17 **Abstract**

18 The phase of precipitation when it reaches the Earth surface is a first-order driver of hydrologic
19 processes in a watershed. The presence of snow, rain, or mixed phase precipitation affect the
20 initial and boundary conditions that drive hydrological models. Despite their foundational
21 importance to terrestrial hydrology, typical phase prediction methods (PPM) specify phase based
22 on near-surface air temperature only. Our review conveys the diversity of tools available for
23 PPM in hydrological modeling and the advancements needed to improve predictions in complex
24 terrain with large spatiotemporal variations in precipitation phase. Initially, we review the
25 processes and physics that control precipitation phase as relevant to hydrologists, focusing on the
26 importance of processes occurring aloft. There are a wide range of options for field observations
27 of precipitation phase, but a lack of a robust observation networks in complex terrain. New
28 remote sensing observations have potential to increase PPM fidelity, but generally require
29 assumptions typical of other PPM and field validation before they are operational. We review
30 common PPM and find that accuracy is generally increased at finer measurement intervals and
31 by including humidity information. One important tool for PPM development is atmospheric
32 modeling, which include microphysical schemes that have not been effectively linked to
33 hydrological models or validated against near-surface precipitation phase observations. The
34 review concludes by describing key research gaps and recommendations to improve PPM ,
35 including better incorporation of atmospheric information, improved validation datasets, and
36 regional-scale gridded data products. Two key points emerge from this synthesis for the
37 hydrologic community: 1) current PPM algorithms are too simple and are not well-validated for
38 most locations, 2) lack of sophisticated PPM increases the uncertainty in estimation of
39 hydrological sensitivity to changes in precipitation phase at local to regional scales. PPM are a
40 critical research frontier in hydrology that requires scientific cooperation between hydrological
41 and atmospheric modelers and field hydrologists.

44
45 1. Introduction and Motivation

46 As climate warms, a major hydrologic shift in precipitation phase from snow to rain is expected
47 to occur across temperate regions that are reliant on mountain snowpack for water resources
48 (Bales et al., 2006; Barnett et al., 2005). Continued changes in precipitation phase are expected

78 to alter snowpack dynamics and streamflow timing and amounts (Cayan et al., 2001; Fritze et al.,
79 2011; Luce and Holden, 2009; Klos et al., 2014; Berghuijs et al., 2014; Jepsen et al., 2016),
80 increase rain-on snow flooding (McCabe et al., 2007), and challenge our ability to make accurate
81 water supply forecasts (Milly et al., 2008). Accurate estimations of precipitation inputs are
82 required for effective hydrological modeling in both applied and research settings. Snow storage
83 delays the transfer of precipitation into surface runoff and subsurface infiltration (Figure 1),
84 affecting the timing and magnitude of peak flows (Wang et al., 2016), hydrograph recession
85 (Yarnell et al., 2010) and the magnitude and duration of summer baseflow (Safeeq et al., 2014;
86 Godsey et al., 2014). Moreover, the altered timing and rate of snow versus rain inputs can
87 modify the partitioning of water to evapotranspiration versus runoff (Wang et al., 2013).
88 Misrepresentation of precipitation phase within hydrologic models thus propagates into spring
89 snowmelt dynamics (Harder and Pomeroy, 2013; Mizukami et al., 2013; White et al., 2002; Wen
90 et al., 2013) and streamflow estimates used in water resource forecasting (Figure 1). The
91 persistence of streamflow error is particularly problematic for hydrological models that are
92 calibrated on observed streamflow because this error can be compensated for by altering
93 parameters that control other states and fluxes in the model (Minder, 2010; Shamir and
94 Georgakakos, 2006; Kirchner, 2006). Expected changes in precipitation phase from climate
95 warming presents a new set of challenges for effective hydrological modeling (Figure 1). A
96 simple yet essential issue for nearly all runoff generation questions is this: Is precipitation falling
97 as rain, snow, or a mix of both phases?
98
99 Despite advances in terrestrial process-representation within hydrological models in the past
100 several decades (Fatichi et al., 2016), most state-of-the-art models rely on simple empirical
101 algorithms to predict precipitation phase. For example, nearly all operational models used by the
102 National Weather Service River Forecast Centers in the United States use some type of
103 temperature-based precipitation phase partitioning methods (PPM) (Pagano et al., 2014). These
104 are often single or double temperature threshold models that do not consider other conditions
105 important to the hydrometeor's energy balance. Although forcing datasets for hydrological
106 models are rapidly being developed for a suite of meteorological variables, to date no gridded
107 precipitation phase product has been developed over a regional to global scale. Widespread
108 advances in both simulation of terrestrial hydrological processes and computational capabilities

117 may have limited improvements on water resources forecasts without commensurate advances in
118 PPM.

119

120 Recent advances in PPM incorporate effects of humidity (Harder and Pomeroy, 2013; Marks et
121 al., 2013), atmospheric temperature profiles (Froidurot et al., 2014), and remote sensing of phase
122 in the atmosphere (Minder, 2010; Lundquist et al., 2008). A challenge to improving and selecting
123 PPM is the lack of validation data. In particular, reliable ground-based observations of phase are
124 sparse, collected at the point scale over limited areas, and are typically limited to research rather
125 than operational applications (Marks et al., 2013). The lack of observations is particularly
126 problematic in mountain regions where snow-rain transitions are widespread and critical for
127 regional water resource evaluations (Klos et al., 2014). For example, direct visual observations
128 have been widely used (Froidurot et al., 2014; Knowles et al., 2006; U.S. Army Corps of
129 Engineers, 1956), but are decreasing in number in favor of automated measurement systems.
130 Automated systems use indirect methods to accurately estimate precipitation phase from
131 hydrometeor characteristics (i.e. disdrometers), as well as coupled measurements that infer
132 precipitation phase based on multiple lines of evidence (e.g. co-located snow depth and
133 precipitation). Remote sensing is another indirect method that typically uses radar returns from
134 the ground and space-borne platforms to infer hydrometeor temperature and phase. A
135 comprehensive description of the advantages and disadvantages of current measurement
136 strategies, and their correspondence with conventional PPM, is needed to determine critical
137 knowledge gaps and research opportunities.

138

139 New efforts are needed to advance PPM to better inform hydrological models by integrating new
140 observations, expanding the current observation networks, and testing techniques over regional
141 variations in hydroclimatology. While calls to integrate atmospheric information are an
142 important avenue for advancement (Feiccabrino et al., 2013), hydrological models ultimately
143 require accurate and validated phase determination at the land surface. Moreover, any
144 advancement that relies on integrating new information or developing a new PPM technique will
145 require validation and training using ground-based observations. To make tangible advancements
146 in hydrological modeling, new techniques and datasets must be integrated with current modeling
147 tools. The first step towards improved hydrological modeling in areas with mixed precipitation

154 | Our review paper is motivated by a lack of a comprehensive description of the state-of-the-art
155 | PPM and observation tools. Therefore, we describe the current state of the science in a way that
156 | clarifies the correspondence between techniques and observations and highlights current
157 | strengths and weaknesses in the science. Specifically, subsequent sections will review: 1) the
158 | processes and physics that control precipitation phase as relevant to field hydrologists, 2) current
159 | options available for observing precipitation phase and related measurements common in remote
160 | field settings, 3) existing methods for predicting and modeling precipitation phase, and 4)
161 | research gaps that exist regarding precipitation phase estimation. The overall objective is to
162 | convey a clear understanding of the diversity of tools available for PPM in hydrological
163 | modeling and the advancements needed to improve predictions in complex terrain characterized
164 | by large spatiotemporal variations in precipitation phase.

166 | 2. Processes and Physics Controlling Precipitation Phase

167 | Precipitation formed in the atmosphere is typically a solid in the mid-latitudes and its phase at
168 | the land surface is determined by whether it melts during its fall (Stewart et al., 2015). Most
169 | hydrologic models do not simulate atmospheric processes and specify precipitation phase based
170 | on surface conditions alone (see Section 4.1), ignoring phase transformations in the atmosphere.

Adrian Harpold 11/20/16 2:22 PM

Deleted: as

171 |
172 | Several important properties that influence phase changes in the atmosphere are not included in
173 | hydrological models (Feiccabrino et al., 2012), such as temperature and precipitation
174 | characteristics (Theriault and Stewart, 2010), stability of the atmosphere (Theriault and Stewart,
175 | 2007), position of the 0 °C isotherm (Minder, 2010; Theriault and Stewart, 2010), interaction
176 | between hydrometeors (Stewart, 1992), and the atmospheric humidity profile (Harder and
177 | Pomeroy, 2013). The vertical temperature and humidity (represented by the mixing ratio) profile
178 | through which the hydrometeor falls typically consists of three layers, a top layer that is frozen
179 | ($T_v \leq 0$ °C) in winter in temperate areas (Stewart, 1992), potentially a mixed layer with $T > 0$ °C
180 | and a surface layer that can be above or below 0 °C (Figure 2). The phase of precipitation at the
181 | surface partly depends on the phase reaching the top of the surface layer, which is defined as the

192 critical height. The temperature profile and depth of the surface layer controls the precipitation
193 phase reaching the ground surface. For example, in Figure 2a, if rain reaches the critical height, it
194 may reach the surface as rain or ice pellets depending on small differences in temperature in the
195 surface layer (Theriault and Stewart, 2010). Similarly, in Figure 2b, if snow reaches the critical
196 height, it may reach the surface as snow if the temperature in the surface layer is below freezing.
197 However, in Figure 2c, when the surface layer temperatures are close to freezing and the mixing
198 ratios are neither close to saturation or very dry the phase at the surface is not easily determined
199 by the surface conditions alone.

200

201 In addition to strong dependence on the vertical temperature and humidity profiles, precipitation
202 phase is also a function of fall rate and hydrometeor size because they affect energy exchange
203 with the atmosphere (Theriault et al., 2010). Precipitation rate influences the precipitation phase;
204 for example, a precipitation rate of 10 mm h^{-1} reduces the amount of freezing rain by a factor of
205 three over a precipitation rate of 1 mm h^{-1} (Theriault and Stewart, 2010) because there is less
206 time for exchange of turbulent heat with the hydrometeor. A solid hydrometeor that originates in
207 the top layer and falls through the mixed layer can reach the surface layer as wet snow, sleet, or
208 rain. This phase transition in the mixed layer is primarily a function of latent heat exchange
209 driven by vapor pressure gradients and sensible heat exchange driven by temperature gradients.
210 Temperature generally increases from the mixed layer to the surface layer causing sensible heat
211 inputs to the hydrometeor. If these gains in sensible heat are combined with minimal latent heat
212 losses resulting from low vapor pressure deficits, it is likely the hydrometeor will reach the
213 surface layer as rain (Figure 2). However, vapor pressure in the mixed layer is often below
214 saturation leading to latent energy losses and cooling of the hydrometeor coupled with diabatic
215 cooling of the local atmosphere, which can produce snow or other forms of frozen precipitation
216 at the surface even when temperatures are above $0 \text{ }^{\circ}\text{C}$. Likewise, surface energetics affect local
217 atmospheric conditions and dynamics, especially in complex terrain. For example, melting of the
218 snowpack can cause diabatic cooling of the local atmosphere and affect the phase of
219 precipitation, especially when air temperatures are very close to $0 \text{ }^{\circ}\text{C}$ (Theriault et al., 2012).

220 Many conditions lead to a combination of latent heat losses and sensible heat gains by
221 hydrometeors (Figure 2). Under these conditions it can be difficult to predict the phase of

Deleted: of

225 precipitation without sufficient information about humidity and temperature profiles, turbulence,
226 hydrometeor size, and precipitation intensity.

227

228 Stability of the atmosphere can also influence precipitation phase. Stability is a function of the
229 vertical temperature structure which can be altered by vertical air movement and hence influence
230 precipitation phase (Theriault and Stewart, 2007). Vertical air velocity changes the temperature
231 structure by adiabatic warming or cooling due to pressure changes of descending and ascending,
232 air parcels, respectively. These changes in temperature will generate under-saturated and
233 supersaturated conditions in the atmosphere that can also alter the precipitation phase. Even a
234 very weak vertical air velocity (< 10 cm/s) significantly influences the phase and amount of
235 precipitation formed in the atmosphere (Theriault and Stewart, 2007). The rain-snow line
236 predicted by atmospheric models is very sensitive to these microphysics (Minder, 2010), and
237 validating the microphysics across locations with complex physiography is challenging.
238 Incorporation and validation of atmospheric microphysics is rarely achieved in hydrological
239 applications (Feiccabrino et al., 2015).

240

241 3. Current Tools for Observing Precipitation Phase

242 3.1 In situ observations

243 In situ observations refer to methods wherein a person or instrument onsite records precipitation
244 phase. We identify 3 classes of approaches that are used to observe precipitation phase including
245 1) direct observations, 2) coupled observations, and 3) proxy observations.

246

247 Direct observations simply involve a person on-site noting the phase of falling precipitation.
248 Such data form the basis of many of the predictive methods that are widely used (Dai, 2008;
249 Ding et al., 2014; U.S. Army Corps of Engineers, 1956). Direct observations are useful for
250 “manned” stations such as those operated by the U.S. National Weather Service. Few research
251 stations, however, have this benefit, particularly in many remote regions and in complex terrain.
252 Direct observations are also limited in their temporal resolution and are typically reported only
253 once per day, with some exceptions (Froidurot et al., 2014). Citizen scientist networks have
254 historically provided valuable data to supplement primary instrumented observation networks.

255 The National Weather Service Cooperative Observer Program

256 (<http://www.nws.noaa.gov/om/coop/what-is-coop.html>, accessed 10/12/2016) is comprised of a

262 network of volunteers recording daily observations of temperature and precipitation, including
263 phase. The NOAA National Severe Storms Laboratory used citizen scientist observations of rain
264 and snow occurrence to evaluate the performance of the Multi-Radar Multi-Sensor (MRMS)
265 system in the meteorological Phenomena Identification Near the Ground (mPING) project (Chen
266 et al., 2015). The Colorado Climate Center initiated Community Collaborative Rain, Hail and
267 Snow Network (CoCoRaHS) supplies volunteers with low cost instrumentation to observe
268 precipitation characteristics, including phase, and enables observations to be reported on the
269 project website (<http://www.cocorahs.org/>, accessed 10/12/2016). Although highly valuable,
270 some limitations of this system include the imperfect ability of observers to identify mixed phase
271 events and the temporal extent of storms, as well as the lack of observations in both remote areas
272 and during low light conditions.

273

274 Coupled observations link synchronous measurements of precipitation with secondary
275 observations to indicate phase. Secondary observations can include photographs of surrounding
276 terrain, snow depth measurements, and measurements of ancillary meteorological variables.
277 Photographs of vertical scales emplaced in the snow have been used to estimate snow
278 accumulation depth, which can then be coupled with precipitation mass to determine density and
279 phase (Berris and Harr, 1987; Floyd and Weiler, 2008; Garvelmann et al., 2013; Hedrick and
280 Marshall, 2014; Parajka et al., 2012). Mixed phase events, however, are difficult to quantify
281 using coupled depth- and photographic-based techniques (Floyd and Weiler, 2008). Acoustic
282 distance sensors, which are now commonly used to monitor the accumulation of snow (e.g. Boe,
283 2013), have similar drawbacks in mixed phase events, but have been effectively applied to
284 separate snow from rain (Rajagopal and Harpold, 2016). Meteorological information such as
285 temperature and relative humidity can be used to compute the phase of precipitation measured by
286 bucket-type gauges. Unfortunately, this approach generally requires incorporating assumptions
287 about the meteorological conditions that determine phase (see section 4.1). Harder and Pomeroy
288 (2013) used a comprehensive approach to determine the phase of precipitation. Every 15 minutes
289 during their study period phase was determined by evaluating weighing bucket mass, tipping
290 bucket depth, albedo, snow depth, and air temperature. Similarly, Marks et al. (2013) used a
291 scheme based on co-located precipitation and snow depth to discriminate phase. A more
292 involved expert decision making approach by L'hôte et al. (2005) was based on six recorded

296 | meteorological parameters: precipitation intensity, albedo of the ground, air temperature, ground
297 | surface temperature, reflected long-wave radiation, and soil heat flux. The intent of most of these
298 | coupled observations was to develop datasets to evaluate PPM algorithms. However, if these
299 | observation systems were sufficiently simple they may have the potential to be applied
300 | operationally across larger meteorological monitoring networks encompassing complex terrain
301 | where snow comprises a large component of annual precipitation (Rajagopal and Harpold, 2016).
302

Adrian Harpold 11/20/16 2:22 PM

Deleted: soil

303 | Proxy observations measure geophysical properties of precipitation to infer phase. The hot plate
304 | precipitation gauge introduced by Rasmussen et al. (2012), for example, uses a heated thin disk
305 | to accumulate precipitation and then measures the amount of energy required to melt snow or
306 | evaporate liquid water. This technique, however, requires a secondary measurement of air
307 | temperature to determine if the energy is used to melt snow or only evaporate rain. Disdrometers
308 | measure the size and velocity of hydrometeors. Although the most common application of
309 | disdrometer data is to determine the drop size distribution (DSD) and other properties of rain, the
310 | phase of hydrometeors can be inferred by relating velocity and size to density. Some disdrometer
311 | technologies, which can be grouped into impact, imaging, and scattering approaches (Loffler-
312 | Mang et al., 1999), are better suited for describing snow than others. Impact disdrometers, first
313 | introduced by Joss and Waldvogel (1967), use an electromechanical sensor to convert the
314 | momentum of a hydrometeor into an electric pulse. The amplitude of the pulse is a function of
315 | drop diameter. Impact disdrometers have not been commonly used to measure solid precipitation
316 | due to the different functional relationships between drop size and momentum for solid and
317 | liquid precipitation. Imaging disdrometers use basic photographic principles to acquire images of
318 | the distribution of particles (Borrmann and Jaenicke, 1993; Knollenberg, 1970). The 2D Video
319 | Disdrometer (2DVD) described by Kruger and Krajewski (2002) records the shadows cast by
320 | hydrometeors onto photodetectors as they pass through two sheets of light. The shape of the
321 | shadows enables computation of particle size, and shadows are tracked through both light sheets
322 | to determine velocity. Although initially designed to describe liquid precipitation, recent work
323 | has shown that the 2DVD can be used to classify snowfall according to microphysical properties
324 | of single hydrometeors (Bernauer et al., 2016). The 2DVD has been used to classify known rain
325 | or snow events individually, but little work has been performed to distinguish between liquid and
326 | solid precipitation. Scattering disdrometers, or optical disdrometers, measure the extinction of

Adrian Harpold 11/20/16 2:22 PM

Deleted: ,

330 light passing between a source and a sensor (Hauser et al., 1984; Loffler-Mang et al., 1999). Like
331 the other types, optical disdrometers were originally designed for rain, but have been periodically
332 applied to snow (Battaglia et al., 2010; Lempio et al., 2007). In a comparison study, by
333 Caracciolo et al. (2006), the PARSIVEL optical disdrometer, originally described by Loffler-
334 Mang et al. (1999) did not perform well against a 2DVD because of problems related to the
335 detection of slow fall velocities for snow. It may be possible to use optical disdrometers to
336 distinguish between rain, sleet, and snow based on the existence of distinct shapes of the size
337 spectra for each precipitation type. More research on the relationship between air temperature
338 and the size spectra produced by the optical disdrometer is needed (Lempio et al., 2007). In
339 summary, disdrometers of various types are valuable tools for describing the properties of rain
340 and snow, but require further testing and development to distinguish between rain and snow, as
341 well as mixed phase events.

342

343 3.2 Ground-based remote sensing observations

344 Ground-based remote sensing observations have been available for several decades to detect
345 precipitation phase using radar. Until recently, most ground-based radar stations were operated
346 as conventional Doppler systems that transmit and receive radio waves with single horizontal
347 polarization. Developments in dual polarization ground radar such as those that function as part
348 of the U.S. National Weather Service NEXRAD network (NOAA, 2016), have resulted in
349 systems that transmit radio signals with both horizontal and vertical polarizations. In general,
350 ground-based remote sensing observation, either single or dual-pol, remain underutilized for
351 detecting precipitation phase and are challenging to apply in complex terrain (Table 2).

352

353 Ground-based remote sensing of precipitation phase using single-polarized radar systems
354 depends on detecting the radar bright band. Radio waves transmitted by the radar system, are
355 scattered by hydrometeors in the atmosphere, with a certain proportion reflected back towards
356 the radar antenna. The magnitude of the measured reflectivity (Z) is related to the size and the
357 dielectric constant of falling hydrometeors (White et al., 2002). Ice particles aggregate as they
358 descend through the atmosphere and their dielectric constant increases, in turn increasing Z
359 measured by the radar, creating the bright band, a layer of enhanced reflectivity just below the
360 elevation of the melting level (Lundquist et al., 2008). Therefore, bright band elevation can be

370 used as a proxy for the “snow level”, the bottom of the melting layer where falling snow
371 transforms to rain (White et al., 2010; White et al., 2002).

372

373 Doppler vertical velocity (DVV) is another variable that can be estimated from single-polarized

374 vertically profiling radar. DVV gives an estimate of the velocity of falling particles; as

375 snowflakes melt and become liquid raindrops, the fall velocity of the altered hydrometeors

376 increases. When combined with reflectivity profiles, DVV helps reduce false positive detection

377 of the bright band, which may be caused by phenomena other than snow melting to rain (White

378 et al., 2002). First, DVV and Z are combined to detect the elevation of the bottom of the bright

379 band. Then the algorithm searches for maximum Z above the bottom of the bright band and

380 determines that to be the bright band elevation (White et al., 2002). However, a test of this

381 algorithm on data from a winter storm over the Sierra Nevada found root mean square errors of

382 326 to 457 m compared to ground observations when bright band elevation was assumed to

383 represent the surface transition from snow to rain (Lundquist et al., 2008). Snow levels in

384 mountainous areas, however, may also be overestimated by radar profiler estimates if they are

385 unable to resolve spatial variations close to mountain fronts, since snow levels have been noted

386 to persistently drop on windward slopes (Minder and Kingsmill, 2013). Despite the potential

387 errors, the elevation of maximum Z may be a useful proxy variable for snow level in

388 hydrometeorological applications in mountainous watersheds because maximum Z will always

389 occur below the freezing level (Lundquist et al., 2008; White et al., 2010)

390

391 Few published studies have explored the value of bright band-derived phase data for hydrologic

392 modeling. Maurer and Mass (2006) compared the melting level from vertically pointing radar

393 reflectivity against temperature-based methods to assess whether the radar approach could

394 improve determination of precipitation phase at the ground level. In that study, the altitude of the

395 top of the bright band was detected and applied across the study basin. Frozen precipitation was

396 assumed to be falling in model pixels above the altitude of the melting level and liquid

397 precipitation was assumed to be falling in pixels below the altitude of the melting layer (Maurer

398 and Mass, 2006). Maurer and Mass (2006) found that incorporating radar-detected melting layer

399 altitude improved streamflow simulation results. A similar study that used bright band altitude to

400 classify pixels according to surface precipitation type was not as conclusive; bright band altitude

407 data did not improve hydrologic model simulation results over those based on a temperature
408 threshold (Mizukami et al., 2013). Also, the potential of the method is limited to the availability
409 of vertically pointing radar; in complex, mountainous terrain the ability to estimate melting level
410 becomes increasingly challenging with distance from the radar.

411

412 Dual-polarized radar systems generate more variables than traditional single-polarized systems.

413 These polarimetric variables include differential reflectivity, reflectivity difference, the
414 correlation coefficient, and specific differential phase. Polarimetric variables respond to
415 hydrometeor properties such as shape, size, orientation, phase state, and fall behavior and can be
416 used to assign hydrometeors to specific categories (Chandrasekar et al., 2013; Grazioli et al.,
417 2015), or to improve bright band detection (Giangrande et al., 2008).

418

419 Various hydrometeor classification algorithms have been applied to X-, C- and S-band
420 wavelengths. Improvements in these algorithms over recent years have seen hydrometeor
421 classification become an operational meteorological product (see Grazioli et al., 2015 for an
422 overview). For example, the U.S. National Severe Storms Laboratory (NSSL) developed a fuzzy-
423 logic hydrometeor classification algorithm for warm-season convective weather (Park et al.,
424 2009) and this algorithm has also been tested for cold-season events (Elmore, 2011). Its skill was
425 tested against surface observations of precipitation type but the algorithm did not perform well in
426 classifying winter precipitation because it could not account for re-freezing of hydrometeors
427 below the melting level (Figure 2, Elmore, 2011). Unlike warm season convective precipitation,
428 the freezing level during a cold-season precipitation event can vary spatially. This phenomenon
429 has prompted the use of polarimetric variables to first detect the melting layer, and then classify
430 hydrometeors (Boodoo et al., 2010; Thompson et al., 2014). Although there has been some
431 success in developing two-stage cold-season hydrometeor classification algorithms, there is little
432 in the published literature that explores the potential contributions of these algorithms for
433 partitioning snow and rain for hydrological modeling.

434

435 3.3 Space-based remote sensing observations

436 Spaceborne remote sensing observations typically use passive or active microwave sensors to
437 determine precipitation phase (Table 2). Many of the previous passive microwave systems were

447
448 Passive microwave radiometers detect microwave radiation emitted by the Earth's surface or
449 atmosphere. Passive microwave remote sensing has potential for discriminating between rainfall
450 and snowfall because microwave radiation emitted by the Earth's surface propagates through all
451 but the densest precipitating clouds, meaning that radiation at microwave wavelengths directly
452 interacts with hydrometeors within clouds (Olson et al., 1996; Ardanuy, 1989). However, the
453 remote sensing of precipitation in microwave wavelengths and the development of operational
454 algorithms is dominated by research focused on rainfall (Arkin and Ardanuy, 1989); by
455 comparison, snowfall detection and observation has received less attention (Noh et al., 2009;
456 Kim et al., 2008). This is partly explained by examining the physical processes within clouds that
457 attenuate the microwave signal. Raindrops emit low levels of microwave radiation increasing the
458 level of radiance measured by the sensor; in contrast, ice hydrometeors scatter microwave
459 radiation, decreasing the radiance measured by a sensor (Kidd and Huffman, 2011). Land
460 surfaces have a much higher emissivity than water surfaces, meaning that emission-based
461 detection of precipitation is challenging over land because the high microwave emissions mask
462 the emission signal from raindrops (Kidd, 1998; Kidd and Huffman, 2011). Thus, scattering-
463 based techniques using medium to high frequencies are used to detect precipitation over land.
464 Moreover, microwave observations at higher frequencies (> 89 GHz) have been shown to
465 discriminate between liquid and frozen hydrometeors (Wilheit et al., 1982).

466
467 Retrieving snowfall over land areas from spaceborne microwave sensors can be even more
468 challenging than for liquid precipitation because existing snow cover increases microwave
469 emission. Depression of the microwave signal caused by scattering from airborne ice particles
470 may be obscured by increased emission of microwave radiation from the snow covered land
471 surface. Kongoli et al. (2003) demonstrated an operational snowfall detection algorithm that
472 accounts for the problem of existing snow cover. This group used data from the Advanced
473 Microwave Sounding Unit-A (AMSU-A), a 15-channel atmospheric temperature sounder with a

Adrian Harpold 11/20/16 2:22 PM

Adrian Harpold 11/20/16 2:22 PM

Deleted: (Wilheit et al., 1982)

476 single high frequency channel at 89 GHz), and AMSU-B, a 5-channel high frequency microwave
477 humidity sounder. Both sensors were mounted on the NOAA-16 and -17 polar-orbiting satellites.
478 While the algorithm worked well for warmer, opaque atmospheres, it was found to be too noisy
479 for colder, clear atmospheres. Additionally, some snowfall events occur under warmer conditions
480 than those that were the focus of the study (Kongoli et al., 2003). Kongoli et al. (2015) further
481 adapted their methodology for the Advanced Technology Microwave Sounder (ATMS, onboard
482 the polar-orbiting Suomi National Polar-orbiting Partnership satellite) a descendant of the
483 AMSU sounders. The latest algorithm assesses the probability of snowfall using the logistic
484 regression and the principal components of seven high frequency bands at 89 GHz and above. In
485 testing, the Kongoli et al. (2015) algorithm has shown skill in detecting snowfall both at variable
486 rates and when snowfall is lighter and occurs in colder conditions. An alternative algorithm by
487 Noh et al., 2009 used physically-based, radiative transfer modeling in an attempt to improve
488 snowfall retrieval over land. In this case, radiative transfer modeling was used to construct an *a*
489 *priori* database of observed snowfall profiles and corresponding brightness temperatures. The
490 radiative transfer procedure yields likely brightness temperatures from modeling how ice
491 particles scatter microwave radiation at different wavelengths. A Bayesian retrieval algorithm
492 was then used to estimate snowfall over land by comparing measurements of brightness
493 temperature with modeled brightness temperature (Noh et al., 2009). The algorithm was tested
494 during the early and late winter for heavier snowfall events. Late winter retrievals indicated that
495 the algorithm overestimated snowfall over surfaces with significant snow accumulation.
496
497 While results have been promising, the spatial resolution at which ATMS and other passive
498 microwave data are acquired is very coarse (15.8 to 74.8 km at nadir), making passive
499 microwave approaches more applicable for regional to continental scales. Temporal resolution of
500 the data acquisition is another challenge. AMSU instruments are mounted on 8 satellites; the
501 related ATMS is mounted on a single satellite and planned for two additional satellites.
502 However, the satellites are polar-orbiting, not geostationary, so it is probable that a precipitation
503 event could occur outside the field of view of one of the instruments.
504
505 Spaceborne active microwave or radar sensors measure the backscattered signal from pulses of
506 microwave energy emitted by the sensor itself. Much like the ground based radar systems, the

511 propagated microwave signal interacts with liquid and solid particles in the atmosphere and the
512 degree to which the measured return signal is attenuated provides information on the
513 atmospheric constituents. The advantage offered by spaceborne radar sensors over passive
514 microwave is the capability to acquire more detailed sampling of the vertical profile of the
515 atmosphere (Kulie and Bennartz, 2009). The first spaceborne radar capable of observing
516 snowfall is the Cloud Profiling Radar (CPR) onboard CloudSat (2006 – present). The CPR
517 operates at 94 GHz with an along-track (or vertical) resolution of ~1.5 km. Retrieval of dry
518 snowfall rate from CPR measurements of reflectivity have been shown to correspond with
519 estimates of snowfall from ground-based radar at elevations of 2.6 and 3.6 km above mean sea
520 level (Matrosov et al., 2008). Estimates at lower elevations, especially those in the lowest 1 km,
521 are contaminated by ground clutter. Alternative approaches, combining CPR data with ancillary
522 data have been formulated to account for this challenge (Kulie and Bennartz, 2009; Liu, 2008).
523 Known relationships between CPR reflectivity data and the scattering properties of non-spherical
524 ice crystals are used to derive snowfall at a given elevation above mean sea level; below this
525 elevation a temperature threshold derived from surface data is used to discriminate between rain
526 and snow events. Liu (2008) used <2 °C as the snow/rain threshold, whereas Kulie and Bennartz
527 (2009) used 0 °C as the snow/rain threshold. Temperature thresholds have been the subject of
528 much research and debate for discriminating precipitation phase, as is further discussed in
529 section 4.1.

530
531 CloudSat is part of the A-train or afternoon constellation of satellites, which includes Aqua, with
532 the Moderate Resolution Imaging Spectrometer (MODIS) and the Cloud–Aerosol Lidar and
533 Infrared Pathfinder Satellite Observations (CALIPSO) spacecraft with cloud-profiling Lidar. The
534 sensors onboard A-train satellites provided the unique combination of data to create an
535 operational snow retrieval product. The CPR Level 2 snow profile product (2C-SNOW-
536 PROFILE) uses vertical profile data from the CPR, input from MODIS and the cloud profiling
537 radar, as well as weather forecast data to estimate near surface snowfall (Kulie et al., 2016;
538 Wood et al., 2013). The performance of 2C-SNOW-PROFILE was tested by Cao et al. (2014).
539 This group found the product worked well in detecting light snow but performed less
540 satisfactorily under conditions of moderate to heavy snow because of the non-stationary effects
541 of attenuation on the returned radar signal.

551

552 | The launch of the Global Precipitation Mission (GPM) core observatory in February 2014 holds
553 | promise for the future deployment of operational snow detection products. Building on the
554 | success of the Tropical Rainfall Monitoring Mission (TRMM), the GPM core observatory
555 | sensors include precipitation radar (DPR) and microwave imager (GMI). The GMI has two
556 | millimeter wave channels (166 and 183 GHz) that are specifically designed to detect and retrieve
557 | light rain and snow precipitation. These are more advanced than the sensors onboard the TRMM
558 | spacecraft and permit better quantification of the physical properties of precipitating particles,
559 | particularly over land at middle to high latitudes (Hou et al., 2014). Algorithms for the GPM
560 | mission are still under development, and is partly being driven by data collected during the GPM
561 | Cold Season Experiment (GCPEX) (Skofronick-Jackson et al., 2015). Using airborne sensors to
562 | simulate GPM and DPR measurements, one of the questions that the GCPEX hoped to address
563 | concerned the potential capability of data from the DPR and GMI to discriminate falling snow
564 | from rain or clear air (Skofronick-Jackson et al., 2015). The initial results reported by the GCPEX
565 | study echo some of the challenges recognized for ground-based single polarized radar detection
566 | of snowfall. The relationship between radar reflectivity and snowfall is not unique. For the GPM
567 | mission, it will be necessary to include more variables from dual frequency radar measurements,
568 | multiple frequency passive microwave measurements, or a combination of radar and passive
569 | microwave measurements (Skofronick-Jackson et al., 2015).

570

571 | 4. Current Tools for Predicting Precipitation Phase

572 | 4.1 Prediction Techniques from Ground-Based Observations

573 | Discriminating between solid and liquid precipitation is often based on a near-surface air
574 | temperature threshold (Martinec and Rango, 1986; U.S. Army Corps of Engineers, 1956; L'hôte et
575 | al., 2005). Four prediction methods have been developed that use near-surface air temperature
576 | for discriminating precipitation phase: 1) static threshold, 2) linear transition, 3) minimum and
577 | maximum temperature, and 4) sigmoidal curve (Table 1). A static temperature threshold applies
578 | a single temperature value, such as mean daily temperature, where all of the precipitation above
579 | the threshold is rain, and all below that threshold is snow. Typically this threshold temperature is
580 | near 0 °C (Lynch-Stieglitz, 1994; Motoyama, 1990), but was shown to be highly variable across
581 | both space and time (Kienzle, 2008; Motoyama, 1990; Braun, 1984; Ye et al., 2013). For

585 example, Rajagopal and Harpold (2016) optimized a single temperature threshold at Snow
586 Telemetry (SNOTEL) sites across the western U.S. to show regional variability from -4 to 3 °C
587 (Figure 3). A second discrimination technique is to linearly scale the proportion of snow and rain
588 between a temperature for all rain (T_{rain}) and a temperature for all snow (T_{snow}) (Pipes and Quick,
589 1977;McCabe and Wolock, 2010;Tarboton et al., 1995). Linear threshold models have been
590 parameterized slightly differently across studies, e.g.: $T_{snow} = -1.0$ °C, $T_{rain} = 3.0$ °C (McCabe and
591 Wolock, 2010), $T_{snow} = -1.1$ °C and $T_{rain} = 3.3$ °C (Tarboton et al., 1995), and $T_{snow} = 0$ °C and T_{rain}
592 $= 5$ °C (McCabe and Wolock, 1999b). A third technique specifies a threshold temperature based
593 on daily minimum and maximum temperatures to classify rain and snow, respectively, with a
594 threshold temperature between the daily minimum and maximum producing a proportion of rain
595 and snow (Leavesley et al., 1996). This technique can have a time-varying temperature threshold
596 or include a T_{rain} that is independent of daily maximum temperature. A fourth technique applies a
597 sigmoidal relationship between mean daily (or sub daily) temperature and the proportion or
598 probability of snow versus rain. For example, one method derived for southern Alberta, Canada
599 employs a curvilinear relationship defined by two variables, a mean daily temperature threshold
600 where 50% of precipitation is snow, and a temperature range where mixed-phase precipitation
601 can occur (Kienzle, 2008). Another sigmoidal-based empirical model identified a hyperbolic
602 tangent function defined by four parameters to estimate the conditional snow (or rain) frequency
603 based on a global analysis of precipitation phase observations from over 15,000 land-based
604 stations (Dai, 2008). Selection between temperature-based techniques is typically based on
605 available data, with a limited number of studies quantifying their relative accuracy for
606 hydrological applications (Harder and Pomeroy, 2014).

607
608 Several studies have compared the accuracy of temperature-based PPM to one another and/or
609 against an independent validation of precipitation phase. Sevruk (1984) found that only about
610 68% of the variability in monthly observed snow proportion in Switzerland could be explained
611 by threshold temperature based methods near 0 °C. An analysis of data from fifteen stations in
612 southern Alberta, Canada with an average of >30 years of direct observations noted over-
613 estimations in the mean annual snowfall for static threshold (8.1%), linear transition (8.2%),
614 minimum and maximum (9.6%), and sigmoidal transition (7.1%) based methods (Kienzle, 2008).
615 An evaluation of PPM at three sites in the Canadian Rockies by Harder and Pomeroy (2013)

616 found the largest percent error to occur using a static threshold (11% to 18%), followed by linear
617 relationships (-8% to 11%), followed by a sigmoidal relationships (-3 to 11%). Another study
618 using 824 stations in China with >30 years of direct observations found accuracies of 51.4%
619 using a static 2.2 °C threshold and 35.7% to 47.4% using linear temperature-based thresholds
620 (Ding et al., 2014). Lastly, for multiple sites across the rain-snow transition in southwestern
621 Idaho, static temperature thresholds produced the lowest proportion (68%) whereas a linear-
622 based model produced the highest proportion (75%) of snow, respectively (Marks et al., 2013).
623 Generally these accuracy assessments demonstrated that static threshold methods produced the
624 greatest errors, whereas sigmoidal relationships produced the smallest errors, although variations
625 to this general rule existed across sites.

626

627 Near surface humidity also influences precipitation phase (see Section 2). Three humidity-
628 dependent precipitation phase identification methods are found in the literature: 1) dewpoint
629 temperature (T_d), 2) wet bulb temperature (T_w), and 3) psychrometric energy balance. The
630 dewpoint temperature is the temperature at which an air parcel with a fixed pressure and
631 moisture content would be saturated. In one approach to account for measurement and
632 instrument calibration uncertainties of ± 0.25 °C each, T_d and T_w below -0.5 °C was assumed to
633 be all snow and above +0.5 °C all rain, with a linear relationship between the two being a
634 proportional mix of snow and rain (Marks et al., 2013). T_d of 0.0 °C performed consistently
635 better than T_a in one study by Marks et al. (2001) while a T_d of 0.1 °C for multiple stations in
636 Sweden was less accurate than a T_a of 1.0 °C (Feiccabrino et al., 2013). The wet or ice bulb
637 temperature (T_w) is the temperature at which an air parcel would become saturated by
638 evaporative cooling in the absence of other sources of sensible heat, and is the lowest
639 temperature that falling precipitation can reach. Few studies have investigated the feasibility of
640 T_w for precipitation phase prediction (Olsen, 2003; Ding et al., 2014; Marks et al., 2013). T_w
641 significantly improved prediction of precipitation phase over T_a at 15-minute time steps, but only
642 marginally improved prediction at daily time steps (Marks et al., 2013). Ding et al. (2014)
643 developed a sigmoidal phase probability curve based on T_w and elevation that outperformed T_a
644 threshold-based methods across a network of sites in China. Conceptually, the hydrometeor
645 temperature (T_i) is similar to T_w but is calculated using the latent heat and vapor density gradient.

646 Use of computed T_i value significantly improved precipitation phase estimates over T_a ,
647 particularly as time scales approached one day (Harder and Pomeroy, 2013).

648

649 There has been limited validation of humidity-based precipitation phase prediction techniques
650 against ground-truth observations. Ding et al. (2014) showed that a method based on T_w and
651 elevation increased accuracy by 4.8% to 8.9% over several temperature-based methods. Their
652 method was more accurate than a simpler T_w based method by (Yamazaki, 2001). Feiccabrino et
653 al. (2013) showed that T_d misclassified 3.0% of snow and rain (excluding mixed phased
654 precipitation), whereas T_a only misclassified 2.4%. Ye et al. (2013) found T_d less sensitive to
655 phase discrimination under diverse environmental conditions and seasons than T_a . Froidurot et
656 al. (2014) evaluated several techniques with a critical success index (CSI) at sites across
657 Switzerland to show the highest CSI were associated with variables that included T_w or relative
658 humidity (CSI=84%-85%) compared to T_a (CSI=78%). Marks et al. (2013) evaluated the time at
659 which phase transitioned from snow to rain against field observations across a range of
660 elevations and found that T_d most closely predicted the timing of phase change, whereas both T_a
661 and T_w estimated earlier phase changes than observed. Harder and Pomeroy (2013) compared T_i
662 with field observations and found that error was <10% when T_i was allowed to vary with each
663 daily time-step and >10% when T_i was fixed at 0 °C. The T_i accuracy increased appreciably (i.e.
664 5%-10% improvement) when the temporal resolution was decreased from daily to hourly or 15-
665 minute time steps. The validation studies consistently showed improvements in accuracy by
666 including humidity over PPM based only on temperature.

667

668 Hydrological models employ a variety of techniques for phase prediction using ground based
669 observations (Table 1). All discrete hydrological models (i.e. not coupled to an atmospheric
670 model) investigated used temperature based thresholds that did not consider the near-surface
671 humidity. Moreover, most models use a single static temperature threshold, which was
672 consistently shown to produce lower accuracy than multiple temperature methods. Hydrological
673 models that are coupled to atmospheric models were more able to consider important controls on
674 precipitation phase, such as humidity and atmospheric profiles. This compendium of model PPM
675 highlights the current shortcomings in phase prediction in conventional discrete hydrological
676 models.

680

681 4.2 Prediction Techniques Incorporating Atmospheric Information

682 While many hydrologic models have their own formulations for determining precipitation phase
683 at the ground, it is also possible to initialize hydrologic models with precipitation phase fraction,
684 intensity, and volume from numerical weather simulation model output. Here we discuss the
685 limitations of precipitation phase simulation inherent to WRF (Kaplan et al., 2012; Skamarock et
686 al., 2008) and other atmospheric simulation models. The finest scale spatial resolution employed
687 in atmospheric simulation models is ~1 km and these models generate data at hourly or finer
688 temporal resolutions. Regional climate models (RCM) and global climate models (GCM) are
689 typically coarser than local mesoscale models. The physical processes driving both the removal
690 of moisture from the air and the precipitation phase (Section 2) occur at much finer spatial and
691 temporal resolutions in the real atmosphere than models typically resolve, i.e. <1 km. As with all
692 numerical models, the representation of sub-grid scale processes requires parameterization. At
693 typical scales considered, characterization of mixed phase processes within a condensing cloud
694 depends on both cloud microphysics and kinematics of the surrounding atmosphere. Replicating
695 cloud physics at the multi-kilometer scale requires empiricism. The 30+ cloud microphysics
696 parameterization options in the research version of WRF (Skamarock et al., 2008) vary in the
697 number of classes described (cloud ice, cloud liquid, snow, rain, graupel, hail, etc.), and may or
698 may not accurately resolve changes in hydrometeor phase and horizontal spatial location (due to
699 wind) during precipitation. All microphysical schemes predict cloud water and cloud ice based
700 on internal cloud processes that include a variety of empirical formulations or even simple
701 lookup tables. These schemes vary greatly in their accuracy with “mixed phase” schemes
702 generally producing the most accurate simulations of precipitation phase in complex terrain
703 where much of the water is supercooled (Lin, 2007; Reisner et al., 1998; Thompson et al., 2004;
704 Thompson et al., 2008; Morrison et al., 2005; Zängl, 2007; Kaplan et al., 2012). Comprehensive
705 validation of the microphysical schemes over different land surface types (e. g. warm maritime,
706 flat prairie, etc.) with a focus on different snowfall patterns is lacking. In particular, in transition
707 zones between mountains and plains or along coastlines, the complexity of the microphysics
708 becomes even more extreme due the dynamics and interactions of differing air masses with
709 distinct characteristics. The autoconversion and growth processes from cloud water or ice to
710 hydrometeors contain a strong component of empiricism, in particular the nucleation media and

Deleted: . For example,

717 their chemical composition. Different microphysical parameterizations lead to different spatial
718 distributions of precipitation and produce varying vertical distributions of hydrometeors
719 (Gilmore et al., 2004). Regardless, precipitation rates for each grid cell are averages requiring
720 hydrological modelers to consider the effects of elevation, aspect, etc. in resolving precipitation
721 phase fractions for finer-scale models.

722

723 Numerical models that contain sophisticated cloud microphysics schemes allow assimilation of
724 additional remote sensing data beyond conventional synoptic/large scale observations (balloon
725 data). This is because the coarse spatial and temporal nature of radiosonde data results in the
726 atmosphere being sensed imperfectly/incompletely compared with the scale of motion that
727 weather simulation models can numerically resolve. These observational inadequacies are
728 exacerbated in complex terrain, where precipitation phase fraction can vary on small scales but
729 radar can be blocked by topography and therefore rendered useless in the model initialization.

730 Accurate generation of liquid and frozen precipitation from vapor requires accurate depiction of
731 initial atmospheric moisture conditions (Kalnay and Cai, 2003; Lewis et al., 2006). In
732 acknowledgement of the difficulty and uncertainty of initializing numerical simulation models,
733 atmospheric modelers use the term “bogusing” to describe incorporation of individual
734 observations at a point location into large scale initial conditions in an effort to enhance the
735 accuracy of the simulation (Eddington, 1989). They also employ complex assimilation
736 methodologies to force the early period of the model solutions during the time integration
737 towards fine scale observations (Kalnay and Cai, 2003; Lewis et al., 2006). These asynoptic or
738 fine scale data sources often substantially improve the accuracy of the simulations as time
739 progresses.

740

741 Hydrologists are increasingly using output from atmospheric models to drive hydrologic models
742 from daily to climate or multi-decadal timescales (Tung and Haith, 1995; Pachauri, 2002; Wood
743 et al., 2004; Rojas et al., 2011; Yucel et al., 2015). These atmospheric models suffer from the
744 same data paucity and scale issues that likewise challenge the implementation and validation of
745 hydrologic models. Uncertainties in their output, including precipitation volume and phase,
746 begins with the initialization of the atmospheric model from measurements, increases with model
747 choice and microphysics as well as turbulence parameterizations, and is a strong function of the

Adrian Harpold 11/20/16 2:22 PM

Deleted: s

749 scale of the model. The significance of these uncertainties varies by application, but should be
750 acknowledged. Furthermore, these uncertainties are highly variable in character and magnitude
751 from day to day and location to location. Thus, there has been very little published concerning
752 how well atmospheric models predict precipitation phase. Finally, lack of ground measurements
753 leaves hydrologists with no means to assess and validate atmospheric model predictions.

Deleted: the hydrologist

754 5. Research Gaps

756 The incorrect prediction of precipitation phase leads to cascading effects on hydrological
757 modeling (Figure 1). Meeting the challenge of accurately predicting precipitation phase requires
758 the closing of several critical research gaps, (Figure 4). Perhaps the most pressing challenge for
759 improving PPM is developing and employing new and improved sources of data. However, new
760 data sources will not yield much benefit without effective incorporation of data into predictive
761 models, (Figure 4). Additionally, both the scientific and management communities lack data
762 products that can be readily understood and broadly used. Addressing these research gaps
763 requires simultaneous engagement both within and between the hydrology and atmospheric
764 observation and modeling communities. Changes to atmospheric temperature and humidity
765 profiles from regional climate change will likely challenge conventional precipitation phase
766 prediction in ways that demand additional observations and improved forecasts.

768 5.1 Conduct focused field campaigns

769 Intensive field campaigns are extremely effective approaches to address fundamental research
770 gaps focused on the discrimination between rain, snow, and mixed-phase precipitation at the
771 ground by providing opportunities to test novel sensors, and detailed datasets to develop remote
772 sensing retrieval algorithms, and improve PPM estimation methods. The recent Global
773 Precipitation Measurement (GPM) Cold Season Precipitation Experiment (GCPEX) is an
774 example of such a campaign in non-complex terrain where simultaneous observations using
775 arrays of both airborne and ground-based sensors were used to measure and characterize both
776 solid and liquid precipitation (e.g. Skofronick-Jackson et al., 2015). Similar intensive field
777 campaigns are needed in complex terrain that is frequently characterized by highly dynamic and
778 spatially variable hydrometeorological conditions. Such campaigns are expensive to conduct, but
779 can be implemented as part of operational nowcasting to develop rich data resources to advance

784 [scientific understanding as was very effectively done during the Vancouver Olympic Games in](#)
785 [2010 \(Isaac et al., 2014; Joe et al., 2014\). The research community should utilize existing](#)
786 [datasets and capitalize on similar opportunities and expand environmental monitoring networks](#)
787 [to simultaneously advance both atmospheric and hydrological understanding, especially in](#)
788 [complex terrain spanning the rain-snow transition zone.](#)

789 [5.2](#) Incorporate humidity information

791 Atmospheric humidity affects the energy budget of falling hydrometeors (Section 4.1), but is
792 rarely considered in precipitation phase prediction. The difficulty in incorporating humidity
793 mainly arises from a lack of observations, both as point measurements and distributed gridded
794 products. For example, while some reanalysis products have humidity information (i.e. National
795 Centers for Environmental Prediction, NCEP reanalysis) they are at spatial scales (i.e. > 1
796 degree) too coarse for resolving precipitation phase in complex topography. Addition of high-
797 quality aspirated humidity sensors at snow monitoring stations, such as the SNOTEL network,
798 would advance our understanding of humidity and its effects on precipitation phase in the
799 mountains. Because dry air masses have regional variations controlled by storm tracks and
800 proximity to water bodies, sensitivity of precipitation phase to humidity variations driven by
801 regional warming remains relatively unexplored.

803 Although humidity datasets are relatively rare in mountain environments, some gridded data
804 products exist that can be used to investigate the importance of humidity information. Most
805 interpolated gridded data products either do not include any measure of humidity (e.g. Daymet or
806 WorldClim) or use daily temperature measurements to infer humidity conditions (e.g. PRISM).

807 [In complex terrain, air temperature can also vary dramatically at relatively small scales from](#)
808 [ridgetops to valley bottoms due to cold air drainage \(Whiteman et al., 1999\) and hence can](#)
809 [introduce errors into inferential techniques such as these.](#) Potentially more useful are data
810 assimilation products, such as NLDAS-2, that provide humidity and temperature values at 1/8th
811 of a degree scale over the continental U.S. In addition, several data reanalysis products are often
812 available at 1 to 3 year lags from present, including NCEP/NCAR, NARR, and the 20th Century
813 reanalysis. Given the relatively sparse observations of humidity in mountain environments, the
814 accuracy of gridded humidity products is rarely rigorously evaluated (Abatzoglou, 2013). More

817 work is needed to understand the added skill provided by humidity datasets for predicting
818 precipitation phase and its distribution over time and space.

819

820 5.2 Incorporate atmospheric information

821 We echo the call of Feiccabrino et al. (2015) for greater incorporation of atmospheric
822 information into phase prediction and additional verification of the skill in phase prediction
823 provided by atmospheric information.

824

825 Several avenues exist to better incorporate atmospheric information into precipitation phase
826 prediction, including direct observations, remote sensing observations, and model products.
827 Radiosonde measurements made daily at many airports and weather forecasting centers have
828 shown some promise for supplying atmospheric profiles of temperature and humidity (Froidurot
829 et al., 2014). However, these data are only useful to initialize the larger scale structure of

830 temperature and water vapor, and may not capture local-scale variations in complex terrain. It is
831 also their lack of temporal and spatial frequency that prevents their use in accurate precipitation
832 phase prediction, which is inherently a mesoscale problem, i.e., scales of motion <100 km.

833 Atmospheric information on the bright-band height from Doppler radar has been utilized for
834 predicting the altitude of the rain-snow transition (Lundquist et al., 2008; Minder, 2010), but has
835 rarely been incorporated into hydrological modeling applications (Maurer and Mass, 2006;
836 Mizukami et al., 2013). In addition to atmospheric observations, modeling products that
837 assimilate observations or are fully physically-based may provide additional information for
838 precipitation phase prediction. Numerous reanalysis products (described in Section 2.2) provide
839 temperature and humidity at different pressure levels within the atmosphere. To our knowledge,
840 information from reanalysis products has yet to be incorporated into precipitation phase
841 prediction for hydrological applications. Bulk microphysical schemes used by meteorological
842 models (i.e. Weather Research and Forecasting WRF model) provide a physically-based estimate
843 of precipitation phase. These schemes capture a wide-variety of processes, including
844 evaporation, sublimation, condensation, and aggradation, and output between two and ten
845 precipitation types. Historically, meteorological models have not been run at spatial scales
846 capable of resolving convective dynamics (e.g. <2 km), which can exacerbate error in
847 precipitation phase prediction in complex terrain with a moist neutral atmosphere. Coarse

Adrian Harpold 11/20/16 2:22 PM

Deleted: 2

Adrian Harpold 11/20/16 2:22 PM

Deleted: and

Adrian Harpold 11/20/16 2:22 PM

Deleted: Reduced computational restrictions on running these models over large geographic extents (Rasmussen et al., 2012)

853 meteorological models also struggle to produce pockets of frozen precipitation from advection of
854 moisture plumes between mountain ranges and cold air wedged between topographic barriers.
855 However, reduced computational restrictions on running these models at finer spatial scales and
856 over large geographic extents (Rasmussen et al., 2012) are enabling further investigations into
857 precipitation phase change under historical and future climate scenarios. This suggests that finer
858 dynamical downscaling is necessary to resolve precipitation phase which is consistent with
859 similar work attempting to resolve winter precipitation amount in complex terrain (Gutmann et
860 al., 2012). A potentially impactful area of research is to integrate this information into novel
861 approaches to improve precipitation phase prediction skill.

862

863 5.3 Disdrometer networks operating at high temporal resolutions

864 An increase in the types and reliability of disdrometers over the last decade has provided a new
865 suite of tools to more directly measure precipitation phase. Despite this new potential resource
866 for distinguishing snow and rain, very limited deployments of disdrometers have occurred at the
867 scale necessary to improve hydrologic modeling and rain-snow elevation estimates. The lack of
868 disdrometer deployment likely arises from a number of potential limitations: 1) known issues
869 with accuracy, 2) cost of these systems, and 3) power requirements needed for heating elements.
870 These limitations are clearly a factor in procuring large networks and deploying disdrometers in
871 complex terrain that is remote and frequently difficult to access. However, we advise that

872 disdrometers offer numerous benefits that cannot be substituted with other measurements: 1)
873 they operate at fine temporal scales, 2) they operate in low light conditions that limit other direct
874 observations, and 3) they provide land surface observations rather than precipitation phase in the
875 atmosphere (as compared to more remote methods). Moreover, improvements in disdrometer and
876 power supply technologies that address these limitations would remove restrictions on increased
877 disdrometer deployment.

878

879 Transects of disdrometers spanning the rain-snow elevations of key mountain areas could add
880 substantially to both prediction of precipitation phase for modeling purposes, as well as
881 validating typical predictive models. We advocate for transects over key mountain passes where
882 power is generally available and weather forecasts for travel are particularly important. In
883 addition, co-locating disdrometers at long-term research stations where precipitation phase

Adrian Harpold 11/20/16 2:22 PM

Deleted: remote areas.

885 observations could be tied to micro-meteorological and hydrological observations has distinct
886 advantages. These areas often have power supplies and instrumentation expertise to operate and
887 maintain disdrometer networks.

888

889 5.4 Compare different indirect phase measurement methods

890 There is an important need to evaluate the accuracy of different PPM to assess tradeoffs between
891 model complexity and skill (Figure 4). Given the potential for several types of observations to
892 improve precipitation phase prediction (section 5.1-5.3), quantifying the relative skill provided
893 by these different lines of evidence is a critical research gap. Although assessing relative
894 differences between methods is potentially informative, comparison to ground truth
895 measurements is critical for assessing accuracy. Disdrometer measurements and video imaging
896 (Newman et al., 2009) are ideal ground truthing methods that can be employed at fine time steps
897 and under a variety of conditions (section 5.3). Less ideal for accuracy assessment studies are
898 direct visual observations that are harder to collect at fine time steps and in low light conditions.
899 Similarly, employing coupled observations of precipitation and snow depth has been used to
900 assess accuracy of different precipitation phase prediction methods (Marks et al., 2013; Harder
901 and Pomeroy, 2013), but accuracy assessment of these techniques themselves are lacking under a
902 wide range of different conditions.

903

904 A variety of accuracy assessments are needed that will require co-located distributed
905 measurements. One critical accuracy assessment involves the consistency of different
906 precipitation phase prediction methods under different climate and atmospheric conditions.
907 Assessing the effects of climate and atmospheric conditions requires measurements from a
908 variety of sites covering a range of hydroclimatic conditions and record lengths that span the
909 conceivable range of atmospheric conditions at a given site. Another important evaluation metric
910 is the performance over different time steps. Harder and Pomeroy (2013) showed that
911 hydrometeor and temperature-based prediction methods had errors that substantially decreased
912 across shorter time steps. Identifying the effects of time step length on the accuracy of different
913 prediction methods has been relatively unexplored, but is critical to selecting the proper method
914 for different hydrological applications. Finally, the performance metrics used to assess accuracy
915 should be carefully considered. The applications of precipitation phase prediction methods are

920 diverse, necessitating a wide variety of performance metrics, including the probability of snow
921 versus rain (Dai, 2008), the error in annual or total snow/rain accumulation (Rajagopal and
922 Harpold, 2016), performance under extreme conditions of precipitation amount and intensity,
923 determination of the snow-rain elevation (Marks et al., 2013), and uncertainty arising from
924 measurement error and accuracy. Comparison of different metrics across a wide-variety of sites
925 and conditions is lacking but is greatly needed to advance cold-region hydrologic science.

926

927 5.5 Develop spatially resolved products

928 Many hydrological applications will benefit from gridded data products that are easily integrated
929 into standard hydrological models. Currently, very few options exist for gridded data
930 precipitation phase products. Instead, most hydrological models have some type of submodel or
931 simple scheme that specifies precipitation phase as rain, snow, or mixed (see Section 4). While
932 testing PPM with ground based observations could lead to improved submodels, we believe
933 development of gridded forcing data may be an easier and more effective solution for many
934 hydrological modeling applications.

935

936 Gridded data products could be derived from a combination of remote sensing and existing
937 model products, but would need to be extensively evaluated. The NASA GPM mission is
938 beginning to produce gridded precipitation phase products at 3-hour and 0.1 degree resolution.
939 However, GPM phase is measured at the top of the atmosphere, typically relies on simple
940 temperature-thresholds, and is yet to be validated with ground based observations. Another
941 existing product is the Snow Data Assimilation System (SNODAS) that estimates liquid and
942 solid precipitation at the 1 km scale. However, the developers of SNODAS caution that it is not
943 suitable for estimating storm totals or regional differences. Furthermore, to our knowledge the
944 precipitation phase product from SNODAS has not been validated with ground observations. We
945 suggest the development of new gridded data products that utilize new PPM (i.e. Harder and
946 Pomeroy, 2013) and new and expanded observational datasets, such as atmospheric information
947 and radar estimates. We advocate for the development of multiple gridded products that can be
948 evaluated with ground observations to compare and contrast their strengths. [Accurate gridded
949 phase products rely on the ability to represent the physics of water vapor and energy flows in
950 complex terrain \(e.g. Holden et al., 2010\) where statistical downscaling methods are typically](#)

951 | insufficient (Gutmann et al., 2012). This would also allow for ensembles of phase estimates to be
952 | used in hydrological models, similar to what is currently being done with gridded precipitation
953 | estimates.

954

955 | 5.6 Characterization of regional variability and response to climate change

956 | The inclusion of new datasets, better validation of PPM, and development of gridded data
957 | products will poise the hydrologic community to improve hydrological predictions and better
958 | quantify regional sensitivity of phase change to climate changes. Because broad-scale techniques

959 | applied to assess changes in precipitation phase and snowfall have relied on temperature, both

960 | regionally (Klos et al., 2014; Pierce and Cayan, 2013; Knowles et al., 2006), and globally

961 | (Kapnick and Delworth, 2013; O’Gorman, 2014), they have not fully considered the potential

962 | non-linearities created by the absence of wet bulb depressions and humidity in assessment of

963 | sensitivity to changes in phase. Consequently, the effects of changes from snow to rain from

964 | warming and corresponding changes in humidity will be difficult to predict with the current

965 | PPM. Recent efforts by Rajagopal and Harpold (2016) have demonstrated that simple

966 | temperature thresholds are insufficient to characterize snow-rain transition across the western

967 | U.S. (Figure 3), perhaps because of differences in humidity. An increased focus on future

968 | humidity trends, patterns, and GCM simulation errors (Pierce et al., 2013) and availability of

969 | downscaled humidity products at increasingly finer scales (e.g.: assessments of the relative role

970 | of temperature and humidity in future precipitation phase changes. Recent remote sensing

971 | platforms, such as GPM, may offer an additional tool to assess regional variability, however, the

972 | current GPM precipitation phase product relies on wet bulb temperatures based on model output

973 | and not microwave-based observations (Huffman et al., 2015). Besides issues with either spatial

974 | or temporal resolution or coverage, one of the main challenges in using remotely sensed data for

975 | distinguishing between frozen and liquid hydrometeors is the lack of validation. Where products

976 | have been validated, the results are usually only relevant for the locale of the study area.

977 | Spaceborne radar combined with ground-based radar offers perhaps the most promising solution,

978 | but given the non-unique relationship between radar reflectivity and snowfall, further testing is

979 | necessary in order to develop reliable algorithms.

987 | [Future work is needed to improve projections of changes in snowpack and water availability](#)
988 | [from regional to global scales.](#) This local to sub-regional characterization is needed for water
989 | resource prediction and to better inform decision and policy makers. In particular, the ability to
990 | predict the transitional rain-snow elevations and its uncertainty is critical information for a
991 | variety of end-users, including state and municipal water agencies, [flood forecasters](#), agricultural
992 | water boards, transportation agencies, and wildlife, forest, and land managers. Fundamental
993 | advancements in characterizing regional variability are possible by addressing the research
994 | challenges detailed in sections 5.1-5.5.

995

996 | 6. Conclusions

997 | [Our](#) review paper is a step towards communicating the potential bottlenecks in hydrological
998 | modeling caused by poor representation of precipitation phase (Figure 1). Our goals [are](#) to
999 | demonstrate that major research gaps in our ability to PPM are contributing to error and reducing
1000 | predictive skill in hydrological modeling. By highlighting the research gaps that could advance
1001 | the science of PPM, we [provide](#) a roadmap for future advances (Figure 4). While many of the
1002 | research gaps are recognized by the community and are being pursued, including incorporating
1003 | atmospheric and humidity information, while others remain essentially unexplored (e.g.
1004 | production of gridded data, widespread ground validation, and remote sensing validation).

1005

1006 | The key points that must be communicated to the hydrologic community and its funding
1007 | agencies can be distilled into the following two statements: 1) current PPM algorithms are too
1008 | simple and are not well-validated for most locations, 2) the lack of sophisticated PPM increases
1009 | the uncertainty in estimation of hydrological sensitivity to changes in precipitation phase at local
1010 | to regional scales. We advocate for better incorporation of new information (5.1-5.2) and
1011 | improved validation methods (5.3-5.4) to advance our current PPM methods [and observations](#).

1012 | These improved PPM algorithms [and remote-sensing observations](#) will be capable of developing
1013 | gridded datasets (5.5) and providing new insight that reduce the uncertainty of predicting
1014 | regional changes from snow to rain (5.6). A concerted effort by the hydrological and atmospheric
1015 | science communities to address the PPM challenge will remedy current limitations in
1016 | hydrological modeling of precipitation phase, advance of understanding of cold regions
1017 | hydrology, and provide better information to decision makers.

1477

1478 Figure 1. Precipitation phase has numerous implications for modeling the magnitude, storage,
 1479 partitioning, and timing of water inputs and outputs. Potentially affecting important
 1480 ecohydrological and streamflow quantities important for prediction.

1481

Adrian Harpold 11/20/16 2:22 PM

Deleted: .

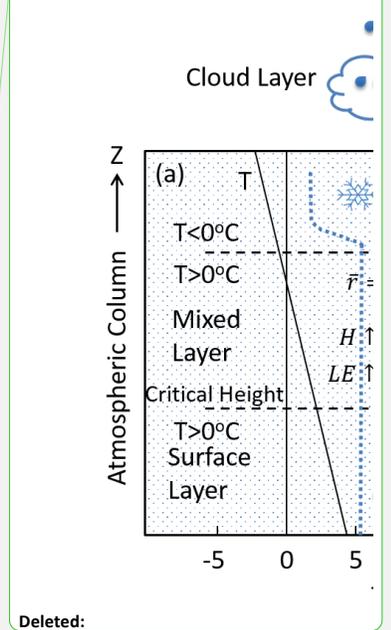

1483

1484 Figure 2: The phase of precipitation at the ground surface is strongly controlled by atmospheric
 1485 profiles of temperature and humidity. While conditions exist that are relatively easy to predict
 1486 rain (a) and snow (b), many conditions lead to complex heat exchanges that are difficult to
 1487 predict with ground based observations alone (c). The blue dotted line represents the mixing
 1488 ratio. H , LE , $f(\text{sat})$, and r are abbreviations for sensible heat, latent heat of evaporation, function
 1489 of saturation and mixing ratio respectively. The arrow after H or LE indicate the energy of the
 1490 hydrometeor either increasing (up) or decreasing (down) which is controlled by other
 1491 atmospheric conditions.

Response to reviewer #1

We appreciate the reviewer's positive overall comments on the manuscript. We make detailed responses below in **blue** and have made the editorial changes wherever possible. We also agree with the more major comments regarding validation of the microphysics schemes and the potential influence of temperature-only PPM in large-scale forecasting of phase under changing climate. Line numbers refer to track changes version of document.

Response to specific comments:

1) Line 21: Change "The review" to "This review" or "Our review". The previous sentence structure made it unclear which review is being referred to and required the reader to go back to the previous sentence wondering what review is being mentioned.

This was changed. We also made similar changes on line 154 and 998.

2) Line 184: either here or elsewhere, it should be mentioned that it is important to validate these microphysics (or other properties if you move this to the discussion) over various land surfaces / types. A microphysics scheme that performs well in Iowa (flat prairie) may not perform well over Idaho (complete mountain terrain) or the Oregon Cascades (coastal warm snow).

This was expanded on line 235 to read "The rain-snow line predicted by atmospheric models is very sensitive to these microphysics (Minder, 2010) and validating the microphysics across locations with complex physiography is challenging."

We agree that a discussion of verifying the microphysics schemes, in particular for the complex terrain that is the focus of the paper, would strengthen the paper. We have added several sentences beginning on line 701-709: "These schemes vary greatly in their accuracy with "mixed phase" schemes generally producing the most accurate simulations of precipitation phase in complex terrain where much of the water is supercooled (Lin, 2007; Reisner et al., 1998; Thompson et al., 2004; Thompson et al., 2008; Morrison et al., 2005; Zängl, 2007; Kaplan et al., 2012). Comprehensive validation of the microphysical schemes over different land surface types (e. g. warm maritime, flat prairie, etc.) with a focus on different snowfall patterns is lacking. In particular, in transition zones between mountains and plains or along coastlines, the complexity of the microphysics becomes even more extreme due the dynamics and interactions of differing air masses with distinct characteristics."

3) Line 248: The "((" should be moved to before 1967 based on how the reference is integrated into the sentence

This was corrected.

4) Line 303: need parenthesis instead of brackets

This was corrected.

5) Lines 433, 601: a space is needed between references

This was corrected.

6) Line 583: what is meant by “performing the best”? The best precipitation over mountains? Lowest errors in climatology? Lowest errors in variability? Please clarify.

This was clarified on line 701: “These schemes vary greatly in their accuracy with “mixed phase” schemes generally producing the most accurate simulations of precipitation phase in complex terrain where much of the water is supercooled (Lin, 2007; Reisner et al., 1998; Thompson et al., 2004; Thompson et al., 2008; Morrison et al., 2005; Zängl, 2007; Kaplan et al., 2012).”

7) Line 641: “too” not “to”

This was corrected.

8) Line 783 and Figure 3: The authors should consider adding an accompanying western U.S. climatology map of humidity to show it has significant spatial variability (implied by the statement here and similar ones elsewhere, but not presently shown).

This is a good suggestion. We will add a map as a second panel to Figure 3 using the University of Idaho Gridded Meteorological Datasets, which is essentially NLDAS-2 data downscaled to 4 km.

9) Conclusion/Discussion: I would like to see a paragraph added here or in the previous section (5.6) discussing the implications of this review / points raised for findings from climate change studies focused on snowfall. For example, there are several done at the global scale / continental scale (O’Gorman 2014; Cayan and Pierce. 2013; Kapnick and Delworth 2012). These studies present large-scale changes in snowfall mainly due to temperature (all use temperature-based metrics for phase partitioning), but based on this review, miss the non-temperature induced sensitivity of phase type, likely with nonlinear consequences. Should the changes found in these studies be expected as the temperature signal at some point overwhelms all other signals? Or might the differences due to climate change be non-linear in all cases? A nice final point of this manuscript would place this study within the framework of these larger scale studies / findings as it is implied that reviewing and exploring phase type will have consequences for understanding future water availability and change.

This is an excellent point that was hinted at in the discussion but not fully addressed. We expanded section 5.6 on line 861 to read: “Because broad-scale techniques applied to assess changes in precipitation phase and snowfall have relied on temperature, both regionally (Klos et al., 2014; Pierce and Cayan, 2013; Knowles et al., 2006) and globally (Kapnick and Delworth, 2013; O’Gorman, 2014), they have not fully considered the potential non-linearities created by the absence of wet bulb depressions and humidity in assessment of sensitivity to changes in phase.”

The questions raised about the non-temperature induced sensitivity of phase type in the future is an excellent point for future work, and is beyond the scope of this review. Future work to address these questions is now called for in this paragraph with explicit references to studies and data products that could enable such investigations to proceed on line 867: “An increased focus on future humidity trends, patterns, and GCM simulation errors (Pierce et al., 2013) and availability of downscaled humidity products at increasingly finer scales (e.g.: Abatzoglou, 2013; Pierce and Cayan, 2016) will enable

detailed assessments of the relative role of temperature and humidity in future precipitation phase changes.”

10) Figure 1: The arrows and curly bracket should be changed to be a different color (not grey) to provide contrast. Perhaps red or blue? They presently do not stand out easily / show the movement of information as presently shown. A more contrasting color choice will make this figure easier to read and understand.

We agree and have made these changes to a new figure.

Response to reviewer #2

We appreciate the reviewer's constructive and specific comments on the manuscript. We have addressed all the minor editorial comments and responded to the more detailed comments in **blue** text below. We agree that the sign of a good review paper is creating something new from the gathered information, which was the objective of Section 5. We will bolster that effort by following the reviewer's recommendation about more details on the incorporation of atmospheric models into PPM and better explaining the importance/role of complex terrain. Line numbers refer to track changes version of document.

2 Specific comments

2.1 Synopsis of remotely sensed information

Section 3.2 and 3.3 are quite long indicating an emphasis on remotely sensed observations. After reading the two sections I feel that a synopsis is missing with general information about the applicability of those observations for PPM, which seems a bit lost in the detailed description in these long sections. I would suggest a summarizing paragraph, or an overview table with the following items, for example: description, coverage, availability, resolution, validated, references. The remotely sensed observations do also hardly appear in section 5 (Research Gaps), while the need to validate these products, was mentioned in the abstract. This synopsis can also be placed in the very short Conclusion section, in which the remotely sensed observations are also only very briefly mentioned (line 800).

We agree that a reader could get lost in the details of this section and not see the bigger picture. To improve this section, we have added both a brief overview at the beginning of section 3.2 and 3.3, as well as a table that more succinctly summarizes the technologies. The research gaps section did discuss remote sensing in section 5.2 and 5.5. Section 5.6 had the following sentence added on line 970: "Recent remote sensing platforms, such as GPM, may offer an additional tool to assess regional variability, however, the current GPM precipitation phase product relies on wet bulb temperatures based on model output and not microwave-based observations (Huffman et al., 2015). Besides issues with either spatial or temporal resolution or coverage, one of the main challenges in using remotely sensed data for distinguishing between frozen and liquid hydrometeors is the lack of validation. Where products have been validated, the results are usually only relevant for the locale of the study area. Spaceborne radar combined with ground-based radar offers perhaps the most promising solution, but given the non-unique relationship between radar reflectivity and snowfall, further testing is necessary in order to develop reliable algorithms."

The first paragraph of section 3.2 now reads "Ground-based remote sensing observations have been available for several decades to detect precipitation phase using radar. Until recently, most ground-based radar stations were operated as conventional Doppler systems that transmit and receive radio waves with single horizontal polarization. Developments in dual polarization ground radar such as those that function as part of the

U.S. National Weather Service NEXRAD network (NOAA, 2016), have resulted in systems that transmit radio signals with both horizontal and vertical polarizations. In general, ground-based remote sensing observation, either single or dual-pol, remain underutilized for detecting precipitation phase and are challenging to apply in complex terrain (Table 2).”

The first paragraph in Section 3.3 now reads “Spaceborne remote sensing observations typically use passive or active microwave sensors to determine precipitation phase (Table 2). Many of the previous passive microwave systems were challenged by coarse resolutions and difficulties retrieving snowfall over snow-covered areas. More recent active microwave systems have advantage for detecting phase in terms of accuracy and spatial resolution, but remain largely unverified. Table 2 provides an overview of these space-based remote sensing technologies that are described in more detail below.”

Table 2 has information on single polarized and dual-polarized ground radar, and spaceborne passive and active microwave sensors. The information in the table will include description, spatial resolution, temporal resolution, phase validation, and relevant references.

2.2 Incorporation of atmospheric information

The authors describe well in section 4.2 the problematic scale issue between kilometer-scaled atmospheric models and processes influencing PP which act on a finer resolution. They emphasize that “. . . grid cells are averages requiring hydrological modellers to consider effects of elevation, aspect, etc. in resolving precipitation phase fractions for finer-scaled models.” (1588ff). I think this is a very relevant topic and I would like to see this topic further discussed in the research gap section, maybe even with some conceptual ideas and/or reference to existing work, or – if not existent – references to similar work done by the downscaling community to represent unresolved variability on the sub-grid scale.

We agree that model scale is an important effect to consider and have added text to section 5.2 starting on line 845: “Historically, meteorological models have not been run at spatial scales capable of resolving convective dynamics (e.g. <2 km), which can exacerbate error in precipitation phase prediction in complex terrain with a moist neutral atmosphere. Coarse meteorological models also struggle to produce pockets of frozen precipitation from advection of moisture plumes between mountain ranges and cold air wedged between topographic barriers. However, reduced computational restrictions on running these models at finer spatial scales and over large geographic extents (Rasmussen et al., 2012) are enabling further investigations into precipitation phase change under historical and future climate scenarios. This suggests that finer dynamical downscaling is necessary to resolve precipitation phase which is consistent with similar work attempting to resolve winter precipitation amount in complex terrain (Gutmann et al., 2012).”

The authors also promote in section 5.5 (Develop spatially resolved products) the benefit of gridded products. Since these products probably suffer the same scale problems as mentioned in 1588 for atmospheric models, the authors may discuss this aspect of including sub-grid variability here as well.

We agree and add this sentence in section 5.5 beginning on line 948: “Accurate gridded phase products rely on the ability to represent the physics of water vapor and energy flows in complex terrain (e.g. Holden et al., 2010) where statistical downscaling methods are typically insufficient (Gutmann et al., 2012).”

2.3 Specific conclusions for complex terrain

The authors mention in the abstract that the manuscript “. . .conveys the advancements needed to improve predictions in complex terrain...” (l22f) and that in complex terrain robust observation networks are missing (l26f). I cannot find many details in the manuscript which allow formulating such a focus on complex terrain in the abstract. I suggest adding a paragraph in the research gap section summarizing specific issues in complex terrain.

The reviewer makes an important point that we address in numerous places within the manuscript. On line 235: “The rain-snow line predicted by atmospheric models is very sensitive to these microphysics (Minder, 2010) and validating the microphysics across locations with complex physiography is challenging.” Line 250: “Few research stations, however, have this benefit, particularly in many remote regions and in complex terrain.” On line 349: “In general, ground-based remote sensing observation, either single or dual-pol, remain underutilized for detecting precipitation phase and are challenging to apply in complex terrain (Table 2).” On line 701: “These schemes vary greatly in their accuracy with “mixed phase” schemes generally producing the most accurate simulations of precipitation phase in complex terrain where much of the water is supercooled (Lin, 2007; Reisner et al., 1998; Thompson et al., 2004; Thompson et al., 2008; Morrison et al., 2005; Zängl, 2007; Kaplan et al., 2012). Comprehensive validation of the microphysical schemes over different land surface types (e. g. warm maritime, flat prairie, etc.) with a focus on different snowfall patterns is lacking. In particular, in transition zones between mountains and plains or along coastlines, the complexity of the microphysics becomes even more extreme due the dynamics and interactions of differing air masses with distinct characteristics.”

We add a new section (5.1) in at the beginning of the research gap section: “Intensive field campaigns are extremely effective approaches to address fundamental research gaps focused on the discrimination between rain, snow, and mixed-phase precipitation at the ground by providing opportunities to test novel sensors, and detailed datasets to develop remote sensing retrieval algorithms, and improve PPM estimation methods. The recent Global Precipitation Measurement (GPM) Cold Season Precipitation Experiment (GCPEX) is an example of such a campaign in non-complex terrain where simultaneous observations using arrays of both airborne and ground-based sensors were used to measure and characterize both solid and liquid precipitation (e.g. Skofronick-Jackson et al., 2015). Similar intensive field campaigns are needed in complex terrain that is frequently characterized by highly dynamic and spatially variable hydrometeorological conditions. Such campaigns are expensive to conduct, but can be implemented as part of operational nowcasting to develop rich data resources to advance scientific understanding as was very effectively done during the Vancouver Olympic Games in 2010 (Isaac et al., 2014; Joe et al., 2014). The research community should utilize existing datasets and capitalize on similar opportunities and expand environmental monitoring networks to simultaneously advance both atmospheric and hydrological understanding, especially in

complex terrain spanning the rain-snow transition zone.” We also add this sentence to section 5.2: “In complex terrain, air temperature can also vary dramatically at relatively small scales from ridgetops to valley bottoms due to cold air drainage (Whiteman et al., 1999) and hence can introduce errors into inferential techniques such as these.” Multiple sentences are added to section 5.3: “Historically, meteorological models have not been run at spatial scales capable of resolving convective dynamics (e.g. <2 km), which can exacerbate error in precipitation phase prediction in complex terrain with a moist neutral atmosphere. Coarse meteorological models also struggle to produce pockets of frozen precipitation from advection of moisture plumes between mountain ranges and cold air wedged between topographic barriers. However, reduced computational restrictions on running these models at finer spatial scales and over large geographic extents (Rasmussen et al., 2012) are enabling further investigations into precipitation phase change under historical and future climate scenarios. This suggests that finer dynamical downscaling is necessary to resolve precipitation phase which is consistent with similar work attempting to resolve winter precipitation amount in complex terrain (Gutmann et al., 2012).” And an additional sentence in section 5.5: “Accurate gridded phase products rely on the ability to represent the physics of water vapor and energy flows in complex terrain (e.g. Holden et al., 2010) where statistical downscaling methods are typically insufficient (Gutmann et al., 2012).”

2.4 Formality issues

I would in general like to see page numbers to relevant sections when citing a book (or similar). One prominent example is the book authored by the U.S. Army Corps of Engineers, which regularly is available as a non-searchable pdf document or as a hardcopy. It contains various topics relevant to snow hydrology. To find the cited paragraph without mentioning page numbers is nearly impossible. I think this example shows that the standard of including page numbers when citing books and similar long references should be used. Similarly, the authors have not included access dates for all cited URL (e.g. line 200, line 1077 and others). Some cited references appear different than others (sometimes white spaces between “;” sometimes italic “et al.”, sometimes with square brackets). More importantly, there are a few citations which do not appear in the reference list. These points are mentioned in my section “Comments line by line” below.

We appreciate the reviewer’s attention to detail and have corrected these in the text and references.

2.5 Motivate Figures in the text

Figure 1 and Figure 4 are hardly described in the text, although containing important information. I would suggest that the authors link their text closer to those Figures, especially to Figure 1 which shows the consequences of wrong PP in a hydrological model.

This is a good point by the reviewer. We add additional references to Figure 1 in the introduction. We also add this sentence to the beginning of section 5: “The cascading effects of incorrectly predicting precipitation phase lead to cascading effects on hydrological modeling (Figure 1).” We also better reference Figure 4 at the beginning of section 5 and within section 5.5.

2.6 Explain abbreviations and lines in Figure 2

It is not clear to me what the blue dotted line is (probably the mixing ratio). I would also suggest to add the used abbreviations for H, LE, f(sat), r etc in the caption. The arrow after H or LE should probably indicate that the energy of the hydrometeor is increasing because of a sensible heat transfer? Please clarify these uncertainties.

The following lines have been added to the caption for figure 2: “The blue dotted line represents the mixing ratio. H, LE, f(sat), and r are abbreviations for sensible heat, latent heat of evaporation, function of saturation and mixing ratio respectively. The arrow after H or LE indicate the energy of the hydrometeor either increasing (up) or decreasing (down) which is controlled by other atmospheric conditions.”

3 Comments line-by-line

Line 33ff: This sentence is the same as the previous.

This was deleted.

Line 200/208: Please use access dates with URLs. I suggest putting the links in the reference list.

This was corrected throughout the document.

Line 231: Lejeune not in reference list.

This was incorrect and changed to L'hôte et al., 2005.

Line 265. Not clear which the comparison study is.

This was corrected to read: In a comparison study by Caracciolo et al., (2006), the PARSIVEL optical disdrometer, originally described by Löffler-Mang et al. (1999) did not perform well against a 2DVD because of problems related to the detection of slow fall velocities for snow.

Line 354. The cited study is called Arkin and Ardanuy (1998).

This was corrected to 1989.

Line 411 and elsewhere: Kulie and Bennartz (2003) not in reference list

This was corrected.

Line 539: Froidurot wrongly spelled.

This was corrected

Line 945: no page numbers

This was corrected

Line 973: Krug (1995) and Bergström (1995) refer to the same document .

This was corrected

Line 978: Missing page numbers

This was corrected
