Abstract. Distributed hydrological model has been successfully used in small watershed flood forecasting, but there are still challenges for the application in large watershed, one of them is the model's spatial resolution effect. To cope with this challenge, two efforts could be made, one is to improve the model's computation efficiency in large watershed, another is implementing the model on high performance supercomputer. This study sets up a physically based distributed hydrological model for flood forecasting of Liujiang River Basin in south China. Terrain data DEM, soil and land use are downloaded from the website freely, and the model structure with a high resolution of 200m*200m grid cell is set up. The initial model parameters are derived from the terrain property data, and then optimized by using the PSO algorithm, the model is used to simulate 29 observed flood events. It has been found that by dividing the river channels into virtual channel sections and assuming the cross section shapes as trapezoid, the Liuxihe Model largely increases computation efficiency while keeping good model performance, thus making it applicable in larger watersheds. This study also finds that parameter uncertainty exists for physically deriving model parameters, and parameter optimization could reduce this uncertainty, and is highly recommended. Computation time needed for running a distributed hydrological model increases exponentially at a power of 2, not linearly with the increasing of model spatial resolution, and the 200m*200m model resolution is proposed for modeling Liujiang River Basin flood with Liuxihe Model in this study. To keep the model with an acceptable performance, minimum model spatial

resolution is needed. The suggested threshold model spatial resolution for modeling Liujiang River Basin flood is 500m*500m grid cell, but the model spatial resolution at 200m*200m grid cell is recommended in this study to keep the model a better performance.

Key words：watershed flood forecasting, distributed hydrological model, Liuxihe Model, parameter optimization, model spatial resolution

1 Introduction

Flooding is one of the most devastating natural disasters in the world, and huge damages has been caused (Krzmm, 1992, Kuniyoshi, 1992, Chen, 1995, EEA, 2010). Flood forecasting is one of the most widely used flood mitigation measurements, and watershed hydrological model is the major tool for flood forecasting. Currently the most popular hydrological model for watershed flood forecasting is still the so-called lumped model (Refsgaard et. al., 1996), which averages the terrain property and precipitation over the watershed, so do the model parameters. Hundreds of lumped models have been proposed and widely used, such as the Sacramento model proposed by Burnash et. al. (1995), the Tank model proposed by Sugawara et. al. (1995), the Xinanjiang model proposed by Zhao (1977), and the ARNO model proposed by Todini (1996), only naming a few among others. It is widely accepted that the precipitation for driving the watershed hydrological processes is usually unevenly distributed over the watershed, particularly for the large watershed, so the lumped model could not easily forecast the watershed flooding of large watersheds. Furthermore, due to the inhomogeneity of terrain property over the watershed, which is true even in very small watershed, so the watershed flood forecasting could not be forecasted accurately if the model parameters are averaged over the watershed. For this reasons, new models are needed to improve the watershed flood forecasting capability, particularly for large watershed flood forecasting.

59   Development of distributed hydrological model in the past decades provides the
60   potential to improve watershed flood forecasting capability. One of the most
61   important features of the distributed hydrological model is that it divides watershed
62   terrain into grid cells, which are regarded to have the same meaning of a real
63   watershed, i.e., the grid cells have their own terrain properties and precipitation. The
64   hydrological processes are calculated at both the grid cell scale and the watershed
65   scale, and the parameters used to calculate hydrological processes are also different at
66   different grid cells. This feature makes it could describe the inhomogeneity of both
67   the terrain property and precipitation over watershed. The distributed feature of the
68   distributed hydrological model is a very important feature compared to lumped model,
69   which makes it could better simulate the watershed hydrological processes at all scale,
70   small or large. The inhomogeneity of precipitation over watershed could also be well
71   described in the model, this is very helpful in modeling large watershed hydrological
72   processes, particularly in the tropical and sub-tropical regions where the flooding is
73   driven by heavy storm. For this reason, distributed hydrological model is usually
74   regarded to have the potential to better simulate or forecast the watershed flood
75   (Ambroise et. al., 1996, Chen et. al., 2016). Employing distributed hydrological
76   model for watershed food forecasting has been a new trend(Vieux et. al., 2004, Chen
77   et. al., 2012, Céline Cattoën et. al., 2016, Witold et. al., 2016, Kauffeldt et. al., 2016).

78

79   The blueprint of distributed hydrological model is regarded to be proposed by Freeze
80   and Harlan (1969), the first distributed hydrological model was the SHE model
81   proposed by Abbott et. al. (1986a, 1986b). Distributed hydrological model requires
82   different terrain property data for every grid cells to set up the model structure, so it is
83   data driven model. In the early stage of distributed hydrological modeling, this posted
84   great challenge for distributed hydrological model's application as the data was not
85   widely available and inexpensively accessible. With the development of remote
86   sensing sensors and techniques, terrain data covering global range with high
87   resolution has got readily available and could be acquired inexpensively. For example,

88　　the DEM at 30m grid cell resolution with global coverage could be freely downloaded

89　　(Falorni et al., 2005, Sharma et. al., 2014), which largely pushes forward the

90　　development and application of the distributed hydrological models. After that, many

91　　distributed hydrological models have been proposed, such as the WATERFLOOD

92　　model (Kouwen, 1988), THALES model (Grayson et al., 1992), VIC model (Liang et.

93　　al., 1994), DHSVM model (Wigmosta et. al., 1994), CASC2D model (Julien et. al.,

94　　1995), WetSpa model (Wang et. al., 1997), GBHM model (Yang et. al., 1997), WEP-L

95　　model (Jia et. al., 2001), Vflo model (Vieux et. al., 2002), tRIBS model(Vivoni et. al.,

96　　2004), WEHY model (Kavvas et al., 2004), Liuxihe model (Chen et. al., 2011, 2016),

97　　and more.

98

99　　Distributed hydrological model derives model parameters physically from the terrain

100　property data, and is regarded not need to calibrate model parameter, so it could be

101　used in data poor or ungauged basins. This feature of distributed hydrological model

102　made it applied widely in evaluating the impacts of climate changes and urbanization

103　on hydrology(Li et. al., 2009, Seth et. al., 2001, Ott, et. al., 2004, Vanrheenen et. al.,

104　2005, Olivera et. al., 2007). But it also was found that this feature caused parameter

105　uncertainty due to the lack of experiences and references in physically deriving model

106　parameters from the terrain property, so could not be used in fields that require high

107　flood simulated accuracy, including watershed flood forecasting. It was realized that

108　parameter optimization for distributed hydrological model is also needed to improve

109　the model's performance, and a few methods for optimizing parameters of distributed

110　hydrological model have been proposed. For example, Vieux et. al. (2003) tried a

111　so-called scalar method to adjust the model parameters, and the model performance is

112　found to be improved largely. Madsen et. al. (2003) proposed an automatic

113　multi-objective parameter optimization method with SCE algorithm for SHE model,

114　which improved the model performance also. Shafii et. al. (2009) proposed a

115　multi-objective genetic algorithm for optimizing parameters of WetSpa model, the

116　improved model result is regarded to be reasonable. Xu et. al. (2012) proposed an

117   automated parameter optimization method with SCE-UA algorithm for Liuxihe Model,

118   which improved the model performance in a small watershed flood forecasting. Chen

119   et. al. (2016) proposed an automated parameter optimization method based on PSO

120   algorithm for Liuxihe Model watershed flood forecasting, and tested in two watershed,

121   one is small, one is large. The results suggested that distributed hydrological model

122   should optimize model parameters even if there is only little available hydrological

123   data, while the derived model parameters physically from the terrain perperty could

124   serve as an initial parameters. The above progresses in distributed hydrological

125   model's parameter optimization has matured, and will largely improve the

126   performance of distributed hydrologcial model, thus pushing forward the application

127   of distributed hydrologcial model in real-time watershed flood forecasting.

128

129   Spatial resolution is a key factor in distributed hydrological modeling. Theoretically if

130   the spatial resolution of a distributed hydrological model is higher, i.e., the grid cell

131   size is smaller, the terrain property could be described finer, and the hydrological

132   processes could be better simulated or forecasted, so the model spatial resolution

133   should be as high as possible. But on the other hand, higher model spatial resolution

134   requires higher resolution terrain property data for model setting up which may not be

135   available in some watersheds. But the most important is that distributed hydrological

136   model uses complex equations with physical meanings to calculate the hydrological

137   processes, so it needs much more computation resources than that of lumped model,

138   and the required computation resources increases exponentially with the increasing of

139   the model spatial resolution. So in modeling flood processes of a large watershed, the

140   computation time needed for running the distributed hydrological model will be huge

141   if the model spatial resolution is kept high, which may make the model application

142   impractical due to high running cost. So if distributed hydrological model is needed to

143   be applied in large watershed, a coarser resolution is the only choose, and the model's

144   capability will be impacted with less satisfactory results. This is also called the scaling

145   effect of distributed hydrological modeling. For this reason, current application for

watershed flood forecasting either limited to small watershed with higher resolution or coarser resolution in large watershed, i.e., a trade-off between the model performance and running cost.

Nowadays forecasting large watershed flooding has been in great demands as it impacts peoples and their properties at large range, but due to the scale effect, current distributed hydrological models employed for large watershed are at coarser resolution, which lowers its capability for flood forecasting and warning. For example, past application of distributed hydrological model for large watershed flood forecating are at the resolution coarser than 1km grid cell (Lohmann et. al., 1998, Vieux et. al., 2004, Stisen et. al., 2008, Rwetabula et. al., 2007), the models employed in the pan-European Flood Awareness System (EFAS; Bartholmes et. al., 2009, Thielen et. al., 2009, 2010, Sood et. al., 2015, Kauffeldt et. al., 2016) are at 1-10km grid cell, which makes the result only applicapble for flood warning.

Challenge for distributed hydrological model application in large watershed flood forecasting is its need for huge computation resources, to cope with this challenge, two efforts could be made. One is to improve the computation efficiency of the distributed hydrological modeling in large watershed, another is implementing the model on high performance supercomputer so in the cases that the users are willing to pay a high computation cost, the flood forecasting of large watershed with high resolution could be done. In this study, the Liuxihe Model (Chen et. al., 2011, 2016), a physically based distributed hydrological model proposed for watershed flood forecasting, has been tried for flood forecasting of a large watershed in southern China to validate the feasibility of distributed hydrological model's application for large watershed flood forecasting.

2 Method and data

2.1 Liujiang River Basin

The river basin studied in this paper is the Liujiang River Basin(herein after referred to as LRB) in south China, which is the first order tributary of the Pearl River. LRB originates from Village Lang in Guizhou Province, and drains though Guizhou Province, Guangxi Zhuang Autonomous Region and Hunan Province with 72% of its drainage area in Guangxi Zhuang Autonomous Region. The length of its main channel is 1121 km, the total drainage area is 58270 km^2 that marks it a large river basin in China.

Fig. 1 sketch map of Liujiang River Basin(LRB)

LRB is a mountainous watershed. There are high mountains in the north and northwest of the watershed with high elevation, while in its south and southeast area, the elevations are relatively low. This topography helps forming severe flooding in the middle and downstream. The basin is in the sub-tropical monsoon climate zone with an average annual precipitation of 1800 mm, and the precipitation distribution is highly uneven both at spatial and temporal with 80% of its annual precipitation occurs in the summer. LRB is in the center of storm zone of Zhuang Autonomous Region, heavy storm was very frequent in the past. There are 59 disastrous flooding in the past 400 years with recording since 1488, which makes LRB the tributary with most disastrous flooding among all the first order tributaries of the Pearl River. In the watershed, there is no significant reservoirs to store flood runoff, so flood forecasting is one of the most effective ways for the flood management.

2.2 Liuxihe Model

Liuxihe Model is a physically based distributed hydrological model proposed mainly for watershed flood forecasting (Chen, 2009, Chen et. al., 2011, 2016). Like other distributed hydrological models, Liuxihe Model divides the watershed into grid cell based on the DEM of the studied watershed. To keep a reasonable model performance, in the past experiences of Liuxihe Model research and application, the model

resolution is limited to 90m*90m or 100m*100m, but only used in small watersheds (Chen, 2009, Chen et. al., 2011, 2013, 2016, Liao et. al., 2012 a, b, Xu et. al., 2012 a, b). Precipitation, evaporation and runoff production are calculated at cell scale, runoff routes first on cell, then along the cell to river channel, and finally to the watershed outlet. As Liuxihe model is mainly used in the sub-tropical regions, so the runoff production is calculated based on the saturation-excess mechanism(Zhao, 1977). The runoff routing is classified as hill slope routing, river channel routing, subsurface routing and underground routing. The hill slope routing is regarded as the one-dimensional unsteady flow, and the kinematical wave approximation is employed to do the routing. The river channel routing is also regarded as the one-dimensional unsteady flow, but the diffusive wave approximation is employed to do the routing. The above methods are widely used in the dominated distributed hydrological models.

What makes Liuxihe Model unique is that the river channel cross section shape is assumed to be trapezoid. With this assumption, the river channel size could be represented with 3 dimensions, including the bottom width, side slope and bottom slope. One of the advantages with this assumption is that the river channel cross section size could be estimated with remotely sensed data(Chen, et.al, 2011), so Liuxihe Model could do river channel runoff routing real physically, thus making Liuxihe Model a fully distributed hydrological model. As there are too many river channel cross sections, and many of them are in the upstream of the watershed where it is not easily accessed, so in real hydrological modeling, directly measuring the river channel cross section sizes are impractical considering the high cost. For this reason, most of the distributed hydrological model could not be applied in real applications, or simply route the runoff with lumped methods which makes the model not a fully distributed hydrological model, thus lowering the model's capability in simulating or forecasting the watershed flood processes. Another advantage of this assumption is that it also simplifies the runoff routing, thus improves the model's computation efficiency. For this reason, even Liuxihe Model has a very high resolution, it still

229 could be used in real-time flood forecasting. This feature of Liuxihe Model in
230 estimating river channel cross section sizes makes it has the potential to be used in
231 large watershed flood forecasting.

232

233 Like other distributed hydrological model, when used in ungauged or data poor
234 watershed flood forecasting, Liuxihe Model derives model parameters physically
235 from the terrain property data. But if there is observed hydrological data, automatic
236 parameter optimization methods could been tried. But as automatic parameter
237 optimization needs thousands model runs, that makes it difficult to be used widely due
238 to huge computing source requirement, which also make it taking long time in setting
239 up the model. For this reason, a public computer cloud was set up for optimizing the
240 parameters of Liuxihe Model which employs parallel computation techniques and was
241 implemented on a supercomputer system(Chen et. al., 2013). With this development,
242 Liuxihe Model could easily optimize its model parameters.

243

244 Above advancements of Liuxihe Model in estimating river channel cross section sizes
245 with remotely sensed data, automatic parameters optimization and supercomputing
246 makes it has the potential to be used in large watershed flood forecasting, so in this
247 study, the Liuxihe model is employed to study the LRB's flood forecasting.

248 **2.3 Hydrological data**

249 There are 66 rain gauges installed in the watershed. In this study, hydrological data of
250 30 flood events has been collected, including the precipitation of the rain gauges and
251 the river discharge of Liuzhou river gauge that locates in the downstream of the
252 watershed and closes to the outlet as shown in Fig. 1 with a hourly step, brief
253 information of these flood events is listed in Table 1.

254 Table1 Brief information of flood events with data collected in LRB

255 **2.4 Terrain property data**

256 Terrain property data includes DEM, land use/cover map and soil map, which are

used for setting up the distributed hydrological model for flood forecasting. In this study, the DEM was downloaded from the SRTM database (Falorni et al., 2005, Sharma et. al., 2014), the land use type was downloaded from the USGS land use type database (Loveland et. al., 1991, Loveland et. al., 2000), and the soil type was downloaded from FAO soil type database (http://www.isric.org). The downloaded DEM has a spatial resolution of 90m*90m, considering LRB is large, the running load for the model with a resolution of 90m*90m may be too heavy to run in this study, so the DEM is rescaled to the resolutions of 200m*200m, as shown in Fig. 2(a). The downloaded land use and soil type were at 1000m*1000m resolution, so there are rescaled to the same resolution of DEM, as shown in Fig. 2(b) and Fig. 2 (c) respectively.

Fig. 2 Terrain properties of LRB

The highest elevation and the lowest elevation of LRB are 2124 m and 42 m respectively. There are 9 land use types, including evergreen needle leaved forest(18.1%), evergreen broadleaved forest(31.0%), shrubbery(32.5%), mountain and alpine meadow(0.1%), slope grassland(13.7%), urban area(0.1%), river(0.2%), lakes(0.3%) and cultivated land(4%).

There are 11 soil types, including Humicacrisol(0.8%), Haplic and high activitive acrisol(1.5%), Ferralic cambisol(5%), Haplicluvisols(3.5%), Dystric cambisol(2.8%), Calcaric regosol(45.5%), Dystric regosol(2.9%), Haplic and weak active acrisol(18%), Artificial accumulated soil(1.5%), Eutricregosols and Black limestone soil(3.5%), Dystric rankers(15%).

3 Results

3.1 Liuxihe Model set up

Considering LRB is large, so the DEM with 200m×200m resolution is adopted to set up the model structure, not at the original 90m×90m resolution. The whole watershed is first divided into 1469900 cells by the DEM horizontally, which were further

285 categorized into hill slope cells and river cells. By using Strahler method (Strahler,

286 1957), the river channel is divided into 3 order system as shown in Fig. 3, which

287 divides the whole cells into 1463204 hill slope cells and 6696 river cells.

288 Fig. 3 Liuxihe Model structure set up for LRB (200m×200m resolution)

289 To estimate the river channel sizes, 178 virtual nodes were set on the river channel

290 system, and 225 virtual channel sections were formed as shown in Figure 3. As in

291 Liuxihe Model, the shape of the virtual channel sections is assumed to be trapezoid,

292 so the cross section size is represented by three dimensions, including bottom width,

293 side slope and bottom slope. As proposed in Liuxihe Model, the bottom width is

294 estimated based on the satellite remote sensing imageries. For the side slope, it is a

295 low sensitive data, so it could be estimated based on local experiences. For the bottom

296 slope, it is calculated with the DEM along the virtual channel section.

3.2 Parameter optimization

298 In Liuxihe Model, an initial parameter set was derived first based on the terrain

299 properties, including the DEM, soil type and land use/cover type, then the parameters

300 will be optimized. In this study, for the insensitive parameter of the land use/cover

301 related parameters, which is the evaporation coefficient, the initial value is set to be

302 0.7 for all cells based on the experiences. The initial value of roughness, i.e., the

303 Manning's coefficient, which is the sensitive parameter of the land use/cover related

304 parameters, is derived from the land use/cover type based on references (Chen et.al.,

305 1995, Zhang et.al., 2006, 2007, Shen et.al., 2007, Guo et.al., 2010, Li et.al., 2013,

306 Zhang et.al., 2015), and listed in Table 2.

307 Table 2 The initial values of land use/cover related parameters

308 For the soil related parameters, including the water content at saturation condition, the

309 water content at field condition, the water content at wilting condition, hydraulic

310 conductivity at saturation condition, soil thickness and soil porosity characteristics

311 coefficient b. Based on past modeling experiences and references (Zaradny, 1993,

312 Anderson et al., 1996), a value of 2.5 is set to b for all soil type, and the water content

313 at wilting condition is set to be 30% of the water content at saturation condition. The

314 soil thickness is estimated based on local experiences and listed in Table 3 for all soil

315 types. The initial values of the water content at saturation condition, the water content

316 at field condition and hydraulic conductivity at saturation condition are estimated by

317 using the Soil Water Characteristics Hydraulic Properties Calculator (Arya et al., 1981)

318 based on soil texture, organic matter, gravel content, salinity and compaction. The

319 estimated initial values of soil-related parameters are listed in Table 3.

320 Table 3 The initial values of soil related parameters

321 In this study, PSO algorithm is employed to optimize the initial model parameters as

322 PSO algorithm has been integrated into the Liuxihe Model Cloud (Chen et. al., 2013,

323 Chen et. al., 2016). The number of particles of PSO algorithm is set to 20, while the

324 value range of inertia weight ω is set to 0.1 to 0.9, the value range of acceleration

325 coefficients C1 is set to 1.25 to 2.75, and C2 to 0.5 to 2.5, and the maximum iteration

326 is set to 50. Flood event of 20080609 is selected to optimize the parameters of Liuxihe

327 model, and Fig. 4 shows the result of the parameter optimization. Among them, Fig.

328 4(a) is the parameters evolving process, Fig. 4(b) is the changing curve of objective

329 function which is set to minimize the peak flow error, Fig.4(c) is the simulated

330 hydrograph of flood event 20080609 with the optimized parameters.

331 Fig. 4 Parameter optimization results of Liuxihe Model for LRB with PSO algorithm

332 From the results in Fig. 4, it could be found that after 14 evolutions, the parameters

333 optimization process converges to its optimal values, and the optimal parameters are

334 achieved, the simulated hydrological process of flood event that is used for parameter

335 optimization is quite good fitting the observed hydrological process, it could be said

336 that the parameter has a good optimization effect.

337

338 As mentioned above, the automatic parameter optimization of the distributed

339 hydrological model is very time consuming. In this study, even supercomputer is

340 employed with parallel computation techniques, the time used for this parameter

optimization is overwhelming, the total time used for achieving the above optimal parameters of Liuxihe model for LRB flood forecasting is 220 hours, more than 9 days. Considering several runs are usually needed before achieving the final results, so the parameter optimization procedure may take a few months, this run time is really a good investment, but the validation results proves this is worth.

3.3 Model validation

The other 29 flood events were simulated by using the Liuxihe model with the above optimized parameters, and the simulated hydrographs of 8 flood events are shown in Fig. 5, the simulated hydrographs of 8 flood events with initial parameters are also shown in Fig. 5.

Fig. 5 Simulated flood events by Liuxihe Model with optimized parameters

From the result of Fig. 5, it has been found that the simulated flood processes fits the observation reasonably well, particularly the simulated peak flow is quite good, and the simulated hydrological processes with optimized model parameter improved the simulated hydrological processes largely. To further analyze the effect of parameter optimization on model performance improvement, five evaluation indices of the simulated flood events, including the Nash–Sutcliffe coefficient, the correlation coefficient, the process relative error, the peak flow error and water balance coefficient are calculated from the simulated results. Table 4 listed the 5 indices for both the simulated results with the initial parameters and the optimized parameters.

Table 4 Evaluation indices of the simulated flood events

From Table 4, it could be seen that the five evaluation indices are quite good for the simulated hydrological processes with the optimized model parameters. The average peak flow error is 5% with 14% the maximum. The average Nash–Sutcliffe coefficient, correlation coefficient, process relative error and water balance coefficient are 0.82, 0.83, 0.22 and 0.87 respectively, that are also quite good for large river basin flood simulation. Five evaluation indices of the simulated hydrological processes with the optimized model parameters are also good improvements to those simulated with

369   the initial parameters, those are 0.64, 0.62, 0.37, 0.29 and 0.78. There are excellent

370   improving in all five indices, with the average increases of 0.18, 0.21 and 0.09 of the

371   average Nash–Sutcliffe coefficient, correlation coefficient and water balance

372   coefficient respectively, and the average decreases of the peak flow error and process

373   relative error are 24% and 15% respectively. So it could be concluded that the Liuxihe

374   Model set up in LRB with optimized parameters are reasonable and could be used for

375   flood forecasting of LRB. This also implies that parameter optimization of distributed

376   hydrological model could improve model performances, and it should be done when it

377   is possible.

378   4 Discussions

379   4.1 Computation time vs model resolution

380   To evaluate the spatial resolution scaling effect of distributed hydrological modeling

381   in LRB, the DEM with 90m*90m resolution is rescaled to the resolutions of

382   400m*400m, 500m*500m, 600m*600m and 1000m*1000m respectively, the land use

383   and soil type at 1000m*1000m resolution are also rescaled to the same resolutions of

384   the DEM used. Liuxihe models for LRB flood forecasting at the above resolutions are

385   then set up with the above methods, and the model structures are shown in Fig. 6.

386   Fig. 6 Liuxihe Model structure set up for LRB with different resolution

387   With different spatial resolution, the numbers of grid cells, hill slope cells and river

388   cells are different, but the river channel order are all set to 3, the numbers of virtual

389   channel nodes for 400m*400m, 500m*500m, 600m*600m and 1000m*1000m

390   resolution models are 100, 68, 46 and 33 respectively, numbers of grid cells, hill slope

391   cells and river cells with different model resolution are listed in Table 5. , the sizes of

392   every virtual cross sections are measured with the above method.

393   Table 5 Grid cell numbers with different model spatial resolution

394   From Table 5, it could be seen, number of grid cells of the model with 200m*200m

395   resolution is 4 times of that with 400m*400m resolution, 6.25 times of that with

396   500m*500m resolution, 9 times of that with 600m*600m resolution, and 25 times of

that with 1000m*1000m resolution, it increases at an approximate exponential of power 2, not linearly with the model resolution.

Parameters of the models with 400m*400m, 500m*500m, 600m*600m and 1000m*1000m resolutions are optimized with PSO algorithm by using the same flood event data, and listed in Table 6. From the results it could be seen that some parameters are significantly different with resolution variation, but some changes little, this implies that the model parameters are resolution-dependent.

Table 6 Optimized parameters with different model spatial resolution

Computation times required for parameter optimization are quite different. For the model with 200m*200m resolution, the time for parameter optimization is 220 hours, while that for models with 400m*400m, 500m*500m, 600m*600m and 1000m*1000m resolutions are 80, 55, 35 and 12 hours respectively. The times needed for parameter optimization of the model at 200m*200m resolution is 2.75 times of that for 400m*400m resolution model, 4 times of that for 500m*500m resolution model, 6.3 times of that for 600m*600m resolution model, and 18.3 times of that for 1000m*1000m resolution model respectively. Considering the time needed for model run, the 200m*200m model resolution is regarded as appropriate for LRB.

5.2 Model performance vs model resolution

The other 29 flood events are also simulated with the models at 400m*400m resolution, 500m*500m resolution, 600m*600m resolution, and 1000m*1000m resolution. Simulated hydrograph of 5 flood events, including 2 big, 2 medium and one small ones are shown in Fig. 7.

Fig. 7 Simulated results with different model resolutions

From the results it could be seen that the simulated hydrological processes with 5 different spatial resolutions are quite different. The result simulated with 1000m*1000m resolution is not so good, although the flood shapes are simulated well,

424 but the peak flow are much lower than that of the observation, so the result is not

425 acceptable, and could not be recommended. The result simulated with 600m*600m

426 resolution is better than that of 1000m*1000m resolution, but there is still big peak

427 flow error, so the result with 600m*600m resolution is also not recommended. The

428 result simulated with 500m*500m resolution model is a big improvement to those

429 simulated with 600m*600m resolution and 1000m*1000m resolution model, the flood

430 shapes are more similar to the observation, and the peak flow is also get closer to the

431 observation, so it could be recommended for flood forecasting if the spatial resolution

432 could not be much finer. The result simulated with 400m*400m resolution has some

433 improvements to that of 500m*500m resolution, but it is not significant, so it is not

434 recommended to replace that at 500m*500m resolution. The result simulated with

435 200m*200m resolution model is a big improvement to those simulated with

436 400m*400m resolution and 500m*500m resolution model, the flood shapes fits the

437 observation much better, and the peak flows are much closer to the observation also, it

438 is a good simulation result and could be recommended for flood forecasting of LRB.

439 As the results are good enough so there is no need to further explore the finer model

440 resolution.

441 **5 Conclusions**

442 By employing Liuxihe Model, a physically based distributed hydrological model, this

443 study sets up a distributed hydrological model for the flood forecasting of Liujiang

444 River Basin in southern China that could be regarded as a large watershed. Terrain

445 data including DEM, soil type and land use type are downloaded from the website

446 freely, and the model structure with a high resolution of 200m*200m grid cell is set

447 up, which divides the whole watershed into 1469900 grid cells that is further divided

448 into 1463204 hill slope cells and 6696 river cells. The initial model parameters are

449 derived from the terrain property data, and then optimized by using the PSO algorithm

450 with one observed flood event, which improves the model performance largely. 29

451 observed flood events are simulated by using the model with optimized parameters,

452 the results are analyzed, and the model scaling effects are studied. Based on these

453   studies, following conclusions are suggested.

454

455   1. In Liuxihe Model, the river channels are divided into virtual channel sections, and

456   the cross section shapes are assumed to be trapezoid and the size is the same within

457   the virtual channel section. The size of the virtual channel section is simplified to

458   three indices, including bottom width, side slope and bottom slope, those are

459   estimated by using remote sensing imageries. This method not only makes the

460   distributed model application practical, but also simplifies the river channel routing

461   method. This significantly increases the model computation efficiency, and makes it

462   could be used in larger watersheds. Results in this study shows the model setting up

463   with this method has a reasonable performance, i.e., this simplification has not

464   sacrificed the model's flood simulation accuracy significantly, so this simplification

465   could be used in large watershed distributed hydrological modelling, including

466   Liuxihe model and other models.

467

468   2. Uncertainty exists for physically derived model parameters. Parameter optimization

469   could reduce parameter uncertainty, and is highly recommended to do so when there

470   is some observed hydrological data. In this study, the simulated hydrograph with

471   optimized model parameters is more fitting the observed hydrograph in shape than

472   that simulated with initial model parameters, the 5 evaluation indices are improved

473   also. The average increases of Nash–Sutcliffe coefficient, correlation coefficient and

474   water balance coefficient are 0.18, 0.21 and 0.09 respectively, the average decreases

475   of the peak flow error and process relative error are 24% and 15% respectively, this

476   implies that the model performance is improved significantly with parameter

477   optimization.

478

479   3. Computation time needed for running a distributed hydrological model increases

480   exponentially at an approximate power of 2, not linearly with the increasing of model

481   spatial resolution. In this study, the computation time required for parameter

optimization for the model with 200m*200m resolution is 220 hours, that is 4 times of that of the model at 500m*500m and 18.3 times of that of the model at 1000m*1000m resolution respectively. Based on the Liuxihe Model cloud system implemented on the high performance supercomputer, the 200m*200m model resolution is the highest resolution that could be fulfilled in modeling Liujiang River Basin flooding with Liuxihe Model considering the computation cost. This also means that if the user could pay high computation cost, then larger watershed could also be modelled with Liuxihe Model by implemented the Liuxihe Model cloud system on a much more advanced high performance supercomputer, this could be easily done nowadays if the user thinks this investment is a worth doing.

4. In forecasting watershed flood by using distributed hydrological model, minimum model spatial resolution needs to be maintained to keeping the model an acceptable performance. Usually if the model spatial resolution increases, i.e., the grid cell gets smaller, the model performance is better, but this will increase the run time significantly, so there is a threshold model spatial resolution to keep the model performance reasonable while keep the model run at the least time. In this study, the threshold model spatial resolution is at 500m*500m grid cell, but the resolution at 200m*200m grid cell is recommended by trading-off between the computation cost and the model performance. This conclusion may be different in different watersheds for Liuxihe Model, or even different in the same watershed for different models.

5. Terrain data downloaded freely from the website derived the river channel system that is very similar to the natural river channel system after it is rescaled from its original spatial resolution of 90m*90m to 200m*200m, 500m*500m and 1000m*1000m, but the higher resolution DEM describes the river channel more in details. This means that the freely downloaded DEM could be used to set up the Liuxihe Model for Liujiang River Basin flood forecasting.

500m	0.67	1.47	1.49	1.37	1.5	0.51
	The river bottom width/Bw	Saturated water content/Csat	Field Capacity/Cfc	Evapotranspiration coefficient/v	Wilting percentage/Cw	Side slope grade/Ss
	0.91	1.16	1.41	1.37	1.37	0.5
600m	Soil saturated hydraulic conductivity/ks	Slope roughness	Manning coefficient	Soil layer thickness/Zs	b	The river bottom slope/Bs
	1.02	0.98	1.24	0.95	1.21	0.86

The river bottom width/Bw	Saturated water content/Csat	Field Capacity/Cfc	Evapotranspiration coefficient/v	Wilting percentage/Cw	Side slope grade/Ss
1.12	0.87	1.28	1.08	1.16	0.95

	Soil saturated hydraulic conductivity/ks	Slope roughness	Manning coefficient	Soil layer thickness/Zs	b	The river bottom slope/Bs
1000m	0.5	1.43	1.17	1.11	1.47	0.57

The river bottom width/Bw	Saturated water content/Csat	Field Capacity/Cfc	Evapotranspiration coefficient/v	Wilting percentage/Cw	Side slope grade/Ss
1.1	0.76	0.53	0.6	1.5	0.54

*Values in the table are adjusting coefficient of the optimized parameters to the initial parameters, so values of the final optimized parameters are initial parameters time adjusting coefficient.
