015), in which it is possible to model the water
25 surface in a two-step approach: 1) Classification of water surface points based on areas with two layers
26 (water surface and seabed) and extending the classification to the entire water body, and 2) Generation of
27 a geometric gridded DWSM for each flight swath based on the classified water surface points. However,
28 *RiHYDRO* is commercial software, and thus the algorithms, which form the basis of the classification
29 and water surface modelling, are not publicly available. Other software packages, such as *HydroFusion*
30 (Optech, 2013) and *LiDAR Survey Studio* (Leica, 2015), also proclaim to have incorporated methods for
31 the entire data processing workflow, but the algorithms in these software packages are also closed and
32 cannot be accessed by public users.

33 Only few research studies have investigated the potential of water surface detection and modelling from
34 green LiDAR data. In a relatively recent publication Guenther et al. (2000) even regarded water surface
35 detection from green LiDAR data as unacceptable and they justified it with two fundamental issues: 1)
36 No water surface returns are detected in the dead zone, and 2) Uncertainty of the water surface elevation,
37 because the green water surface returns are actually a mix of returns from the air/water interface and from
38 volume backscatter returns, and they are generally found as a cloud of points below the water surface.

1 Mandlbürger et al. (2013) addressed the second issue by comparing the water surface points of NIR and
2 green LiDAR data, and they concluded that it is possible to derive the water surface elevation from the
3 green LiDAR data with sub-decimetres vertical precision relative to a reference water surface derived by
4 the NIR LiDAR data. However, their work addressed only the determination of the water surface
5 elevation, without going into detail on the actual procedure of generating a DWSM. An approach for
6 modelling the water surface from green LiDAR data was presented by Mandlbürger et al. (2015), who did
7 their study in a riverine environment with only few return signals from the water surface. Their method
8 was based on manual estimates of the water level in a series of river cross sections, after which
9 interpolation between the cross sections filled out the gaps with no water surface points to derive a
10 continuous water surface model.

11 The aim of this study was to investigate the potential of improving the procedure of processing green
12 LiDAR data and generating DEMs in tidal environments, and of improving the classification of
13 morphological units in such environments. More specifically, the objectives were:

- 14 1. To develop a robust, repeatable and user friendly processing procedure of raw green LiDAR data
15 for generating high resolution DEMs in land-water transition zones.
- 16 2. To quantify the accuracy and precision of the green LiDAR data based on object detection.
- 17 3. To automatically classify morphological units based on geomorphometric analyses of the
18 generated DEM.

19 The investigations were based on studies undertaken in a section of the Knudedyb tidal inlet system in the
20 Danish Wadden Sea.

21 **2 Study area**

22 The Knudedyb tidal inlet system is located between the barrier islands of Fanø and Mandø in the Danish
23 Wadden Sea (Fig. 1a). The tidal inlet system is a natural environment without larger influence from
24 human activity. The tides in the area are semi-diurnal, with a mean tidal range of 1.6 m, and the tidal
25 prism is in the order of $175 \cdot 10^6 \text{ m}^3$ (Pedersen and Bartholdy, 2006). The main channel is approximately
26 1 km wide and with an average water depth of approx. 15 m (Lefebvre et al., 2013).

27 The study site is an elongated 3.2 km^2 ($0.85 \times 4 \text{ km}$) section of the Knudedyb tidal inlet system (Fig. 1b).
28 The section is located perpendicular to the main channel and stretches across both topography and
29 bathymetry. The study site extends towards north into an area on Fanø with dispersed cottages (Fig. 1c).
30 The most prominent morphological features within the study site include beach dunes (Fig. 1d), small
31 mounds (Fig. 1e), swash bars (Fig. 1f-g) and linear bars (Fig. 1h).

1 **3 Methods**

2 **3.1 Topobathymetric LiDAR**

3 The topobathymetric LiDAR technique is based on continuous measurements of the distance between an
4 airplane and the ground/seabed. The distance (or range) is calculated by half the travel time of a laser
5 beam, going from the airplane to the surface of the earth and back to the airplane. The wavelength of the
6 laser beam is in the green spectrum, usually 532 nm, since this wavelength is found to attenuate the least
7 in the water column, resulting in the largest penetration depth of the laser (Jensen, 2009). In literature,
8 topobathymetric LiDAR data is sometimes referred to as either bathymetric LiDAR or Airborne LiDAR
9 bathymetry. These are different terms with the same meaning, and in this paper, topobathymetric LiDAR
10 is preferred, since it describes the system's ability to simultaneously measure bathymetry as well as
11 topography.

12 A single laser beam may encounter many targets of varying nature on its way from the airplane and back
13 again, and different processes are influencing the laser beam propagation through air and water. First, the
14 laser beam may be reflected by targets in the air, such as birds or dust particles, and these can show up as
15 LiDAR points in the space between the airplane and the surface. When encountering water, the speed of
16 the laser decreases from $3 \times 10^8 \text{ ms}^{-1}$ to e.g. $2.25 \times 10^8 \text{ ms}^{-1}$ in 10°C freshwater or e.g. $2.24 \times 10^8 \text{ ms}^{-1}$ in
17 10°C saltwater of 30 PSU (Millard and Seaver, 1990).

18 The changing speed of the laser beam also affects the direction of the laser beam when penetrating the
19 water surface with an angle different from nadir (Fig. 2) (Guenther, 2007; Jensen, 2009). The laser beam
20 will be refracted according to Snell's Law:

$$21 \quad \frac{\sin\alpha_{\text{air}}}{\sin\alpha_{\text{water}}} = \frac{c_{\text{air}}}{c_{\text{water}}} = \frac{n_{\text{water}}}{n_{\text{air}}} \quad (1)$$

22 where α_{air} is the incidence angle of the laser beam relative to the normal vector of the water surface and
23 α_{water} is the refraction angle in water. n_{water} and n_{air} are the refractive indices of water and air,
24 respectively (Mandlbürger et al., 2013).

25 The penetration depth in water is limited by the attenuation of the laser beam. Water molecules,
26 suspended sediment and dissolved material all act on the laser beam by absorption and scattering,
27 resulting in substantial reduction in power as the signal propagates into the water (Guenther, 2007;
28 Mandlbürger et al., 2013; Steinbacher et al., 2012). The laser beam also diverges in the water column,
29 resulting in a wider laser beam footprint (Guenther et al., 2000), and this effect reduces the resolving
30 capability of fine-scale morphology the deeper the laser beam penetrates.

31 The returned signal is represented as a distribution of energy over time, also called the 'full-waveform'
32 (Alexander, 2010; Chauve et al., 2007; Mallet and Bretar, 2009). The peaks in the full-waveform are
33 detected as individual targets encountered by the propagating laser beam. If the laser hits two targets with
34 a small vertical difference, such as a water surface and seabed in very shallow water, then the two peaks
35 in the full-waveform may merge together, resulting in the detection of only one target (Fig. 2). This

1 results in a detection minimum of successive returns from a single laser pulse, referred to as the ‘dead
2 zone’ (Mandlbürger et al., 2011; Nayegandhi et al., 2009). The dead zone is a clear limitation to the
3 LiDAR measurements, which is an important parameter to consider in very shallow water, such as
4 intertidal environments.

5 **3.2 Surveys and instruments**

6 LiDAR data and orthophotos were collected by Airborne Hydro Mapping GmbH (AHM) during two
7 surveys on 19 April 2014 and 30 May 2014.

8 On 19 April 2014, the quality of the LiDAR data was validated at two sites along Ribe Vesterå River
9 (Fig. 1i-j):

- 10 • Validation site 1 with a $2.50 \times 1.25 \times 0.80$ m cement block located on land next to the mouth of
11 Ribe Vesterå River (Fig. 1i). The block was covered by 7 swaths retaining 227 LiDAR points
12 from the block surface, which were used for assessing the accuracy and precision of the LiDAR
13 data.
- 14 • Validation site 2 with a $0.92 \times 0.92 \times 0.30$ m steel frame located in the Ribe Vesterå River, its
15 top situated just below the water surface (Fig. 1j). The frame was covered by 4 swaths retaining
16 46 LiDAR points from the surface of the frame, which were used for precision assessment, and
17 for testing the feature detection capability of the LiDAR system. According to the International
18 Hydrographic Organization survey standards, cubic features of at least 1 m^2 should be detectable
19 in Special Order areas, which are areas with very shallow water as in the study site (IHO, 2008).

20 Ground control points (GCPs) were measured for the four corners of the block with accuracy better than 2
21 cm using a Trimble R8 RTK GPS. Measurements were repeated three times and averaged to minimize
22 errors caused by measurement uncertainties. GCPs were also collected for the frame; however, during the
23 LiDAR survey the frame experienced an unforeseen intervention by local fishermen using the frame as
24 fishing platform. Therefore, the frame was only used to assess the deviation between the LiDAR points
25 (the precision), and not to assess the deviation between the LiDAR points and the GCP’s (the accuracy).

26 On 30 May 2014, the study site was covered by 11 swaths, which were used for generating the DWSM
27 and DEM. The overflight was carried out during low tide, and the water level was measured to -1 m
28 DVR90 at Grådyb Barre, approx. 20 km NW of the study site.

29 The weather conditions were similar during the two surveys, with sunny conditions, average wind
30 velocities of 7-8 m/s (DMI, 2014) and significant wave heights, measured west of Fanø at 15 m water, of
31 approx. 0.5 m coming from NW (DCA, 2014). However, the waves in the less exposed Knudedyb tidal
32 inlet were observed in the 30 May LiDAR point cloud to be 0.2-0.3 m, which can be explained by the
33 location of the study site in lee of the western most intertidal flats and the ebb-tidal delta. The wave
34 heights in the rest of the study site (flood channel and intertidal ponds) were in the scale of sub
35 decimetres. There were no waves at validation site 2 during the 19 April LiDAR survey.

1 LiDAR data were collected with a RIEGL VQ-820-G topobathymetric airborne laser scanner in both
2 surveys (RIEGL, 2014). The scanner was characterized by emitting green laser pulses with 532 nm
3 wavelength and 1 ns pulse width. It had a very high laser pulse repetition rate of up to 520,000 Hz. The
4 flying altitude was 400 m, which combined with a beam divergence of 1 mrad created a laser beam
5 footprint of 40 cm diameter at the ground. The high repetition rate and narrow footprint made it well
6 suited to capture fine-scale landforms (Doneus et al., 2013; Mandlbürger et al., 2011). An arc shaped scan
7 pattern results in a swath width of approx. 400 m, while maintaining an almost constant $20^\circ (\pm 1^\circ)$
8 incidence angle of the laser beam when penetrating the water surface (Niemeyer and Soergel, 2013). The
9 typical water depth penetration of the laser scanner is claimed by the manufacturer to be 1 Secchi disc
10 depth (RIEGL, 2014).

11 For each returned signal, the collected LiDAR data contained information of x, y and z, as well as a GPS
12 time stamp and values of the amplitude, reflectance, return number, attribute and laser beam deviation
13 (RIEGL, 2012).

14 **3.3 Processing raw topobathymetric LiDAR data into a gridded DEM**

15 The essential processing steps, which are standard procedure when processing topobathymetric LiDAR
16 data, were followed to produce a DEM in the study area. These steps included:

- 17 1. Determination of flight trajectory.
- 18 2. Bore-sight calibration: Calculating internal scanner calibration.
- 19 3. Collecting topobathymetric LiDAR data.
- 20 4. Swath alignment based on bore-sight calibration: The bias between individual swaths was
21 minimized.
- 22 5. Filtering: The raw data contained noise located both above and below ground, which needed to
23 be filtered from the point cloud.
- 24 6. Water surface detection: A DWSM had to be established in order to correct for refraction in the
25 following step.
- 26 7. Refraction correction: All the points below the water surface in the DWSM were corrected for
27 the refraction of the laser beam.
- 28 8. Point cloud to DEM: The points were transformed into a gridded elevation model representing
29 the real world terrain in the study area, including cottages and vegetation on Fanø in the northern
30 part.

31 Step 1 and 2 were performed prior to the LiDAR survey. The different instruments (LiDAR, IMU and
32 GPS) were integrated spatially by measuring their position relative to each other, when mounted on the
33 airplane, and temporally by calibrating their time stamps.

34 Step 3 was the actual LiDAR survey and step 4 was the initial processing step after the LiDAR survey.
35 The bias between the swaths was minimized in the software RiPROCESS (RIEGL LMS) by
36 automatically searching for planes in each swath and then matching the planes between the swaths.

1 Steps 5-8 represent the processing of the point cloud into a DEM. The methods involved in these steps are
2 the main focus in this study and they are described in detail in the following sub-sections. Each swath was
3 pulled individually through the processing workflow to account for the continually changing water level
4 in the study area due to tides. The broad term “DEM” is used, rather than the more specific terms “Digital
5 Terrain Model (DTM)” or “Digital Surface Model (DSM)”, because the generated model includes both
6 natural terrain in the tidal environment, which is the main focus area in this study, as well as vegetation
7 and cottages on Fanø.

8 **3.3.1 Filtering**

9 The raw LiDAR data contained noise in the air column originating from the laser being scattered by birds,
10 clouds, dust and other particles, and noise was also appearing below the ground/seabed (Fig. 3a-b). This
11 noise had to be filtered before further processing. The filtering process involved both automatic and
12 manual filtering.

13 The automatic filtering was carried out in HydroVish (AHM) with the tool *Remove flaw echoes* (Fig. 3c).
14 The filtering tool was controlled by three variable parameters: search radius, distance and density. The
15 search radius parameter specified the radius of a sphere in which the distance and density filters were
16 utilized. The distance parameter rejected a point, if it was too far from any other point within the sphere.
17 The density parameter specified the lower limit of points within the sphere. The automatic filter iterated
18 through all the points in the point cloud. The settings for the automatic filtering were based on a
19 sensitivity analysis of three fragments of the LiDAR data, and the settings were selected so that a
20 minimum of valid points were removed by the automatic filter. The settings were: Search radius = 1 m,
21 distance = 0.75 m and density = 4.

22 The automatic filter could not to remove two layers of noise points closely above and below ground, but
23 on the other hand, more widely dispersed points in the deeper bathymetry were removed. To account for
24 this, the point cloud went through manual filtering in Fledermaus (QPS) software, where the remaining
25 noise points were rejected and the valid bathymetric points were accepted (Fig. 3d).

26 The filtered point cloud (with water points) was used in the following step to detect the water surface.
27 Meanwhile, a copy of the data was undergoing additional manual filtering, removing all the water points
28 (Fig. 3e). After this final filtering step, there were only points representing topography, bathymetry,
29 vegetation and man-made structures left in the dataset.

30 **3.3.2 Water surface detection**

31 The water surface detection was based on determining the water surface *elevation* and the water surface
32 *extent*, thereby producing a DWSM. The water surface elevation was determined based on the water
33 surface points, and the extent was determined by extrapolating the water surface until it intersected the
34 surface of the topography. Two assumptions were made in the production of the DWSM:

- 1 1. The water surface was horizontal. This was a simplification of the real world. Tidal processes
2 and wind- and wave-setup may cause the water surface to be sloping, and the water is often
3 topped by more or less significant waves. A linear fit through the water surface LiDAR points
4 along the main channel, showed a changing water level of 0.13 m over a distance of 400 m,
5 corresponding to a 0.325×10^{-3} (0.019 deg.) sloping water surface. A similar fit through the
6 LiDAR points along the flood channel showed a slope of 0.156×10^{-3} (0.009 deg.). The
7 maximum wave heights observed in the main channel were 20-30 cm. Based on the moderate
8 slope of the water surface and relatively low wave height, the water surface was assumed flat.
9 This assumption is deemed error prone, but at the time of this study, it was our best estimate.
- 10 2. The study area contained water bodies with two different water levels: One represented the water
11 level in the main channel and the other represented the water level in the flood channel. This was
12 also a simplification, as the tidal flat contained small ponds with potentially different water
13 levels. However, almost all of these ponds contained no LiDAR points of the water surface,
14 which means that the water depth in the ponds must have been within the limitation of the dead
15 zone. Therefore, it was impossible to detect individual water surfaces in the ponds.

16 A series of processing steps were performed to produce the DWSM. The first step was to extract a
17 *shallow surface* and a *deep surface* from the filtered point cloud (with water points) in Fledermaus (Fig.
18 3f). Both surfaces consisted of 0.5×0.5 m cells, and the elevation of each cell was equal to the highest
19 point within the cell (shallow surface) and the lowest point within the cell (deep surface), respectively.
20 The shallow surface should then display the topography along with the water surface, whereas the deep
21 surface should display the topography and the seabed (as long as the seabed was detected by the laser). It
22 is worth noting, that the extraction of the shallow surface and the deep surface had nothing to do with the
23 final DEM, as they were merely intermediate steps performed for the water surface detection.

24 The following steps were focused on the shallow surface to determine the elevation of the water surface
25 (Fig. 3g). First, the shallow surface was down-sampled to a surface with a cell size of 2×2 m, and the
26 new cells were populated with the maximum elevation of the input cells. The down-sampling was done
27 for smoothing the water surface, and thereby eliminating most of the outliers. The exact cell size of
28 2×2 m, as well as populating them with the maximum value, was chosen based on the work by
29 Mandlbürger et al. (2013). They compared water surface detection capability between green LiDAR data,
30 collected with the same RIEGL-VQ-820-G laser scanner, and NIR LiDAR data, which was assumed to
31 capture the true water surface. They found that the green LiDAR generally underestimated the water
32 surface elevation, but that reliable results were achieved by increasing the cell size and only taking the top
33 1-5% of water points into account. According to their work, it was assumed that placing the water surface
34 on the highest points in 2 m cells provided a good estimate of the true water level. However, based on
35 their results it could be expected that the water surface elevation in this case would be underestimated in
36 the order of 2-4 cm.

37 The water-covered areas in the main channel and the flood channel were manually extracted from the
38 newly down-sampled shallow surface. The average elevation of the 2 m cells within each area was

1 calculated, and these values constituted the elevation of the water surfaces in the main channel and in the
2 flood channel, respectively. Two horizontal water surfaces were created in the flood channel and the main
3 channel with a cell size of 0.5×0.5 m and cell values equal to the calculated water surface elevations.
4 The high spatial resolution of 0.5 m cells was chosen to produce a detailed DWSM along the edges of the
5 land-water transition.

6 Finally, the extent of the water surfaces was determined by subtracting the deep surface cell elevations
7 from the water surface elevation and discarding all cells with resulting negative values (Fig. 3h), together
8 forming the DWSM.

9 **3.3.3 Refraction correction**

10 The refraction correction of all the points below the DWSM was calculated in HydroVish (AHM). The
11 input parameters were the filtered point cloud (without water points), the derived DWSM and the
12 trajectory data of the airplane. The refraction correction was calculated automatically for each point based
13 on the water depth, the incident angle of the laser beam, and the refracted angle according to Snell's Law
14 (Eq. 1 and Fig. 3i).

15 **3.3.4 Point cloud to DEM**

16 After iterating through the processes of filtering, water surface detection and refraction correction for all
17 the individual swaths, the LiDAR points of all swaths were combined. The transformation from point
18 cloud into a DEM was performed with ArcGIS (ESRI) software. The DEM was created as a raster surface
19 with a cell size of 0.5×0.5 m, and each cell was attributed the average elevation of the points within the
20 cell-boundaries. It was chosen to make the resolution of the DEM lower than the laser beam footprint size
21 (i.e. 40 cm), due to the inaccuracies arising from attributing smaller cells with measured elevation values
22 spanning across a larger area. Furthermore, the 0.5 m cell size was chosen to get as high resolution as
23 possible without making any significant interpolation between the measurements. In this way, each cell
24 represented actually measured elevations instead of interpolated values. However, there were still very
25 few gaps of individual cells with no data in the resulting raster surface in areas with relatively low point
26 density. Despite of the general intention of avoiding interpolation it was chosen to populate these cells
27 with interpolated values to obtain a full coverage DEM (except for the bathymetric parts beyond the
28 maximum laser penetration depth). The arguments for interpolation were that: 1) the interpolated cells
29 were scattered and represented only 1.7 % of all the cells, 2) they were found primarily on the tidal flat
30 where the slope is generally less than 1° , meaning that the elevation difference from one cell to a
31 neighbouring cell is usually less than 1 cm, and 3) the general point density in most of the study area was
32 so high that the loss of information by lowering the DEM resolution would represent a larger sacrifice
33 than interpolating a few scattered cells. The interpolation was performed by assigning the average value
34 of all neighbouring cells to the empty cells. The final DEM was thereby fully covering the topography,
35 and the bathymetry was covered down to a depth equal to the maximum laser penetration depth.

3.4 Accuracy and precision of the topobathymetric LiDAR data

The term *accuracy* refers to the difference between a point coordinate (in this case a LiDAR point) compared to its “true” coordinate measured with higher accuracy, e.g. by a total station or a differential GPS; while the term *precision* refers to the difference between successive point coordinates compared to their mean value, i.e. the repeatability of the measurements (Graham, 2012; Jensen, 2009; RIEGL, 2014).

Two “best-fit planes” based on the LiDAR points on the block and the frame surfaces were established with the *Curve Fitting tool* in MATLAB (MathWorks). We propose the use of these two planes to give an indication of the relative precision of the LiDAR measurements.

Another best-fit plane was established based on the block GPS measurements, and this plane was regarded as the “true” block surface for assessment of the accuracy of the LiDAR measurements. The established planes were described by the polynomial equation:

$$z(x, y) = a + bx + cy \quad (2)$$

where x , y and z are coordinates and a , b and c are constants. Inserting x and y coordinates for the LiDAR surface points in Eq. (3) led to a result of the corresponding elevation (z) as projected on the fitted plane. The difference between the elevation of the LiDAR point and the corresponding elevation on the fitted plane was used as a measure of the vertical accuracy (for the GCP fitted plane of the block) and the vertical precision (for the LiDAR point fitted plane of the block and the frame). Statistical measures of the standard deviation (σ), mean absolute error (E_{MA}), and root mean square error (E_{RMS}) were calculated by:

$$\sigma = \sqrt{\frac{\sum(z_i - z_{\text{plane}})^2}{n-1}} \quad (3)$$

$$E_{MA} = \frac{\sum|z_i - z_{\text{plane}}|}{n} \quad (4)$$

$$E_{RMS} = \sqrt{\frac{\sum(z_i - z_{\text{plane}})^2}{n}} \quad (5)$$

where z_i is the elevation of the measured LiDAR points, z_{plane} is the corresponding elevation on the best-fit plane, and n is the number of LiDAR points. The vertical accuracy and precision were determined at a 95% confidence level based on the accuracy standard presented in *Geospatial Position Accuracy Standards Part 3: National Standard for Spatial Data Accuracy* (NSSDA) (FGDC, 1998):

$$C/_{95\%} = E_{RMS} \cdot 1.96 \quad (6)$$

The horizontal accuracy was determined as the horizontal mean absolute error ($E_{MA,xy}$) based on the horizontal distances between the block corners, measured with RTK GPS, and the best approximation of the block corners derived from the LiDAR points of the block surface. The minimum distance between a block corner and the perimeter of the LiDAR points was regarded as the best approximation. Hereafter $E_{MA,xy}$ was calculated as the average of the four corners.

3.5 Geomorphometric and morphological classifications

The processed DEM was applied in two classification analyses; first a *geomorphometric* classification and then a *morphological* classification. Both were based on the DEM and derivatives of the DEM, but they differentiated by the resulting classification classes, which showed 1) Surface geometry and 2) Surface morphology. The analysis mode, as defined by Pike et al. (2009), was “general” in the geomorphometric classification where the surface geometry was continuously classified within the study site, while being “specific” in the morphological classification where discrete morphological units were classified. The northern part of the study site with cottages on Fanø was excluded in the classification analyses, as the objective of this work was to classify the natural terrain (geomorphometry and morphology) in the high-energy and dynamic tidal environment.

3.5.1 Geomorphometric classification analysis

The tool Benthic Terrain Modeler (BTM) (Wright et al., 2005) was used for the geomorphometric classification. The tool is an extension to ArcGIS Spatial Analyst, originally used for analysing MBES data (Diesing et al., 2009; Lundblad et al., 2006; Rinehart et al., 2004). The BTM classification tool uses fine- and broad-scale Bathymetric Positioning Indexes (BPIs) (Verfaillie et al., 2007) in a multiple-scale terrain analysis to classify fine- and broad-scale geometrical features. The BPIs are measures of the elevation of a cell compared to the elevation of the surrounding cells within the determined scale (radius) size. Positive BPI values indicate a higher elevation than the neighbouring cells and negative BPI values indicate a lower elevation than the neighbouring cells. For instance, a BPI value of 100 corresponds to 1 standard deviation and a value of -100 corresponds to -1 standard deviation of the cell elevation compared to the elevation of the surrounding cells within the determined scale size. BPI values close to zero are derived from flat areas or from constant slopes.

The elevation values of each cell in the DEM were exaggerated by a factor of 10 before the classification, to enable the BTM to detect the shapes of the terrain. The fine- and broad-scales were determined based on the BPI results for different radius sizes. The best results were obtained from a broad-scale BPI of 100 m radius and a fine-scale BPI of 10 m radius, based on visual inspection. The fine- and broad-scale BPIs were used, together with the slope of the actual DEM (not the exaggerated) to classify the investigated area into the geomorphometric classes: Fine-scale crests, broad-scale crests, depressions, slopes and flats (Fig. 4). The classification classes were decided based on previous studies using the BTM classification tool with success (Diesing et al., 2009; Lundblad et al., 2006). The thresholds for the fine- and broad-scale BPIs were in previous studies often defined as 1 standard deviation (Lundblad et al., 2006; Verfaillie et al., 2007), however, thresholds of 0.5 standard deviations have also previously been applied (Kaskela et al., 2012). We used a low threshold of 0.5 standard deviations due to the generally very gentle variations in the terrain geometry of the tidal inlet system. We defined the threshold between slopes and flats as 2°. This definition was a compromise between detecting as many slopes as possible but avoiding too many “false slopes” being detected along the swath edges, which seemed to be a consequence of lower precision at the outer beams of the swath, as well as differences between overlapping swaths.

3.5.2 Morphological classification analysis

A morphological classification was developed for delineating actual morphological features in the study area. The classification was built partly on different neighbourhood analyses and slopes derived from the DEM, and partly on the local tidal range. Broad-scale crests from the geomorphometric classification were also incorporated in the analysis. Figure 5 describes the steps performed in ArcGIS, which led to the classification of 6 morphological classes: Swash bars, linear bars, beach dunes, intertidal flats, intertidal creeks and subtidal channels. All the criteria for defining a particular morphological class had to be fulfilled for a cell to be classified into that class. Cells that did not meet the criteria to be classified into any of the morphological classes were assigned the class “unclassified”.

33 years of continuous measurements of the water level at Havneby on Rømø, 25 km south of the study area, showed a mean low water level of -0.94 m (DVR90) and a mean high water of 0.94 m (DVR90) (Klagenberg et al., 2008). Although the tidal range in Knudedyb was probably slightly different, it was the best estimate for the study site. Therefore, these water levels were used to separate between the supratidal, intertidal and subtidal zones.

Subtidal channels were defined as everything below the mean low water, which was -0.94 m. A “smooth DEM” was created, in which each cell of the original DEM was assigned the average elevation value of its surrounding cells in a window size of 100×100 m (actually 199×199 cells, i.e. 99.5×99.5 m). The result was subtracted from the original DEM, creating an Elevation Change Model (ECM), which made it possible to extract information about the deviation of the cells in the DEM compared to its surrounding cells. The principle is similar to the BPI, and again the purpose was to locate cells, with a higher/lower elevation than its surrounding cells. Positive values were higher cells and negative values were lower cells. Certain thresholds were found suitable for classifying beach dunes (> 0.8 m) and intertidal creeks (< -0.3 m). These two classes were furthermore classified into their respective tidal zones (supratidal and intertidal) based on the elevation. Intertidal flats were classified by low slope values ($< 1^\circ$) of a down-sampled 2 m DEM (each down-sampled cell was assigned the mean value of its 4×4 original cells). Moreover, to be classified as a flat, the ECM had to be within ± 10 cm to avoid any incorrect intertidal flat classification of flat crests on top of bars or flat bottoms inside creeks or channels. The BTM classification class “broad-scale crests” was used as an input, since it was found to capture bar features. However, the thresholds used in the BTM classification resulted in capturing features larger than bars in the broad-scale crests class. To distinguish between bars and larger features, the standard deviation of each DEM cell in a moving window size of 250×250 m (actually 249×249 cells, i.e. 124.5×124.5 m) was calculated. A suitable threshold to distinguish between bars and larger features was 0.6 standard deviations. Finally, swash bars and linear bars were identified by an area/perimeter-ratio, based on the assumption that linear bars have smaller ratio than swash bars, due to the different shapes. Based on visual interpretation, a ratio of 4 was found to be a suitable threshold.

1 **4 Results**

2 **4.1 Refraction correction and dead zone extent**

3 The vertical adjustment of the LiDAR points (z_{diff}) due to refraction correction is linearly correlated with
4 the water depth (d) (Fig. 6). An empirical formula is derived for this relationship:

$$5 z_{\text{diff}} = 0.227 \cdot d, R^2 = 0.997 \quad (7)$$

6 A LiDAR point at 1 m water depth is vertically adjusted by approximately 0.23 m (Fig. 6). The variations
7 around the linear trend in Fig. 6 are due to changing incidence angles of the laser beam that varies with
8 the airplane attitude (roll, pitch and yaw).

9 The vertical extent of the dead zone is approx. 28 cm, determined by plotting the vertical difference
10 between the shallowest and the deepest LiDAR point within 0.5 m cells – i.e. between the shallow surface
11 and the deep surface (Fig. 7). The difference is manifested by an abrupt change at the dead zone, and the
12 highest rate of change is shown to be at a water depth of approx. 28 cm.

13 **4.2 Sub-decimetre accuracy and precision**

14 The vertical root mean square error of the LiDAR data is ± 4.1 cm, and the accuracy is ± 8.1 cm with a
15 95% confidence level (Table 1 and Fig. 8a). The vertical precision of the LiDAR data with a 95 %
16 confidence level is ± 3.8 cm for the points on the frame, and ± 7.6 cm for the points on the block (Table 1).

17 The horizontal accuracy calculated as the horizontal mean absolute error ($E_{\text{MA,xy}}$) is determined to ± 10.4
18 cm (Fig. 8b).

19 **4.3 Point density and resolution**

20 The average point density is 20 points per m^2 , which equals an average point spacing of 20 cm (Table 2).
21 The point density of the individual swaths varies between 7-13 points per m^2 , and the point density of the
22 combined swaths in the study area, varies between 0-216 points per m^2 , although above 50 points per m^2
23 are rare.

24 **4.4 DEM and landforms**

25 The elevations in the studied section of the Knudedyb tidal inlet system range from -4 m DVR90 in the
26 deepest parts of the flood channel and main channel to 21 m DVR90 on top of the beach dunes on Fanø
27 (Fig. 9). Beach dunes and cottages of the village Sønderho are clearly visible in the northern part of the
28 study site (Fig. 9a-b). The intertidal zones are generally flat, while the most varying morphology is found
29 in the area of the flood channel (Fig. 9c-d), and in the area close to the main channel (Fig. 9e-f). The flood
30 channel is approximately 200 m wide in the western part and it divides into two channels towards east.
31 The bathymetry of the channel bed is clearly captured by the LiDAR data in the eastern part, and also in
32 the western part down to -4 m DVR90, which approximately equals a water depth of 3 m at the time of
33 survey. An intertidal creek joins the flood channel from the north (Fig. 9d). From the flood channel

1 towards south, the tidal flat is vaguely upward sloping, until reaching two distinct swash bars, which are
2 rising 0.9 m above the surrounding tidal flat, reaching a maximum elevation of 1.5 m DVR90 (Fig. 9e-f).
3 Further south, the linear bars along the margin of the main channel are clearly captured in the DEM (Fig.
4 9e).

5 **4.5 Geomorphometric and morphological classifications**

6 The geomorphometric and morphological classifications show that most of the study area is located in the
7 intertidal zone, and is mostly flat. This is manifested by the dominating two classes; flats and intertidal
8 flats (Fig. 10a-b). The geomorphometric classification identifies slopes as stripes with NNW-SSE
9 directionality across the flats. These are following the direction of the survey lines, and thus, they are not
10 real morphological features but more an indication of lower precision of the LiDAR data, especially at the
11 outer beams of the swath. These swath artefacts are smoothed out in the morphological classification by
12 down-sampling the DEM to 2 m resolution, and therefore, the intertidal flats appear uniform and
13 seamless. The bar features close to the main channel are well defined in the geomorphometric
14 classification where they are classified as broad-scale crests and fine-scale crests surrounded by slopes. In
15 the morphological classification, these are identified based on neighbourhood analyses and separated by
16 the area/perimeter-ratio into two classes, swash bars and linear bars (Fig. 10c). Broad-scale crests are also
17 found on Fanø in the northern part of the area, and most of these are classified as beach dunes in the
18 morphological classification. The geomorphometric classification identifies more broad-scale crests along
19 the banks of the flood channel, however, these are not real bar features but they are identified as crests
20 due to the nearby flood channel and creeks resulting in a positive broad-scale BPI. In the morphological
21 classification it is possible to distinguish between these and the actual bar features, by looking at elevation
22 deviations at an even broader scale than the broad-scale BPI. The intertidal creek in the NWern part of the
23 area is a mix of depressions, slopes and fine-scale crests in the geomorphometric classification, whereas it
24 is relatively well defined and properly delineated in the morphological classification (Fig. 10d).

25 The geomorphometric classification identifies slopes along the banks of the main channel, flood channel
26 and the intertidal creek, as well as in front of the beach dunes and along the edges of the swash bars and
27 linear bars. The slopes seem particularly reliable at delineating the features in the intertidal zone, i.e.
28 swash bars, linear bars and creeks. Depressions are primarily identified in the deepest detected parts of
29 the main channel and in the flood channel, in the intertidal creek and in the beach dunes. Fine-scale crests
30 are found in the geomorphometric classification in locations which are high compared to its near
31 surroundings. They are primarily seen as parts of the linear bars close to the main channel, in the beach
32 dunes on Fanø and along the banks of the intertidal creeks.

33 A few small circular mounds of approx. 5 m diameter with patches of *Spartina Townsendii* (Common
34 Cord Grass) located on the intertidal flat are classified as fine-scale crests in the geomorphometric
35 classification (Fig. 11). It clearly shows the capability of capturing fine-scale features in the DEM and in
36 the derived classification.

1 **5 Discussion**

2 **5.1 Performance of the water surface detection method**

3 The water surface in topobathymetric LiDAR surveys is most often detected from NIR LiDAR data,
4 which is simultaneously collected along with the green LiDAR data (Collin et al., 2012; Guenther et al.,
5 2000; Parker and Sinclair, 2012; Wang and Philpot, 2007). However, detecting the water surface and
6 generating a DWSM based on the green LiDAR data alone provides a potential to perform
7 topobathymetric surveys with just one sensor, thus optimizing the survey costs as well as data handling
8 and storage.

9 The two critical issues risen by Guenther et al. (2000), as mentioned in the introduction, concerning the
10 water surface detection with green LiDAR were thoroughly investigated in this study. The first issue,
11 regarding the gap of detected water surface signals in the dead zone, is addressed by detecting the water
12 surface based on areas which are known to be covered by water, and thereafter extending the water
13 surface until it intersects the topography, so that also the dead zone is covered by the modelled water
14 surface. The second issue, regarding uncertainty in the water surface elevation determination, is addressed
15 using the results presented by Mandlbürger et al. (2013) who found a statistical relationship between the
16 cloud of water surface points in the green LiDAR data and the water surface elevation derived from NIR
17 LiDAR data. Mandlbürger et al. (2013), however, did not describe the actual method of modelling a
18 DWSM, which is done in this study. Mandlbürger et al. (2015), on the other hand, did propose a method
19 for modelling the water surface, however, it was done in a fluvial environment and the water level was
20 based on manual determinations of cross sectional water levels. The water surface detection method in
21 this study is thus new in combining the properties: 1) It is only using green LiDAR data, 2) it is based on
22 automatic water level determination, 3) it is applied in a tidal environment (can be applied in any coastal
23 environment) and 4) it is transparent and repeatable due to the detailed description of data processing
24 steps given in the text.

25 The developed water surface detection method is new but it must be pointed out that the assumption of a
26 flat DWSM leaves room for improvements for the future, especially if it is applied in a fluvial
27 environment. Assuming a flat water surface is indeed a simplification of the real world, since the water
28 surface in reality can be inclined, and it can be topped by waves.

29 **5.2 Implications of the dead zone**

30 The vertical extent of the dead zone is in this study determined to approx. 28 cm (Fig. 7), which means
31 that no return signal is detected from the water surface when the water depth is less than 28 cm. The
32 implication of the dead zone along the channel edges is minimised by extending the DWSM until it
33 intersects the topography, but the setting is different for the small ponds on the intertidal flats. They may
34 have different water levels than in the large channels, but no detected water surface points, since the water
35 depth in the ponds are generally less than the vertical extent of the dead zone, i.e. approx. 28 cm. The
36 presented method is not capable of detecting a water surface in these ponds, which means that the bottom

1 points of the ponds are not corrected for refraction. Omitting refraction correction of a 28 cm deep pond
2 will result in -6 cm elevation error according to the calculated refraction (Fig. 6).

3 **5.3 Evaluation of the topobathymetric LiDAR data quality**

4 The vertical accuracy of conventional topographic LiDAR data has previously been determined to ± 10 -15
5 cm (Hladik and Alber, 2012; Jensen, 2009; Klemas, 2013; Mallet and Bretar, 2009). Only few previous
6 studies have focused on the accuracy of shallow water topobathymetric LiDAR data (Mandlbürger et al.,
7 2015; Nayegandhi et al., 2009; Steinbacher et al., 2012). Nayegandhi et al. (2009) determined the vertical
8 E_{RMS} of LiDAR data in 0-2.5 m water depth to ± 10 -14 cm, which is above the ± 4.1 cm E_{RMS} found in this
9 study (Table 1). Steinbacher et al. (2012) compared topobathymetric LiDAR data from a RIEGL VQ-
10 820-G laser scanner with 70 ground-surveyed river cross sections, serving as reference, and found that the
11 system's error range was ± 5 -10 cm, which is comparable to the ± 8.1 cm accuracy found in this study.
12 Mandlbürger et al. (2015) compared ground-surveyed points from a river bed with the median of the four
13 nearest 3D-neighbors in the LiDAR point cloud, and they found a standard deviation of 4.0 cm, which is
14 almost equal to the ± 4.1 cm standard deviation found in this study (Table 1). In comparison with these
15 previous findings of LiDAR accuracy, the assessment of the vertical accuracy in this study indicates a
16 good quality of the LiDAR data.

17 Mapping the full coverage of tidal environments, such as the Wadden Sea, requires a combination of
18 topobathymetric LiDAR to capture topography and shallow bathymetry and MBES to capture the deeper
19 bathymetry. The two technologies make it possible to produce seamless coverage of entire tidal basins;
20 however, merging the two products raises the question whether the quality of the data from the two
21 different sources is comparable. Comparing the LiDAR accuracy with previous findings of accuracy
22 derived from MBES systems indicates similar or slightly better accuracy from the MBES systems (Dix et
23 al., 2012; Ernstsén et al., 2006). Dix et al. (2012) determined the vertical accuracy of MBES data by
24 testing the system on different objects and in different environments, and found the vertical E_{RMS} to be ± 4
25 cm. Furthermore, they tested a LiDAR system on the same objects and found a similar vertical E_{RMS} of
26 ± 4 cm. The vertical E_{RMS} of ± 4.1 cm found in this study is very close to both the MBES accuracy and
27 LiDAR accuracy determined by Dix et al. (2012). Another study by Ernstsén et al. (2006) determined the
28 vertical precision of a high-resolution shallow-water MBES system based on 7 measurements of a ship
29 wreck from a single survey carried out in similar settings as the present study, namely in the main tidal
30 channel in the tidal inlet just north of the inlet investigated in this study. They found the vertical precision
31 to be ± 2 cm, which is slightly better than the vertical precision of ± 3.8 cm (frame) and ± 7.6 cm (block)
32 found in this study. Overall, accuracy and precision are within the scale of sub decimetres for both
33 topobathymetric LiDAR and MBES systems, which enables the mapping of tidal basins with full
34 coverage and with comparable quality.

35 Due to technical and logistical reasons, the data validation and the actual survey were carried out on
36 different days and in different locations. Based on this, it is a fair question to ask, whether the determined
37 quality actually represents the quality of the data within the study site. Differences between the

1 determined data quality at the validation sites and the data quality at the study site may arise from 1)
2 different environmental conditions on the two surveying days and/or 2) different environments at the
3 validation sites compared to the study site.

4 The environmental conditions were similar on the two surveying days (as mentioned in Sect. 3.2),
5 meaning that the different days are not affecting the representation of the data quality within the study
6 site.

7 The environmental differences between validation site 2 and the study site include the presence of up to
8 0.2-0.3 m waves in the main channel next to the study site. The waves introduce a source of error,
9 because the proposed water surface detection method is not modelling the waves. The precision of the
10 seabed points within the study site are therefore expected to be worse than the ± 3.8 cm precision
11 determined at validation site 2.

12 The water clarity/turbidity impacts the accuracy of the LiDAR data negatively, due to scattering on
13 particles in the water column, which causes the laser beam to spread (Kunz et al., 1992; Niemeyer and
14 Soergel, 2013). Moreover, part of the light is reflected in the direction of the receiver, and such return
15 signals can be difficult to distinguish from the seabed return (Kunz et al., 1992). The turbidity was
16 measured at validation site 2 and in the flood channel close to the study site during the 19 April survey by
17 collecting water samples and subsequently analysing the samples for suspended sediment concentration
18 (SSC) and organic matter content (OMC). The analyses showed that the average SSC was higher in the
19 flood channel (17.2 mg/kg) than in the river (10.2 mg/kg). In contrast, the average OMC was lower in the
20 flood channel (25.5 %) than in the river (40.0 %). These observations indicate that 1) the underwater
21 precision is assessed in a location with higher turbidity than the environment within the study site;
22 therefore, the turbidity cannot be a cause of lower precision in the study site, and 2) the penetration depth
23 seems to be controlled by the OMC rather than by the SSC. This is new knowledge, since no previous
24 studies (from what we know) have investigated the relative effect of organic matter as opposed to
25 inorganic matter on the laser beam penetration depth. However, in order to determine the relationship
26 with statistical confidence, a more comprehensive study is needed, involving measurements of
27 penetration depth at different SSCs and OMCs, and without disturbance from other environmental
28 parameters.

29 **5.4 Spatial variations of topobathymetric LiDAR data quality**

30 The quality of spatial datasets is often provided as single values, such as ± 8.1 cm for the vertical accuracy
31 in this case, and then the determined value represents the accuracy/precision of the whole dataset.
32 However, in reality the value is only a measure of the local quality at the location where the assessment is
33 conducted. The quality of the dataset varies spatially, and one way to illustrate this is to extract the
34 maximum vertical difference between the LiDAR points of the processed point cloud within every
35 0.5×0.5 m cell throughout the study site (Fig. 12). In flat areas, without multiple return signals, this shows
36 the spatially varying precision of the dataset. There are large differences on Fanø, which is expected due
37 to vegetation causing multiple LiDAR returns from both the vegetation canopy and from the bare ground.

1 In contrast, the differences on the very gently sloping, non-vegetated tidal flat are up to 10 cm, and there
2 is no simple and natural reason for this variation. A range of factors contribute to the observed variations:

3 Laser beam incidence angle: The incidence angle, at which the laser beam hits the ground/seabed, is
4 determined by a combination of the scan angle, the water surface angle and the terrain slope. The shape of
5 the footprint is stretched with larger incidence angles, and this effect can cause pulse timing errors in the
6 detected signal, which leads to a decreasing vertical accuracy (Baltsavias, 1999). The error associated
7 with larger scan angles is generally causing the outer beams, toward the swath edges, to attain a lower
8 accuracy (Guenther, 2007). This is a reason for the observed variations along the swath edges (Fig. 12).
9 Terrain slopes have the same effect of decreasing the vertical accuracy due to the footprint stretching. The
10 measured elevation tends to be biased toward the shallowest point of the slope within the laser beam
11 (Guenther, 2007). However, the influence of slope is not crucial in the Knudedyb tidal inlet system, since
12 it is generally a very flat area.

13 Vertical bias between overlapping swaths: Areas covered by more than a single swath tend to show more
14 vertical variation in the LiDAR point measurements. This can be caused by variance/error in the GPS
15 measurements and/or IMU errors (Huising and Gomes Pereira, 1998). The vertical bias between swaths
16 has been observed in the point cloud to be up to 5 cm, but it is varying throughout the study site. In most
17 environments, a bias of 5 cm would be unnoticeable, but because of the large and very flat parts of the
18 Knudedyb tidal inlet system, even a small bias becomes readily evident.

19 Water depth: The accuracy and precision are expected to be lower as the laser beam penetrates deeper
20 into the water column (Kunz et al., 1992). The laser beam footprint is diverging as it moves through the
21 water column, resulting in a larger footprint on the seabed. The elevation of the detected point is thus
22 derived from the measurement on a larger area on the seabed, which will decrease the vertical accuracy,
23 as well as decrease the capability of detecting small objects. With this in mind, the higher precision at the
24 frame compared to the block is opposite of what would be expected, since the frame is below water and
25 the block is on land. In this case, other factors, such as overlapping swaths and/or scan angle deviations,
26 have more influence on the precision than the water depth. Also, it should be remembered that the frame
27 surface was close to the water surface, and the effect of the water depth on the precision would most
28 likely be more evident if it was located in deeper water.

29 Additional factors, beside the ones mentioned above, may influence the quality of LiDAR datasets. For
30 instance, a dense vegetation cover of the seabed or breaking waves that makes the laser detection of the
31 seabed almost impossible. However, these factors do not have a great influence in the studied part of the
32 Knudedyb tidal inlet system, and thus they are not further elaborated.

33 **5.5 Evaluation of the morphological classification**

34 The morphological classification presented in this study is based on the studied section of the Knudedyb
35 tidal inlet system. The overall concept of using tidal range, slope and variations of the elevation at
36 different spatial scales proves to be a reliable method for delineating the morphological features in this

1 tidal environment. The concept, however, can be applied in other environments. The specific thresholds
2 in the classification determined in this study may deviate in other areas. Morphological features of
3 different sizes require steps of other spatial scales in the neighbourhood analyses to produce a successful
4 classification. In the future the classification method will be improved by implementing an objective
5 method for determining the scales, which can make it applicable in areas with different morphological
6 characteristics. Such an objective scale determination method is presented by (Ismail et al. (2015)), who
7 determined the scales based on the variance of the DEM at progressively larger window sizes. In this
8 way, the sizes of the morphological features are determining the scales for the classification.

9 **5.6 Using topobathymetric LiDAR data to map morphology in a highly dynamic tidal** 10 **environment**

11 The study demonstrates the capability of green topobathymetric LiDAR to resolve fine-scale features,
12 while covering a broad-scale tidal inlet system. Collecting topobathymetric LiDAR data with a high point
13 density of 20 points/m² on average enables detailed seamless mapping of large tidal environments, and the
14 LiDAR data has further proved to maintain a high accuracy. The combined characteristics of mapping
15 with high resolution and high accuracy in a traditionally challenging environment provide many potential
16 applications, such as mapping for purposes of spatial planning and management, safety of navigation,
17 nature conservation, or morphological classification, as demonstrated in this study. The developed
18 LiDAR data processing method is tailored to a morphological analysis application. The best
19 representation of the morphology is mapped by gridding the average value of the LiDAR points into a
20 DEM with a 0.5 × 0.5 resolution. Other applications would require different gridding techniques. For
21 instance hydrographers, who are generally interested in mapping for navigational safety, would use the
22 shallowest point for gridding. However, the overall method for processing the point cloud can be used
23 regardless of the application. Only the last and least challenging/time consuming step of gridding the
24 point cloud into a DEM, may vary depending on the application.

25 Applying topobathymetric LiDAR data for morphological analyses in tidal environments enables a
26 holistic approach of seamlessly merging marine and terrestrial morphologies in a single dataset. However,
27 a combination of topobathymetric LiDAR and MBES data is required, in order to map the morphology of
28 tidal environments in full coverage. The comparable quality and resolution of LiDAR and MBES data
29 gives a potential to map broad-scale tidal environments, such as the Wadden Sea, in full coverage and
30 with high resolution and high accuracy.

31 **6 Conclusions**

32 A method was developed for processing raw topobathymetric Light Detection and Ranging (LiDAR) data
33 into a Digital Elevation Model (DEM) with seamless coverage across the land-water transition zone. The
34 method relies on basic principles, and the entire processing method is described with a high level of
35 detail, which makes it transparent and easy to implement for future studies. Specifically a new procedure
36 was developed for water surface detection in a tidal environment utilizing automatic water level

1 determination solely based on green LiDAR data. The water surface detection method presented in this
2 work did not take into account the variation in wave heights and surface slopes, which therefore
3 constitutes a challenge to be addressed in future studies.

4 The vertical accuracy of the LiDAR data was determined by object detection of a cement block on land to
5 ± 8.1 cm with a 95% confidence level. The vertical precision was determined at the cement block to ± 7.6
6 cm, and ± 3.8 cm at a steel frame, placed just below the water surface. The horizontal mean error was
7 determined at the block to ± 10.4 cm. Overall, vertical and horizontal precision are within sub decimetre
8 scale.

9 A seamless topobathymetric DEM was created in a 4×0.85 km section in the Knudedyb tidal inlet
10 system. An average point density of 20 points per m^2 made it possible to create an elevation model of 0.5
11 $\times 0.5$ m resolution without significant interpolation. The DEM extended down to water depths of 3 m,
12 which was determined as the maximum penetration depth of the laser scanning system at the given
13 environmental conditions. Measurements of suspended sediment concentration and organic matter content
14 indicated that the penetration depth was limited by the amount of organic matter rather than the amount of
15 suspended sediment.

16 The vertical “dead zone” of the LiDAR data was determined to approx. 0-28 cm in the very shallow
17 water.

18 The DEM was used as input in the Benthic Terrain Modeler tool to classify the study area into 5 classes
19 of geomorphometry: broad-scale crests, fine-scale crests, depressions, slopes and flats. A morphological
20 classification method was developed for classifying the area into 6 morphological classes: swash bars,
21 linear bars, beach dunes, intertidal flats, intertidal creeks and subtidal channels. The morphological
22 classification method was based on parameters of tidal range, terrain slope, a combination of various
23 statistical neighbourhood analyses with varying window sizes and the area/perimeter-ratio of
24 morphological features. The concept can be applied in any coastal environment with knowledge of the
25 tidal range and the input of a DEM; however, the thresholds may need adaptation, since they have been
26 determined for the given study area. In the future the classification method should be improved by
27 implementing an objective method for determining thresholds, which makes it immediately applicable
28 across different environments.

29 Overall this study has demonstrated that airborne topobathymetric LiDAR is capable of seamless
30 mapping across land-water transition zones even in environmentally challenging coastal environments
31 with high water column turbidity and continuously varying water levels due to tides. Furthermore, we
32 have demonstrated the potential of topobathymetric LiDAR in combination with morphometric analyses
33 for classification of morphological features present in coastal land-water transition zones.

1 **Author contribution**

2 VBE designed the study within the research project “Process-based understanding and prediction of
3 morphodynamics in a natural coastal system in response to climate change”. FS and LRL collected the
4 LiDAR data. MSA and ÁG performed the groundtruthing fieldwork, and processed the LiDAR and
5 groundtruthing data. MSA, ZA-H and VBE analysed and interpreted the data and drafted the paper, which
6 was then edited by all co-authors.

7 **Competing interests**

8 The authors declare that they have no conflict of interest.

9 **Acknowledgements**

10 This work was funded by the Danish Council for Independent Research | Natural Sciences through the
11 project “Process-based understanding and prediction of morphodynamics in a natural coastal system in
12 response to climate change” (Steno Grant no. 10-081102) and by the Geocenter Denmark through the
13 project “Closing the gap! – Coherent land-water environmental mapping (LAWA)” (Grant no. 4-2015).
14 Thanks to QPS for providing the Fledermaus software suite. We thank the anonymous reviewers and the
15 editor for comments and suggestions which improved the final version of the paper.

Figure 2: Conceptual sketch of the laser beam propagation and return signals. The beam refracts upon entering the water body, and it diverges as it propagates through the water column. Return signals are produced both in the air, at the water surface, in the water column and at the seabed. The LiDAR instrument has limited capability in very shallow water (the “dead zone” in the figure) because the successive peaks from the water surface and the seabed are not individually separated in time and amplitude. Only the largest peak, which is from the seabed, is detected.

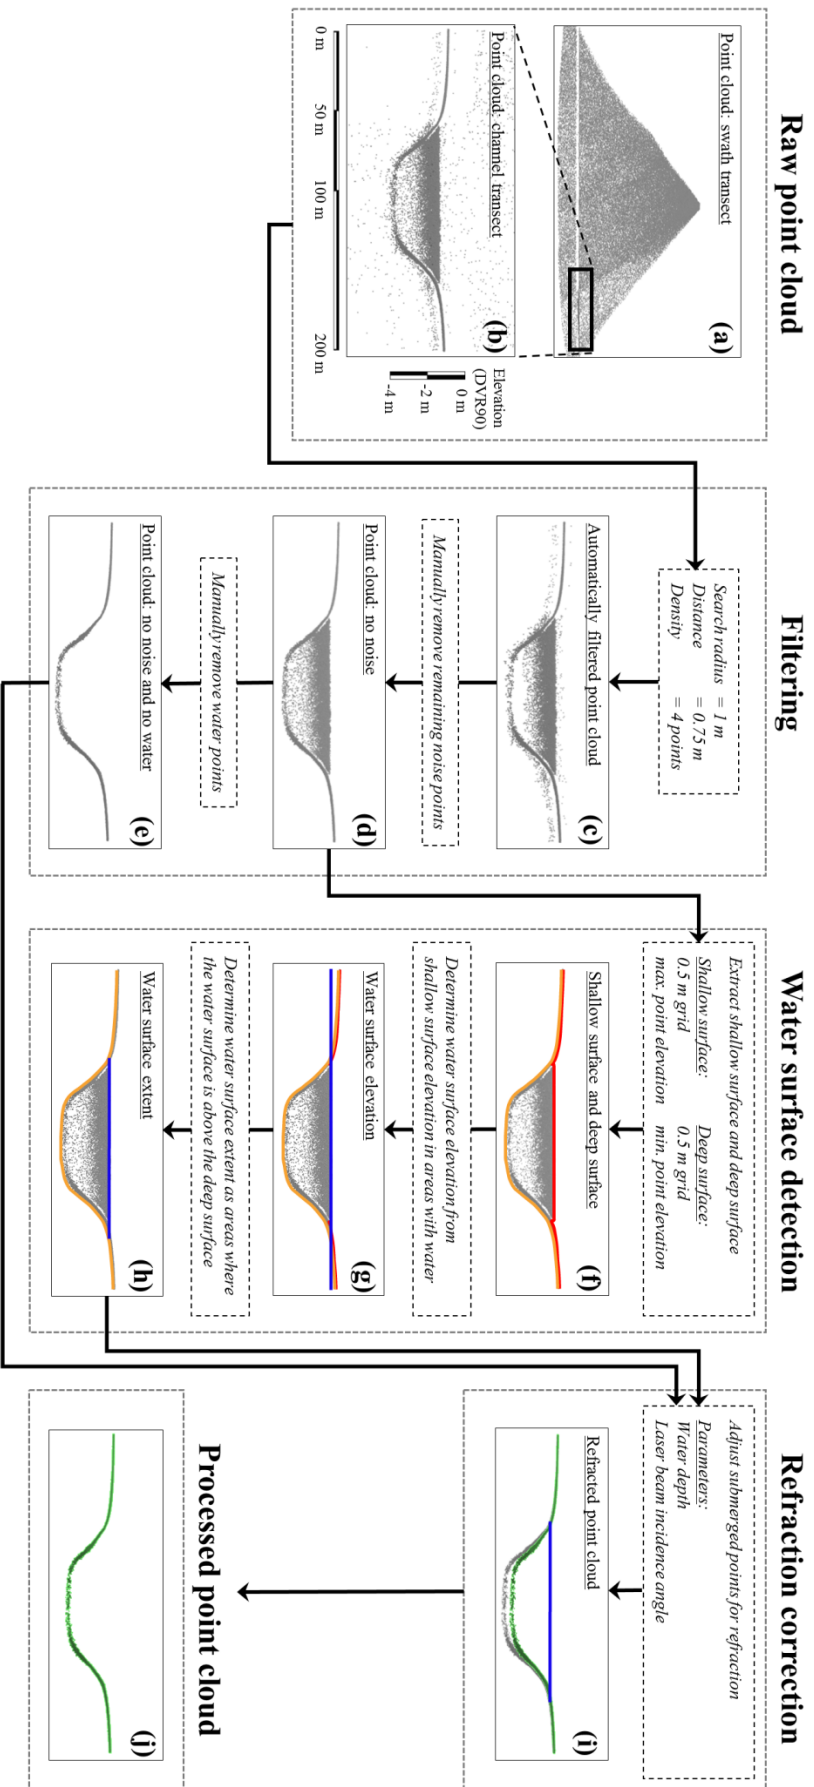

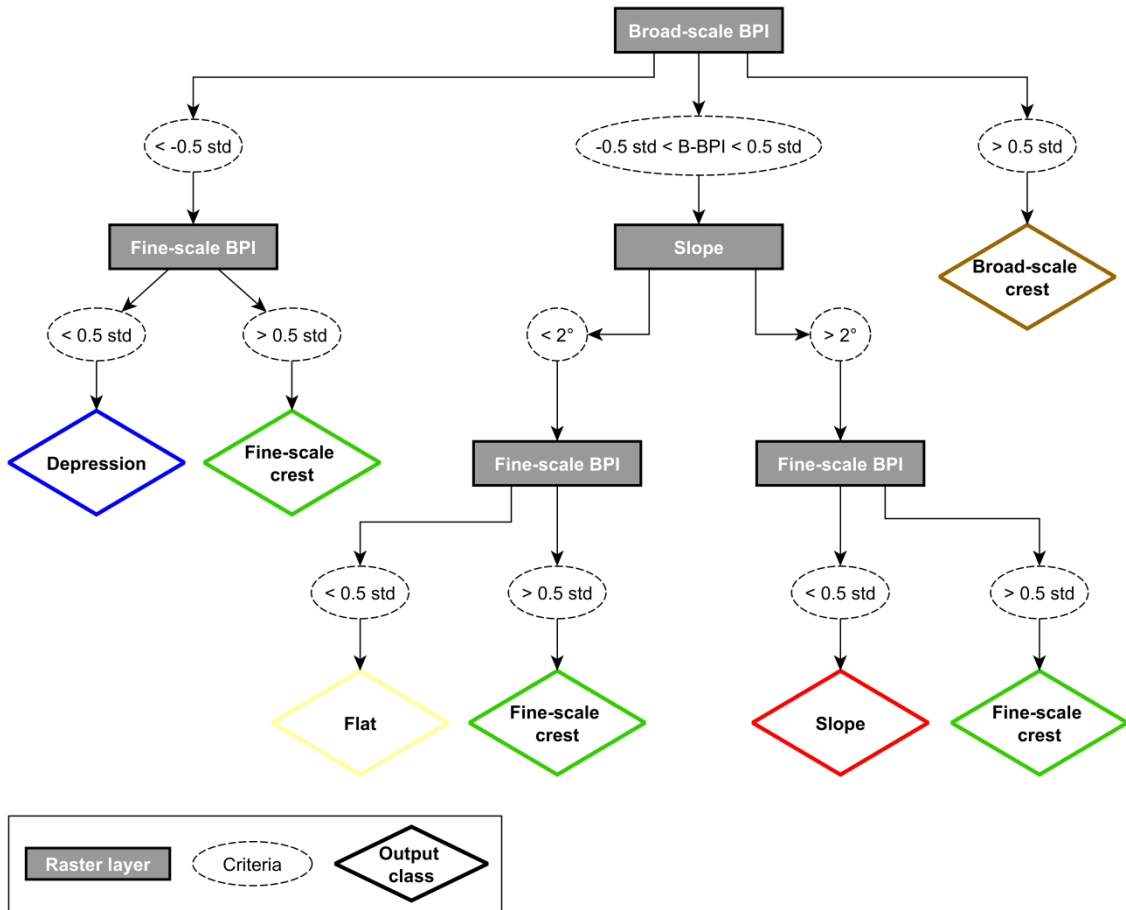

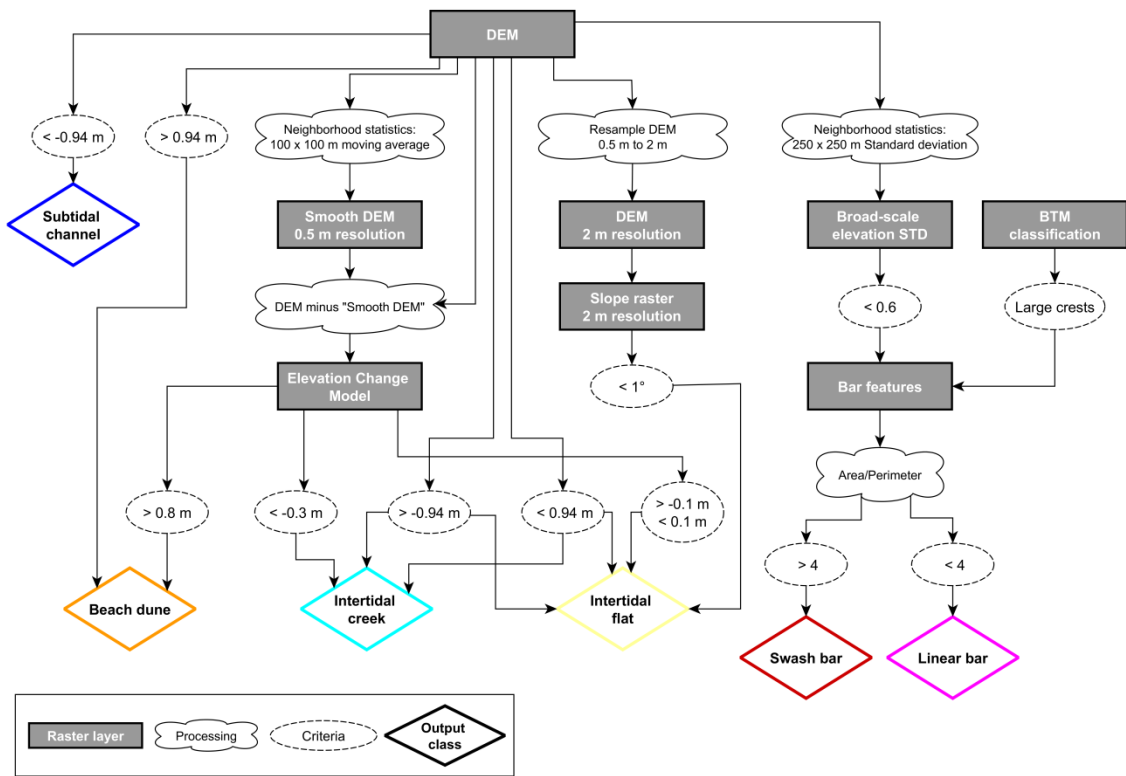

Figure 3: Workflow for processing the LidAR point cloud. (a) Point cloud from a single swath with points ranging from -100 m to 300 m elevation. (b) Zoom-in on a cross section of the flood channel with elevation exaggerated $\times 15$ for visualization purpose. (c-e) Method for filtering the point cloud. (f-h) Method for detecting a water surface (blue) based on the extraction of a shallow surface (red) and a deep surface (orange). (i) Correction for the effect of refraction on all the submerged points. (j) Processed point cloud.

Figure 9: Topobathymetric DEM across the northern part of the Knudedyb tidal inlet system with close-up views of different detail level in specific areas. The northern supratidal part of the study area (a and b) includes beach dunes, vegetation and cottages, thus the DEM can be regarded as a DSM in this specific section. In the sub- and intertidal parts of the study area (c, d, e and f), the DEM reflects the natural terrain, thus it can be regarded as a DTM. (a) Beach dunes, vegetation and cottages. (b) Cottages. (c) Flood channel. (d) Intertidal creek. (e) Swash bars, linear bars and bathymetry of the main channel. (f) Swash bar. A hillshade is draped upon the close-up views for improved visualization of morphological features.
