

Response to Reviewer #1

We thank the Reviewer #1 for their useful comments. These comments highlighted some areas of weakness within the discussion paper.

Reviewer quote #1:

This work approaches a very challenging issue: how far we are from a satellite-based estimation of every term of the terrestrial water balance? Probably this is the underlying idea of the authors, but for some reason the focus of the paper, as reflected by the title, is switched to the possibility of estimating water storage from microwave-based surface water content. May be the intention is still there, and this paper represents just a first piece of results. However, it would be useful to clarify the original idea behind the concepts presented here

Response:

The motivation (or in the words of the reviewer “the original idea”) for estimating surface water storage from microwave remote sensing is laid out in the first paragraph of the original discussion paper. To quote:

“Within the past decade, the analysis of data products from the Gravity Recovery and Climate Experiment (GRACE) satellite mission (Tarpley et al., 2004a; 2004b) has led to an enhanced appreciation of the role played by inter-annual variations of total terrestrial water storage (S) within the terrestrial water budget (Chen et al., 2009; Rodell et al., 2007; Syed et al. 2008). However, the application of GRACE S retrievals is potentially limited by their extremely coarse spatial resolution (~200,000 km²). In contrast, microwave-based surface soil moisture (θ) retrievals can be obtained at relatively finer resolutions (typically ~1,000 km²). However, such retrievals are hampered by both shallow vertical support (reflecting soil moisture conditions only in the top several centimeters of the soil column) and substantially-reduced accuracy for dense vegetative cover. As a result, they are generally assumed to be of limited value for examination of S variations and commonly neglected in water budget studies. However, recent empirical work demonstrates that microwave-based θ retrievals are well correlated with GRACE-based S estimates in certain regions (Abelen et al., 2013; 2015). This suggests that θ retrievals retain some value for water-balance studies - particularly at spatial scales finer than the resolution of GRACE products.”

Or stated more concisely: 1) gravity remote sensing has revealed that inter-annual variations in terrestrial water storage are important; 2) gravity remote sensing suffers from severe resolution limitations; and 3) microwave remote sensing of soil moisture offers a potential approach for providing higher-resolution assessments. This is the rationale behind looking at microwave remote sensing.

We feel this rationale is laid out clearly early in the manuscript. However, it could perhaps be (re-)emphasized more throughout the entire manuscript to address the confusion noted by the reviewer.

New text has been added to the first paragraph of Section 4 to ensure that these objectives are alluded to throughout the paper (and not just at the start).

Reviewer quote #2:

...alternatively, it should be emphasized the relevance of thermal data in context of this study.

Response:

This point is directly addressed by the second paragraph in the original discussion paper. To quote:

10 *“Confirming such potential will require the availability of accurate terrestrial water flux variables. Recent progress in the remote sensing of S and θ has been mirrored by the increased consideration of satellite-derived evapotranspiration (E_T) retrievals in a water balance context (Senay et al., 2011; Hain et al., 2015; Hendrickx et al., 2016; Wang-Erlandsson et al., 2016). In particular, when combined with precipitation (P) and basin-outlet stream flow (Q) measurements, satellite-derived E_T estimates can be*
15 *used to verify estimates of S variations (dS/dt) obtained from various independent sources (Han et al., 2015). This opens up the possibility for the objective “top-down” evaluation of dS/dt estimates obtained from various remote sensing sources and the opportunity to empirically confront “bottom-up”*
20 *expectations for these products based solely on theoretical considerations.”*

Or stated more concisely, thermal-based remote sensing observations are needed to provide
20 evapotranspiration estimates which - when combined with rainfall and stream flow measurements - can be used to independently verify estimates of terrestrial water storage variations obtained from various remote sensing sources.

Again, we feel that these first two paragraphs of the discussion paper directly address the overarching motivation issues raised by the reviewer. New text has been added to the first paragraph of Section 4 to
25 ensure that these objectives are alluded to throughout the paper (and not just at the start).

Reviewer quote #3:

In a similar way, the calendar year aggregation deemed as questionable by the authors themselves (pag.16, Discussion) appears as an “exit-strategy” following a monthly-scale analysis that provided unsatisfactory results.

Response:

30 The reviewer is misunderstanding our point on page 16 (of the original discussion paper) regarding the use of calendar year averaging. Our point here is not to undercut the motivation for an analysis of inter-annual water storage variations, rather to acknowledge that there is some sensitivity to the particular set
35 of “book-end” months used to define a year (i.e., January 1 to December 31 versus June 1 to July 30).

This was simply done to acknowledge a potential source of sensitivity in inter-annual results and not to underline the value of inter-annual results in general.

In fact, the impact of inter-annual terrestrial water storage variability on the terrestrial water cycle is an area of significant scientific interest. See, for example, recent work aimed on the detection of decadal-scale variability in terrestrial storage due to long-term meteorological drought and patterns of anthropogenic ground water extraction or work on the role of groundwater in modulating the impact of climate trends on the hydrologic cycle. These are important scientific issues which can be largely addressed via the measurement of inter-annual water storage variations. This can (and should) be emphasized more in the discussion paper.

- 10 Obviously, improved temporal resolution (down to e.g. monthly) would be useful in some cases. However, it is unfair to characterize the resolution of inter-annual variations as a fall-back “exit-strategy” meant to mask a failure to achieve a more important goal. The characterization of inter-annual variability is a key goal in and of itself.

The above points are now clarified via new text added to the last paragraph of Section 5.

15 **Reviewer quote #4:**

It would have been reasonable to support the period of temporal aggregation with some considerations about the hydrological yearly cycle in each basin.

Response:

- 20 This is a fair point. Ideally, the period of temporal aggregation would have been based on hydrological considerations. However, there is an important practical issue to consider. Preliminary analysis suggests that adequately capturing monthly variations requires seasonally and spatially-varying parameters (to capture the relationship between surface soil moisture and terrestrial water storage). Given the (quite-limited) effective sampling size at our disposal (i.e., 8 years), it quickly becomes impossible to
25 adequately calibrate and validate such a high-parameter approach. So while we suspect that a finer (e.g. seasonal) scale approach is possible, we simply lack the data to adequately validate it. This point was already made in Section 5 of the original discussion paper; however, we have revised this section (see last paragraph of Section 5) to further clarify this key point.

Reviewer quote #5:

- 30 **At the end, the overall impression is that the authors tried in every possible way to extract a similarity between Grace and AMSR-E datasets, and they finally got it.**

Response:

This is not a fair impression (although we acknowledge that weaknesses in our write-up may have contributed to it).

As described in discussion paper, we “tried” only two operations (i.e. linear smoothing and temporally lagging) to resolve both monthly and inter-annual water storage variations (dS/dt). Both operations were applied via only two parameter degrees of freedom (i.e. the application of 3 monthly weighting parameters constrained to sum to one).

Based on our attempts, we did not feel like we could adequately validate the monthly approach and stated that conclusion clearly in the original discussion paper (see above and Section 5 of the write-up).

In contrast, inter-annual dS/dt estimates derived from both water balance consideration and GRACE are actually extremely robust. This point was made in Section 4.2 of the original discussion paper:

“Our primary goal is determining the potential for explaining observed annual $P-Q-E_T$ variations in Figure 4 using the microwave-based dS_{PM}/dt proxy introduced above. Our first priority is empirically evaluating the assumptions - expressed in (4-6) - which underlie the proxy. The first issue is the degree to which the appropriate temporal averaging of microwave-based soil moisture via (4) can be used to obtain a robust linear proxy for $P-Q-E_T$. Figure 5a addresses this by plotting the average linear correlation for all the medium-scale basins between annual $P-Q-E_T$ and $d\theta_{PM}/dt$ obtained using all potential combinations of W_{Dec} , W_{Nov} and W_{Oct} (where $W_{Dec} + W_{Nov} + W_{Oct} = 1.0$). Plotted correlations in Figure 5a are generally greater than 0.50 [-]. In fact, even after realistically accounting for the impact of over-sampling due to spatial and temporal auto-correlation in the $P-Q-E_T$ fields (Section 2.3), sampled correlations are statistically-significant (one-tailed, 95% confidence) for all possible combinations of W_{Dec} , W_{Nov} , and W_{Oct} .”

To summarize, AMSR-E is transformed into a proxy representation of inter-annual dS/dt ($d\theta_{PM}/dt$) via the application of only three monthly weighting parameters (constrained to sum to one). All possible combinations of these parameters lead to an expression of $d\theta_{PM}/dt$ which has a statistically-significant relationship with (independent) basin-scale measurements of rainfall minus evapotranspiration minus stream flow.

Therefore, this is not a result that needs to be aggressively “extracted.” It is a robust relationship which emerges from any parameterization of a simple weighted average. Also, given the important role of inter-annual water storage variations in a number of research and water resource application issues, it is not a conclusion which can be fairly characterized as a “fall-back” consolation prize. We feel like the original discussion paper made this point adequately.

Reviewer quote #6:

To this extent, the paper is valuable, and it is able to bring new knowledge, even if the fee paid to the empiricism is probably too high.

Response:

5 We are unclear what empirical “price” is actually being paid here. As described above the proposed empirical relationship (between surface soil moisture and annual dS/dt) is simple, robust, and statistically-significant (when applied appropriately at an inter-annual time) scale. It is a robust empirical “top down” result which will potentially shape our “bottom-up” understanding of large-scale processes linking surface soil moisture with deeper hydrologic units As such it provides a “dividend” rather than paying a “price.”

10

Response to Reviewer #2

We thank the reviewer for their generally positive comments and useful suggestions. With only a few minor exceptions (noted below), we agree with all their comments and have modified the manuscript accordingly.

Review Quote #1:

Title: I think the title is somewhat too broad. I would prefer the title also states you are looking at medium scale catchments (just add in medium-scale catchments to the title)

Response:

Good point. We have modified our title accordingly.

Reviewer Quote #2:

Although you make several remarks on the use of a calendar year instead of a hydrological year and discuss it in section 5, I think especially this parts could benefit from some extra details.

Maybe you could add some of the “Preliminary sensitivity analysis data to the paper. Maybe even a complete sub-section under section 4.

Response:

We agree - this was a weak link in our original write-up. In response, we have significantly expanded the discussion of this issue in Section 5 of the revised manuscript. In particular, we present new sensitivity results which demonstrate that key manuscript conclusions are not significantly impacted by the particular set calendar months used to define a year.

Reviewer Quote #3:

Your approach (eq.4-6) is fully empirical, testing a pseudo-hydrological year and e.g. using less months (or add one month with more vegetation but with lower weight factor) seems so logical.

Response:

The impact of removing one month is already described in the tertiary plot in Figure 5 (by simply setting the weighting of one particular month to zero). However, the reviewer is correct that there is no analogous discussion concerning the impact of adding one more month. Therefore, in response, new text has been added to Section 4.2 of the revised manuscript which specifically discusses the impact of adding an additional month to equation (4) on optimization results presented in Figure 5.

Reviewer Quote #4:

5 **You clearly show the value of microwave soil moisture for downscaling GRACE information. Can you discuss whether there are other down-scaling possibilities to have the same effect on GRACE derived storage variations?**

Response:

10 The revised manuscript now describes alternative strategies for downscaling GRACE-based water storage estimates (see new text added to the first paragraph of Section 1). However, an objective comparison with these earlier strategies is beyond the scope of this paper. The need for such a comparison; however, is now noted in the revised manuscript (see 2nd-to-last paragraph in Section 6 of the revised manuscript).

15

Reviewer Quote #5:

P1L18: “contain significant” maybe it is more accurate to say “contain statistically significant”

20 **Response:**

Agreed. Changed.

Reviewer Quote #6:

25

P2L5: certain regions: please specify

Response:

30 The spatial variation of results in Abelen and Seitz, 2013; Abelen et al. 2015 is difficult to summarize briefly. However, we agree that simply referring to “certain regions” (without providing any specifics) is likely to cause frustration on the part of the readers. Therefore we have modified the sentence to remove any reference to the geographic variation of results these studies (which is not relevant for the current study).

35

Reviewer Quote #7:

P2L12 steam > stream

40 **Response:**

Fixed.

Reviewer Quote #7:

P2L19: Q and P are not products but ground based data.

5 **Response:**

To avoid confusion, “products” has been changed to “datasets.”

Reviewer Quote #8:

10

Please rephrase P7L18: closure of (1). For me it would be easier if you insert ‘equation’ between “of (1)”.

Response:

15

Agreed...our original phrasing was awkward. It has been rephrased along the lines suggested by the reviewer.

Reviewer Quote #9:

20

P9L20: snow/could > snow/cold P11L9: suggestion to remove () around “credible”

Response:

25

Removed.

Estimating Annual Water Storage Variations in Medium-Scale (2,000-10,000 km²) Basins Using Microwave-based Soil Moisture Retrievals

Abstract. Due to their shallow vertical support, remotely-sensed surface soil moisture retrievals are commonly regarded as being of limited value for water budget applications requiring the characterization of temporal variations in total terrestrial water storage $-(dS/dt)$. However, advances in our ability to estimate evapotranspiration remotely now allow for the direct evaluation of approaches for quantifying dS/dt annual variations in S via water budget closure considerations. By applying an annual water budget analysis within a series of medium-scale (2,000-10,000 km²) basins within the United States, we demonstrate that, despite their clear theoretical limitations, surface soil moisture retrievals derived from passive microwave remote sensing contain statistically significant information concerning dS/dt relative inter-annual variations in S . This suggests the possibility of using (relatively) higher-resolution microwave remote sensing products to enhance the spatial resolution of dS/dt estimates acquired from gravity remote sensing. However, challenging calibration issues regarding the relationship between S and surface soil moisture must be resolved before the approach can be used for absolute water budget closure.

25 | 1 Introduction

Within the past decade, the analysis of data products from the Gravity Recovery and Climate Experiment (GRACE) satellite mission (Tarpley et al., 2004a; 2004b) has led to an enhanced appreciation of the role played by inter-annual variations of total terrestrial water storage (dS/dt) within the terrestrial water budget (Chen et al., 2009; Rodell et al., 2007; Syed et al. 2008). However, the application of GRACE S retrievals is potentially limited by their extremely coarse spatial resolution (~200,000 km²). This has spurred interest in the development

Formattato: Tipo di carattere: 14 pt, Grassetto

Formattato: Tipo di carattere: 14 pt

Formattato: Tipo di carattere: Corsivo

of spatial downscaling techniques for GRACE-based dS/dt . These approaches have generally been based on the use of (relatively) higher-resolution water storage predictions obtained from distributed land surface model predictions (Reager et al., 2015; Wan et al., 2015) or a combination of land surface model output and independent evapotranspiration (E_T) and precipitation (P) flux estimates (Ning et al., 2014). In contrast, microwave-based surface soil moisture (θ) retrievals provide a direct assessment of soil water storage that can be obtained at relatively finer resolutions (typically $\sim 1,000$ km²). However, such retrievals are hampered by both shallow vertical support (reflecting soil moisture conditions only in the top several centimetres of the soil column) and substantially-reduced accuracy for dense vegetative cover. As a result, they are generally assumed to be of limited value for the examination of dS/dt ~~S variations~~ and commonly neglected in water budget studies. However, recent empirical work demonstrates that microwave-based θ retrievals are generally well-correlated with GRACE-based S estimates ~~in certain regions~~ (Abelen and Seitz, 2013; Abelen et al., 2013, 2015). This suggests that θ retrievals retain some value for water-balance studies - particularly at spatial scales finer than the resolution of GRACE products.

Formattato: Tipo di carattere: Corsivo

Confirming such potential will require the availability of accurate terrestrial water flux variables. Recent progress in the remote sensing of dS/dt and θ has been mirrored by the increased consideration of satellite-derived evapotranspiration (E_T) retrievals in a water balance context (Senay et al., 2011; Hain et al., 2015; Hendrickx et al., 2016; Wang-Erlandsson et al., 2016). In particular, when combined with precipitation (P) and basin-outlet stream flow (Q) measurements, satellite-derived E_T estimates can be used to verify estimates of S variations (dS/dt) obtained from various independent sources (Han et al., 2015). This opens up the possibility for the objective “top-down” evaluation of dS/dt estimates obtained from various remote sensing sources and the opportunity to empirically confront “bottom-up” expectations for these products based solely on theoretical considerations.

Here, we combine E_T estimates acquired from thermal infrared (TIR) remote sensing with ground-based Q and P measurements to evaluate the water balance performance of passive microwave (PM) estimates of annual dS/dt for a set of medium-scale (2,000-10,000 km²) river basins within the United States. The analysis will focus on two primary tasks: 1) evaluating the suitability of existing E_T , Q and P data products/datasets to accurately estimate dS/dt and 2) empirically investigating the ability of inter-annual dS/dt estimates (acquired from microwave remote sensing of soil moisture) to close the inter-annual terrestrial water balance. As discussed above, this particular application of θ is arguably inconsistent with their known theoretical limitations. Therefore,

our focus will be on empirically ~~measuring-evaluating~~ their ability to provide dS/dt closure within an annual water budget analysis and examining how these ~~empirical~~ results fit with *a priori* theoretical expectations.

Section 2 describes the water balance data sets and study basins. Section 3 examines the ability of existing flux and storage products to close the terrestrial water balance closure within a set of larger-scale (150,000-1,000,000 km²) hydrologic basins where GRACE-based dS/dt can be directly utilized (see task #1 defined above). Based on verification results in Section 3, Section 4 derives a technique for estimating dS/dt from microwave remote sensing and evaluates the ability of microwave-based dS/dt to close the terrestrial water balance within a second set of medium-scale (2,000-10,000 km²) basins (see task #2 defined above). Results ~~in-are~~ discussed in Section 5 and conclusions summarized in Section 6.

10 2 Study basins and data sets

Within a closed hydrologic basin, the annual water budget equation can be summarized as:

$$P - Q - E_T = dS/dt \quad (1)$$

where P , Q and E_T [mm yr⁻¹] represent annual sums of fluxes, and dS/dt [mm yr⁻¹] is the annual change in terrestrial water storage. Besides Q , all other lateral water fluxes (into or out of the basin) are assumed to be negligible. See Section 2.2 below for a description of data products used to describe flux terms on the left-hand-side of (1). The storage change term dS/dt is independently obtained using both gravity-based (GR) retrievals of total terrestrial water storage and passive microwave-based (PM) retrievals of surface soil moisture content. In both cases, annual change estimates are based on the differencing of temporally-averaged storage retrievals acquired at (or near) the end of each calendar year. Based on constraints associated with the availability of various remote sensing products, the analysis is conducted within a January 1, 2003 to December 31, 2010 time period. Additional methodological details are given below.

2.1 Study basins

For the analysis, hydrologic basins are sought with: excellent ground-based rain gauge coverage, the availability of good remotely-sensed E_T products, and the relative absence of complex topography and/or dense vegetation conditions known to reduce the accuracy of existing long-term, satellite-based soil moisture products. In addition,

arid areas are avoided due to their known lack of inter-annual dS/dt variations. The North American Mississippi River system is one of only a handful of continental-scale river basins ~~which-that~~ generally meets all of these criteria. Therefore, water budget closure will be examined in two separate sets of basins within the Mississippi River system. To start, a large-scale analysis will be conducted on five major Mississippi River sub-basins: the Missouri, the Arkansas, the Red, the Ohio and the Upper Mississippi - see Figure 1 and Table 1. The primary focus in these large-scale basins will be evaluating the ability of existing P , Q , E_T and GRACE-based dS/dt product to close the annual water budget. The results of this water balance analysis will ~~subsequently-then~~ be used to refine the geographic focus and water flux processing approach applied in the medium-scale analysis described below.

Following this large-scale water balance analysis, the performance of a microwave-based dS/dt proxy is examined within 16 (smaller) medium-scale (~~10^3-10^4~~ 2,000-10,000 km²) unregulated basins positioned along an east/west transect across the United States Southern Great Plains (SGP) region (see Figure 1 and Table 2). A complete justification of this geographic emphasis is given in Section 3. However, in general, medium-scale basins were selected following a screening analysis applied by the Model Parameter Estimation Experiment project (Duan et al., 2006) which removed basins with either inadequate rain gauge coverage or excessive human regulation of stream flow. Moving from west to east, these basins exhibit progressively higher mean P and annual runoff ratios (Q/P) (Figure 1 and Table 2). Associated with this climatic gradient is a gradual west-to-east increase in vegetation biomass. Western basins are characterized by large fractions of rangeland, grassland and winter wheat land cover with relatively low biomass. In contrast, basins located along the eastern edge of the transect contain significant upland forest cover and intensive summer agricultural cultivation in low-lying areas.

2.2 Data Products and Processing

A range of ground and remotely-sensed data sets were acquired to characterize components of the terrestrial water balance summarized in (1). The acquisition and processing of these datasets is described below.

2.2.1 Thermal remote sensing of E_T

Daily evapotranspiration estimates were obtained from the Atmosphere-Land EXchange Inverse (ALEXI) algorithm. In particular, ALEXI exploits the moisture signal conveyed by the mid-morning rise in satellite observed land surface temperature (LST) in order to capture water limitations on surface energy fluxes (Anderson

et al. 2007a,b; Hain et al. 2009, 2011). Based on this principle, ALEXI produces estimates of daily evapotranspiration without any direct knowledge of antecedent precipitation or soil water balance considerations (Anderson et al., 2011). This ensures that ALEXI evapotranspiration estimates are independent of those derived via water balance calculations.

- 5 ALEXI evapotranspiration has been evaluated using a spatial disaggregation technique (DisALEXI) which uses high resolution LST retrievals from Landsat to downscale ALEXI fluxes to a 30-m pixel level (Anderson et al., 2004). Typical accuracies obtained in comparison with eddy-covariance tower observations are on the order of 5 to 15% for daily to seasonal evapotranspiration estimates during snow-free periods (Anderson et al., 2012; Cammalleri et al., 2013, 2014a; Semmens et al., 2016).
- 10 Here, the ALEXI model was processed over CONUS at a spatial resolution of 4-km for the period of 2003-2010 and forced with: meteorological inputs from the Climate Forecast System Reanalysis (CFSR; Saha et al. 2010), TIR land surface temperature from the Geostationary Operational Environmental Satellites (GOES East and West), and leaf area index estimates obtained from the 4-day 1-km Combined Aqua-Terra MODIS product (MCD15A3).
- 15 Daily, instantaneous clear-sky latent heat fluxes retrieved from ALEXI were upscaled to daytime-integrated evapotranspiration estimates assuming a self-preservation of the ratio of latent heat flux and incoming shortwave radiation (f_{SUN}) during daytime hours (Cammalleri et al., 2014b). Hourly CFSR incoming shortwave radiation inputs were integrated to produce daily estimates (24-h) of insolation used in this temporal upscaling. Currently, ALEXI is not executed over snow-covered surfaces. These periods were instead gap-filled with a linear
20 interpolation of f_{SUN} and a snow albedo correction to account for differences in surface net radiation over snow-covered versus snow-free surfaces. Resulting 4-km ALEXI daily evapotranspiration estimates were temporally-summed within calendar years to produce annual E_T [mm yr^{-1}] and spatially-averaged within each of the basins listed in Tables 1 and 2. Annual ALEXI E_T estimates acquired in this way have been successfully applied to verify inter-annual evapotranspiration estimates acquired from land surface modeling (Han et al., 2015).

25 **2.2.2 Land surface model predictions of E_T**

For the purposes of cross-comparison with ALEXI E_T results, annual E_T was also acquired from 0.125°-resolution Noah v3.2 simulations (Chen et al., 1996; Chen and Dudhia, 2001; Ek et al., 2003) generated as part of North

American Land Data Assimilation Phase 2 (NLDAS-2) activities (Xia et al. 2012). Hourly Noah predictions of: 1) direct evaporation from the surface soil, 2) direct evaporation of canopy-intercepted precipitation, and 3) transpiration via plant root uptake of water were aggregated to produce an hourly evapotranspiration estimate. Annual E_T averages were then obtained by summing these estimates for the calendar years 2003 to 2010 and spatially-averaging these summations within the basins indicated in Figure 1.

2.2.3 Ground-based observations of P and Q

Daily stream flow magnitudes were obtained from United States Geologic Survey (USGS) stream gauging stations located at the outlet of basins listed in Tables 1 and 2. These values were aggregated into (calendar year) sums and normalized by basin drainage area to obtain units of water depth per year [mm yr^{-1}]. Annual total (liquid plus solid phase) precipitation (P) [mm yr^{-1}] was based on the temporal aggregation of rain gauge observations acquired by the National Centers for Environmental Prediction (NCEP)'s Climate Prediction Center (CPC) and re-sampled onto a 0.125° grid by the NLDSE-2 project (Xia et al., 2012). These annual averages were then spatially-averaged within each of basins listed in Tables 1 and 2.

2.2.4 Gravity remote sensing of dS/dt

Monthly GRACE terrestrial water storage deviations (S_{GR}) data were obtained by separately applying the rescaling coefficients of Landerer and Swenson (2012) to gridded 1° GRACE Level-3 terrestrial water storage products provided by the GeoForschungsZentrum (GFZ; version RL05.DSTvSCS1409), University of Texas Center for Space Research (CSR; version RL05.DSTvSCS1409), and the NASA/Cal-Tech Jet Propulsion Laboratory (JPL; version RL05.DSTvSCS1411). GRACE-based annual estimates of terrestrial water storage variations (dS_{GR}/dt) were then derived via simple linear averaging of the GFZ, CSR and JPL terrestrial storage product to estimate $S_{GR,Dec,i}$ and $S_{GR,Jan,i+1}$ (where i is an annual index) and the subsequent application of year-over-year differencing:

$$(dS_{GR}/dt)_i = (S_{GR,Dec,i} + S_{GR,Jan,i+1})/2 - (S_{GR,Dec,i-1} + S_{GR,Jan,i})/2. \quad (2)$$

Finally, gridded 1° dS_{GR}/dt [mm yr^{-1}] products were spatially-averaged within all of the coarse-scale basins listed in Table 1. Note that GRACE Level-3 S_{GR} values capture monthly deviations from a long-term average datum

(based on average 2004-2009 conditions) and not absolute S values/levels. However, the distinction is immaterial since our focus lies solely on annual dS_{GR}/dt , which is insensitive to the presence or absence of any such datum.

The primary application of dS_{GR}/dt retrievals will be to verify annual water balance closure within the coarse-scale basins listed in Table 1. However, we will also apply dS_{GR}/dt within the medium-scale basins as a source of parameterization information for microwave-based dS/dt estimates and as a baseline for evaluating microwave-based dS/dt as a source of downscaling information (see Section 4.2). ~~T~~Naturally, these applications will be approached with caution since the spatial resolution of the dS_{GR}/dt retrievals ($\sim 200,000 \text{ km}^2$) is much coarser than the size of the medium-scale basins considered here (2,000-10,000 km^2). The impacts of this significant scale mismatch will be discussed below.

10 2.2.5 Passive microwave remote sensing of soil moisture

Passive microwave-based surface soil moisture retrievals were based on the application of the Land Parameter Retrieval Model (LPRM; Owe et al., 2001) to Advanced Microwave Scanning Radiometer – EOS (AMSR-E) C- and X-band brightness temperature observations obtained from both ascending (1:30 PM LST) and descending (1:30 AM LST) orbits of the NASA Aqua satellite (Owe et al., 2008). AMSR-E LPRM Level 3 soil moisture data products were downloaded from the NASA Global Change Master Directory (<http://gcmd.nasa.gov>). The Aqua satellite was launched in June 2002 and remained operational until October 2011. Soil moisture datasets acquired from AMSR-E represent the longest surface soil moisture data record currently available from a single satellite sensor. The processing of these datasets into dS/dt estimates is discussed in Section 4.

2.3 Statistical approach

20 The temporal length of required remotely-sensed data sets imposes a serious challenge for this analysis. The primary limiting factor for this length is the availability of a consistent microwave-based θ dataset. As noted above, ~~t~~The data period utilized here (2003-2010) represents the longest current period of (temporally-consistent) microwave-based θ retrievals available from any single sensor (AMSR-E). Nevertheless, it still provides only eight annual values upon which to evaluate the annual closure ~~of expressed in~~ (1). Longer θ datasets based on the merger of multi-satellite/multi-sensor θ retrievals exist (Liu et al., 2011). However, concerns about their temporal consistency currently limit their value for analyses conducted at inter-annual time scales (Loew et al., 2013).

The restriction of the annual analysis to only 8 years limits our ability to robustly assess closure using temporal sampling alone. Therefore, whenever possible, we will sample closure evaluation statistics across both space and time to maximize the total degrees of freedom available for a statistical analysis. However, due to significant amounts of both spatial and temporal auto-correlation in *P-Q-E_T* ~~fields, datasets~~, considerations must be made for oversampling (in both space and time) when calculating effective sample sizes. To address this we ~~followed~~ **applied** the approach of Bretherton et al. (1999) who recommended (for the case of sampling quadratic statistics) an effective sampling size N^* of:

$$N^* = N(1 - \rho^2)/(1 + \rho^2) \quad (3)$$

where N is the original sample size and ρ the auto-correlation at individual sampling points. In particular, we applied (3) separately in both space and time utilizing both temporal (separated in time, sampled over time and then averaged across various basins) and spatial (separated in space, sampled over space and then averaged over various years) samples of ρ to obtain both spatial and temporal sample size reduction factors. Next, the total sample size (i.e., total time samples x total space samples) was multiplied by both reduction factors to estimate effective sample size in both time and space. For example, in the large-scale basin analysis, we have a total sample size of 40 annual values (5 basins over 8 years); however, after accounting for over-sampling in both space and time, the effective sample size was reduced to 9.7. Likewise, for the medium-scale basins analysis, the total sample size of 128 annual values (16 basins over 8 years) was reduced to an actual effective size of 48.4. These effective sample sizes were then used to calculate effective degrees-of-freedom for all statistical hypothesis tests.

20 **3 Water balance closure within large-scale basins**

All water storage and flux products described above contain significant errors and biases. In addition, it is possible that non-resolved flux terms in (1) may hinder closure versus observed storage changes. Therefore, before deriving and evaluating an approach to estimate dS/dt for medium-scale basins using microwave-based remote sensing, we will first verify the ability of water balance data sets introduced in Section 2 to close the terrestrial water balance via (1). Due to the coarse spatial resolution of GRACE, a direct closure analysis is possible only for the large-scale basins listed in Table 1. Based on E_T values derived from ALEXI, Figure 2 plots annual variations of *P-Q-E_T* and (GRACE-based) dS_{GR}/dt for all 5 large-scale basins listed in Table 1. In all

basins except the Missouri, annual values of $P-Q-E_T$ depart significantly from zero – illustrating the general importance of annual dS/dt on the terrestrial water budget. Within the Missouri, $P-Q$ is roughly balanced by E_T , and therefore, alone among other basins examined here, the annual estimation of dS_{GR}/dt does not appear to be a requirement for closing the annual water budget. This may be linked to the very large reservoir capacity of the Missouri River Basin system; and the active management of Q to minimize inter-annual reservoir and channel level variability. This aggressive level of management ensures that the Missouri River Basin exhibits the smallest standard deviation of inter-annual $P-Q-E_T$ variability ($\sim 30 \text{ mm yr}^{-1}$ - see Figure 2) of any large basin considered in this analysis.

The best closure results in Figure 2 are obtained in the Arkansas River and Red River basins. In these two basins, GRACE-based dS_{GR}/dt closely matches inter-annual variations in $P-Q-E_T$. This suggests that in the United States Southern Great Plains (SGP) region, both the assumptions underlying (1) and the water flux data sets considered are sufficiently accurate to characterize inter-annual variations in S . In contrast, there is clear evidence of a low bias in annual $P-Q-E_T$ relative to dS_{GR}/dt within both the Upper Mississippi and Ohio River Basins. Given the frequency and extent of winter-time snow cover in these basins, it seems reasonable to ascribe this bias to known under-catch issues associated with the gauge-based measurement of snowfall (Goodison et al., 1998). In addition, there exists a potential for systematic error in cold-season ALEXI E_T estimates (which are based on a simple extrapolation approach).

Figure 3a show annual $P-Q-E_T$ versus dS_{GR}/dt for all 5 large-scale basins. The sampled correlation in Figure 3a is marginal (0.37 [-]) but improves considerably (0.52 [-]) when the 8-year mean of annual $P-Q-E_T$ is subtracted from yearly $P-Q-E_T$ results for each basin (Figure 3b). This is equivalent to imposing closure of $P-Q-E_T$ within each basin over the entire 8-year time period. In addition, replacing ALEXI E_T with Noah-based E_T reduces the sampled correlations in both Figure 3a and 3b (from 0.37 to 0.33 [-] and from 0.52 to 0.33 [-], respectively). This implies that preference should be given to the remotely-sensing-based ALEXI E_T product.

Due to the coarse spatial resolution of GRACE-based dS_{GR}/dt , a comparable water balance analysis cannot be applied to the medium-scale basins listed in Figure 1 and Table 2. Instead we will cross-apply general tendencies observed in the large-scale closure analysis (Figures 2 and 3) to refine the medium-scale analysis presented below. In particular, the medium-scale basins listed in Table 2 are selected based on the principal of minimization of both human regulation (to avoid the lack of annual $P-Q-E_T$ signal noted in the Missouri Basin) and snow/cold

season impacts (to avoid the low bias in annual $P-Q-E_T$ observed in the Ohio and Upper Mississippi River Basins). Overall, these two considerations motivate our decision to utilize only lightly-regulated MOPEX basins within the SGP portion of the Mississippi River system (see Figure 1 and earlier discussion in Section 2.1). In addition, based on annual water balance closure results presented in Figures 2-3, ALEXI-based (as opposed to
5 Noah-based) E_T will be used and closure will be imposed on 8-year $P-Q-E_T$ totals.

4 Microwave-based closure for medium-scale basins

As discussed above, the primary focus of this analysis is ~~on the utilization of new E_T remote sensing products to objectively evaluate the contribution of microwave surface soil moisture retrievals towards describing resolving inter-annual variations of $P-Q-E_T$ variations within for a series of medium-scale basins, basins using a new microwave-based proxy for dS/dt . To this end, t~~ This section will describe the derivation ~~of the proxy of a new microwave-based proxy for dS/dt~~ and its empirical evaluation within the ~~specific set of~~ medium-scale basins listed in Table 2.
10

Formattato: Tipo di carattere: Corsivo

4.1 Microwave-based dS/dt estimation

Any transition between surface soil moisture and S must account for relative variations in the temporal scale and
15 phase of both quantities. In particular, the tendency for S ~~variations to be~~ temporally-smoothed, and lagged (in time), with respect to corresponding surface soil moisture ~~variations~~ variability (Chagnon 1987; Entekhabi et al., 1992; Swenson et al., 2008). Based on this reasoning, instantaneous 0.25° LPRM surface soil moisture retrievals (see Section 2.2) were averaged in time and space into a single monthly value for each of the basins in Tables 1 and 2. Next monthly (basin-scale) soil moisture averages for October, November and December ($\theta_{PM,Oct}$, $\theta_{PM,Nov}$, and
20 $\theta_{PM,Dec}$) were merged into a single, end-of-calendar-year estimate of passive-microwave-based θ_{PM} :

$$\theta_{PM,i} = W_{Oct} \theta_{PM,Oct,i} + W_{Nov} \theta_{PM,Nov,i} + W_{Dec} \theta_{PM,Dec,i} \quad (4)$$

where i is an annual index (here corresponding to calendar years between 2003 and 2010), and W are constant weighting factors (summing to unity) applied to each month. Annual changes in θ_{PM} ($d\theta_{PM}/dt$) were then derived from annual differencing of $\theta_{PM,i}$ with $\theta_{PM,i-1}$. This entire procedure was done separately for LPRM retrievals
25 acquired during both ascending and descending AMSR-E orbits. Finalized values of $d\theta_{PM}/dt$ were then obtained by averaging results obtained from both orbits. Our decision to utilize a calendar year to accumulate annual

flux/storage change totals in (1) is largely arbitrary, and the impact of utilizing other annual periods will be discussed below.

In addition to the specification of W , we also allowed for the application of a single calibration factor K_{PM} [mm] when converting volumetric $d\theta_{PM}/dt$ [$\text{m}^3\text{m}^{-3}\text{yr}^{-1}$] variations into annual dS/dt depth changes [mm yr^{-1}]:

$$5 \quad dS_{PM}/dt = K_{PM} d\theta_{PM}/dt. \quad (5)$$

Our approach for obtaining K_{PM} was based on scaling $d\theta_{PM}/dt$ to match the sampled temporal variance of gravity-based dS_{GR}/dt . Therefore, K_{PM} was defined as the ratio:

$$K_{PM} = \sigma(dS_{GR}/dt)/\sigma(d\theta_{PM}/dt) \quad (6)$$

where the σ operator indicates a temporally-sampled inter-annual standard deviation.

10 | Despite some evidence for significant large-scale correlation between θ and S (Abelen and Seitz, 2013; Abelen et al. 2015)(Abelen et al., 2013; 2015), there are ~~strong~~-a priori reasons for scepticism regarding the application of (4-6) to a water budget application. First, due to the extremely shallow vertical support of passive microwave-based surface soil moisture retrievals, it is uncertain if $d\theta_{PM}/dt$ actually provides an effective linear proxy for dS/dt . Second, even if such a linear relationship can be established, it is unclear if the ratio $\sigma(dS_{GR}/dt)/\sigma(d\theta_{PM}/dt)$ in (6) provides a robust calibration coefficient to convert surface soil moisture variations into annual variations in S . ~~Below we will attempt to provide empirical evidence to allay these (credible) theoretical concerns. These theoretical concerns are addressed below.~~

4.2 Evaluation of proxy assumptions and calibration

Figure 4 plots (annual) variations of $P-Q-E_T$ and dS_{PM}/dt for all 16 medium-scale basins listed in Table 1. See Section 3 for the rationale behind the selection of these particular basins. The large plotted departures (from zero) seen for $P-Q-E_T$ confirms that inter-annual variations in S play a significant role in the application of (1) at an annual time scale.

In addition, consistently negative $P-Q-E_T$ estimates are observed within several medium-scale basins (see e.g., basins #5, #8, #9, and #12 in Figure 4). Because these basins cannot be directly resolved by GRACE, it is

difficult to confirm whether this tendency is a real (i.e., a decadal-scale ~~reduction-trend~~ in S) or an artefact of the summed impact of multiple long-term measurement biases in independent P , Q and E_T products. However, based on the large-basin analysis presented in Section 3, the latter appears more likely. Therefore, annual $P-Q-E_T$ values are de-biased by subtracting out (on a basin-by-basin basis) the 8-year annual mean of $P-Q-E_T$ (see dashed line in Figure 4). The impact of this assumption on subsequent results will be discussed below.

Our primary goal is determining the potential for explaining observed annual $P-Q-E_T$ variations in Figure 4 using the microwave-based dS_{PM}/dt proxy introduced above. ~~Our first priority is and~~ empirically evaluating the assumptions - expressed in (4-6) - which underlie the proxy. The first issue is the degree to which the appropriate temporal averaging of microwave-based soil moisture via (4) can be used to obtain a robust linear proxy for $P-Q-E_T$. Figure 5a addresses this by plotting the average linear correlation for all the medium-scale basins between annual $P-Q-E_T$ and $d\theta_{PM}/dt$ obtained using all potential combinations of W_{Dec} , W_{Nov} and W_{Oct} (where $W_{Dec} + W_{Nov} + W_{Oct} = 1.0$). Plotted correlations in Figure 5a are generally greater than 0.50 [-]. In fact, even after realistically accounting for the impact of over-sampling due to spatial and temporal auto-correlation in the $P-Q-E_T$ fields (Section 2.3), sampled correlations are statistically-significant (one-tailed, 95% confidence) for all possible combinations of W_{Dec} , W_{Nov} and W_{Oct} . Since these correlations are based on annual values (where there is no potential for obtaining spurious fitting due to the trivial representation of an obvious seasonal cycle), and there is no credible reason to suspect cross-correlated errors between the wholly independent $P-Q-E_T$ and dS_{PM}/dt fields, the statistical significance of sampled correlation in Figure 5a can be taken as clear evidence of a **robust** linear underlying relationship between $d\theta_{PM}/dt$ and $P-Q-E_T$. As such, it provides **clear** empirical support for (4-5).

Nevertheless, the performance of the $d\theta_{PM}/dt$ proxy does vary as a function of W_{Dec} , W_{Nov} and W_{Oct} in Figure 5a and feasible parameterization strategies will be required to fix their values. To this end, Figure 5b plots the sampled correlation between $d\theta_{PM}/dt$ and dS_{GR}/dt as a function of W_{Dec} , W_{Nov} and W_{Oct} . Note that monthly weighting values which maximize this correlation in Figure 5b also tend to maximize the correlation between $d\theta_{PM}/dt$ and $P-Q-E_T$ in Figure 5a. Based on Figure 5b, the maximum correlation between $d\theta_{PM}/dt$ and dS_{GR}/dt is found at $W_{Oct} = 0.4$ [-], $W_{Nov} = 0.5$ [-], and $W_{Dec} = 0.1$ [-]. These (spatially and seasonally-fixed) weighting values will be used for all subsequent calculations of $d\theta_{PM}/dt$ via (4). The relative lack of weight applied to December surface soil moisture retrievals is likely reflective of frozen soil moisture conditions at this time and the need for S anomalies to be lagged in time with respect to superficial surface soil moisture variations. Adding monthly-

averaged θ retrievals from September ($\theta_{PM, Sep}$) - into (4) - so that end-of-year θ_{PM} was calculated using a four-month weighted-average product - produced essentially no change to Figure 5.

Formattato: Non Apice / Pedice

Formattato: Non Apice / Pedice

This-The parameterization of W_{Oct} , W_{Nov} , and W_{Dec} alone is sufficient if $d\theta_{PM}/dt$ is to be interpreted solely as a linear proxy for relative inter-annual variations in dS/dt ; however, interpretation of $d\theta_{PM}/dt$ as an absolute measure will-requires the additional parameterization of K_{PM} [mm] in (5) to transform $d\theta_{PM}/dt$ into a representation-of- dS/dt estimates with units of [mm yr⁻¹] (i.e., dS_{PM}/dt). Figure 6 shows the impact of K_{PM} in (5) on the root-mean-square difference (RMSD) between dS_{PM}/dt and $P-Q-E_T$. Results are obtained by lumping annual results for all years within all medium-scale basins listed in Table 2, and the assumption that K_{PM} is fixed in both space and time. The plotted horizontal line plots the inter-annual standard deviation of $P-Q-E_T$ - which is equivalent to the RMSD accuracy achievable by assuming $dS/dt = 0$ in (1). This baseline is improved upon by a wide range of K_{PM} values. However, the absolute accuracy of the dS_{PM}/dt proxy is maximized near $K_{PM} = 900$ mm.

The K_{PM} estimation approach in (6) is based on the assumption that this optimal value can be obtained via a simple variance matching approach applied to $d\theta_{PM}/dt$ and dS_{PM}/dt . Applying (6) (in a lumped manner to all years and all medium-scale basins in Table 2) leads to a value of $K_{PM} = 1080$ mm, which is reasonably close to the optimal value of K_{PM} (900 mm). It is also well-within the broad range of K_{PM} which improves upon a baseline of neglecting dS/dt entirely (see Figure 6).

It should be noted that the parameterization strategies presented above involve direct comparison between (relatively) high-resolution θ products obtained from microwave remote sensing with lower-resolution GRACE-based dS_{GR}/dt retrievals (which have been trivially re-sampled to capture a basin-scale mean). Despite the inability of GRACE retrievals to spatially-resolve the medium-scale basins considered here, Figures 5 and 6 suggest these comparisons are still able to yield useful calibration information. However, it is possible that resolution inconsistencies between GRACE and AMSR-E may have a degrading impact on results. One strategy for resolving this scale inconsistency is to first degrade the spatial resolution of the AMSR-E θ field to match the ~200,000 km² GRACE resolution prior to applying the calibration approach outlined in Figures 5a and 6. However, attempts to do this (via smoothing of the AMSR-E θ fields using a 2-dimensional Gaussian filter) actually led to a small decrease in the quality of the W_{Oct} , W_{Nov} , W_{Dec} , and K_{PM} calibration. This implies that,

despite their resolution differences, direct comparisons between AMSR-E and GRACE products appears to offer the most viable calibration approach.

4.3 Microwave-based closure evaluation

Utilizing the calibrated W and K_{PM} derived in Section 4.2 leads to the dS_{PM}/dt values plotted in Figure 7. Each point in the scatter plot represents one annual value within a single medium-scale basin. Our microwave-based dS_{PM}/dt proxy product has a linear correlation with independently-acquired $P-Q-E_T$ values of 0.71 [-], which is statistically-significant (one-tailed, at 99% confidence) even after allowances have been made for over-sampling in both time and space (see Section 2.3). Note that all calibrated parameters (W and K_{PM}) are constant in both space and time and therefore cannot provide a spurious source of skill for dS_{PM}/dt temporal variations. In addition, all calibration is against GRACE-based dS_{GR}/dt and ~~plotted~~ $P-Q-E_T$ ~~fields~~ values are used solely for the purpose of independent verification.

While $P-Q-E_T$ derived in medium-scale basins cannot be directly validated against GRACE-based dS_{GR}/dt retrievals (due to the ground-resolution of GRACE being much coarser than the size of the medium-scale basins), the significant correlation in Figure 7 strongly suggests that they are adequately representing the net annual flux of water into and out of the medium-scale basins. A slight reduction in correlation (from 0.71 to 0.62 [-]) is found when $P-Q-E_T$ is *not* corrected to close water balance over the 8-year study period. Likewise, replacing ALEXI E_T with NOAA-based E_T leads to another (very) slight reduction in correlation in Figure 7 (from 0.71 to 0.69 [-]). However, it should be stressed that, in all cases, the correlation between dS_{GR}/dt and plotted $P-Q-E_T$ remains statistically significant (one-tailed, at 95% confidence). See Figure 4 for dS_{PM}/dt time series results within individual medium-scale basins.

4.4 Downscaling evaluation

An important follow-on question is the degree to which the skill demonstrated in Figure 7 enhances our ability to track dS/dt in medium-scale basins above and beyond existing GRACE products. To this end, Figure 8a plots annual GRACE-based dS_{GR}/dt versus $P-Q-E_T$ for all medium-scale basins. Since the ground resolution of GRACE is significantly coarser than the size of these basins, it is unfair to evaluate dS_{GR}/dt based on these comparisons. However, despite this severe resolution penalty, dS_{GR}/dt still manages to correlate relatively well (i.e., a linear correlation of 0.66 [-]) with independently-acquired estimates of annual $P-Q-E_T$. The tendency for

skill in GRACE-based dS_{GR}/dt to persist even at these (sub-resolution) scales implies that annual dS/dt fields in this region contain spatial auto-correlation at length scales finer than the GRACE spatial resolution. However, it should be stressed that the use of GRACE-based dS_{GR}/dt fields at these spatial resolutions is not recommended and applied here only to define a baseline upon which to evaluate the benefits of subsequent downscaling using
5 microwave-based dS_{PM}/dt estimates.

To this end, Figure 8b plots the relationship between annual $P-Q-E_T$ and dS/dt estimates obtained via a simple downscaling strategy based on the direct averaging of annual dS_{GR}/dt and dS_{PM}/dt estimates for each medium-scale basin. Relative to GRACE-only results presented in Figure 8a, this simple downscaling strategy leads to a significant improvement in the degree of correlation with independent $P-Q-E_T$ values. Specifically, this
10 correlation is increased from 0.66 [-] for the GRACE-only dS_{GR}/dt case in Figure 8a to 0.77 [-] for the case of averaging dS_{GR}/dt and dS_{PM}/dt in Figure 8b. Application of a Fisher z -transformation and the effective degree sample size calculation presented in Section 2.3 confirms that this increase in correlation is statistically significant (two-tailed, at 95% confidence).

In order to further examine geographic trends in results, Figure 9 evaluates dS_{PM}/dt , dS_{GR}/dt and downscaling
15 results (based on the simple linear averaging dS_{PM}/dt and dS_{GR}/dt) obtained individually for each medium-scale basin in Table 2. Results are shown for both the linear correlation and absolute RMSD match with annual $P-Q-E_T$ variations. It is reasonable to expect that the accuracy of microwave-based θ retrievals, and thus their value as the basis of dS_{PM}/dt estimates, should progressively degrade for higher-numbered study basins (which generally have wetter climates and denser vegetation coverage – see Figure 1). Therefore, it is somewhat surprising that no clear
20 trend between basin land cover and the relative performance of the microwave based dS_{PM}/dt proxy is discernible in Figure 9. However, dS_{PM}/dt results demonstrate relatively poor accuracy for the furthest north (and most heavily-cultivated) basin (i.e., basin #7) and for the wettest basin (i.e., basin #16). The downscaled results (based on the simple averaging of dS_{PM}/dt and dS_{GR}/dt) generally produce results which are superior to the isolated application of either dS_{PM}/dt or dS_{GR}/dt ; however, basin-to-basin variations are large and metric values for
25 individual basins are likely to be impacted by large sampling errors.

It is possible to replicate the dS_{PM}/dt approach applied to the medium-scale basins for the larger-scale basins listed in Table 1. However, large-scale dS_{PM}/dt proxies calculated in this way (not shown) are significantly less accurate than GRACE-based dS_{GR}/dt results. There is no indication that a microwave-based dS_{PM}/dt proxy can

consistently improve upon the relative accuracy of annual dS/dt in large basins beyond what is already possible via the utilization of existing GRACE-based dS_{GR}/dt . As a result, the added benefits of a microwave-based dS_{PM}/dt proxy appear limited to basins which cannot be directly resolved by GRACE.

5 Discussion

5 Passive microwave-based estimates of surface soil moisture capture only soil water storage variations occurring within the couple of centimetres of the vertical soil column and cannot directly detect storage dynamics occurring in deeper layers of the unsaturated zone - to say nothing of even deeper variations in groundwater storage or reservoir storage. However, despite this severe theoretical limitation, passive microwave surface soil moisture retrievals (θ) appear to retain significant value as an indicator of relative inter-annual variations in $P-Q-E_T$ (see
10 e.g., Figure 7). This implies that, at least at an annual time scale and for certain conditions, unobserved components of S are sufficiently correlated with *observable* trends in surface soil moisture such that θ retrievals may serve as a potential proxy for variations in total S . Given the two orders of magnitude difference in the spatial resolution of microwave-based θ (1,000 km²) versus gravity-based (200,000 km²) dS/dt estimates, the
| microwave-based proxy appears to enhance our existing ability to closure the terrestrial water budget within the
15 medium scale (2,000-10,000 km²) basins listed in Table 2 (Figure 8).

Intuitively, the ability of surface θ retrievals to capture (much deeper) S variations is likely due to the tendency for (non-anthropogenic) variations in dS/dt to be forced, in a “top-down manner”, by atmospherically-driven anomalies in P and E_T . In this simple conceptual model, variations in surface soil moisture provide a leading indicator of these anomalies as they are propagated downward into deeper hydrologic storage units (Chagnon
20 1987; Entekhabi et al., 1992; Swenson et al., 2008). However, it must be stressed that this conceptual model is likely to break down for a number of cases; in particular, in instances in which variations in S are forced by anthropogenic modification of the hydrologic cycle. For example, S variations due to direct ground-water pumping (Rodell et al., 2009), particularly when associated with increased surface soil moisture via irrigation, will almost certainly confound the ability of θ retrievals to effectively capture inter-annual variability in S .
25 Likewise, it is difficult to imagine microwave-based θ providing an effective representation of variations in S due to large changes in reservoir storage and/or river system management. Finally, even in cases lacking significant anthropogenic modifications of the hydrologic cycle, the relationship between soil moisture and groundwater memory is known to vary significantly as a function of climate (Lo and Famiglietti, 2010). Some modes of soil

moisture/groundwater interactions are almost certainly inconsistent with the application of (4-6). Therefore, additional study is required to better understand the geographic limitations of $d\theta_{PM}/dt$ as a credible dS/dt proxy.

The geographic scope of this study was limited by two considerations. First, the evaluation analysis required access to sufficiently accurate annual $P-Q-E_T$ time series to serve as an independent benchmark for microwave-based dS_{PM}/dt estimates. As discussed in Section 2, this requirement restricts the geographic domain over which the analysis can currently be conducted. Second, the long-term AMSR-E LPRM soil moisture dataset utilized in the analysis has known limitations within areas of moderate and/or dense vegetation cover. Datasets based on lower-frequency L-band observations are currently being produced but will require 2 or 3 more years (beyond 2017) to match the temporal length of the existing AMSR-E data record. However, once longer-term L-band datasets becomes available, they will enable the expansion of this analysis into more densely vegetated areas.

Our decision to calculate annual flux quantities using a calendar year (i.e., January 1 to December 31) approach is admittedly arbitrary. This choice ~~will almost certainly may~~ impact the accuracy of dS_{PM}/dt proxy estimates due to seasonal variations in the availability and accuracy of remotely-sensed soil moisture retrievals acquired from passive microwave remote sensing (due to e.g. vegetation phenology and/or the presence of snow or frozen soils).

~~The impact of frozen soils could, for example, be circumvented by defining years as ending in early fall and therefore requiring sampling of θ_{PM} only during spring and summer months. However, high amounts of vegetation biomass during these months leads to a higher amount of uncertainty in sampled θ_{PM} and thus dS_{PM}/dt . In order to directly examine this issue, results in Figure 8 were re-generated using a September 1 to August 31 annual time period. Relative to earlier January 1 to December 31 results, this new annual definition resulted in less skill for both the gravity based and merged gravity/microwave estimates of inter-annual storage (i.e., a reduction in correlation from 0.66 to 0.39 [-] for dS_{GR}/dt results in Figure 8a and from 0.77 to 0.54 [-] for the simple average of dS_{PM}/dt and dS_{GR}/dt in Figure 8b). However, the relative improvement of the averaged dS_{PM}/dt and dS_{GR}/dt remained statistically-significant (two-tailed, at 95% confidence). The reason for the reduction in performance for both dS/dt products is unclear; however, the added value of the microwave-based dS_{PM}/dt retrievals appears to be robust regardless of whether the fixed annual cycle is defined to end during the summer (August 31) or the winter (December 31). A more detailed sensitivity analysis involving a more continuous range of annual end dates is possible; however, it is complicated by the relatively small number of annual cycles currently available for this analysis and thus the tendency to significantly change temporal sampling supports in order to accommodate changes in the definition of an annual period.~~

Formattato: Tipo di carattere: Non Corsivo

The targeting of annual variations in S . A preliminary sensitivity analysis suggests that, despite the complication of frozen soil and snow cover, dS_{PM}/dt results based on November to December θ_{PM} samples provide superior water budget closure than comparable results based on June to September θ_{PM} . As a result, for the specific set of basins examined here, the use of a calendar year (January 1 to December 31) appears to maximize the value of dS_{PM}/dt for water balance applications.

is motivated by the need to address important questions surrounding inter-annual variations in the hydrologic cycle. Finally, however, a natural extension of this work is the application of the dS_{PM}/dt at a finer monthly (as opposed to annual) time scale. In theory this is possible; however, there are several practical obstacles which must be overcome. First, as noted above, the accuracy of the dS_{PM}/dt proxy appears to be reduced when applied during heavier biomass conditions found outside of winter. This implies that it may be difficult to adequately characterize monthly scale storage variations based on calculating dS_{PM}/dt at multiple points over the season cycle. In addition, based on a preliminary analysis, optimal values of W and K_{PM} appear to vary within the seasonal cycle. Therefore, a seasonally-varying W and/or K_{PM} parameterization would likely be required for dS_{PM}/dt to accurately capture monthly variations in S . Given that monthly dS_{PM}/dt variations are commonly dominated by a fixed seasonal cycle, it is very difficult/challenging to discern whether any apparent skill in monthly dS_{PM}/dt variations is real or simply an artefact of over-fitting such a seasonally-varying W and/or K_{PM} parameterization. As a result, the objective validation of a monthly dS_{PM}/dt proxy will likely will require the availability of longer-term (i.e., 10+ years) dS_{PM}/dt and $P-Q-E_T$ datasets capable of supporting mutually-exclusive calibration and validation time periods. As discussed above, the current limiting factor on the length of this analysis is the availability of temporally consistent, satellite-based soil moisture products. Our current 8-year dataset is almost certainly too short to support such an analysis.

6 Conclusions

Advances in the remote sensing of E_T currently afford an opportunity to independently verify other annual components of the terrestrial water budget - including changes in terrestrial water storage (dS/dt). Confirming recent work with GRACE, results clearly demonstrate the importance of dS/dt for closing the annual water budget. In particular, GRACE-based dS_{GR}/dt estimates appear to provide a reliable source of such information

Formattato: Tipo di carattere: Corsivo

Formattato: SpazioDopo: Automatico

within large-scale river basins with relative low annual snowfall totals and anthropogenic management (Figures 2-3). In addition, for basins smaller than the 200,000 km² GRACE spatial resolution, estimates of dS_{PM}/dt derived from passive microwave remote sensing and (4-6) also demonstrate clear value for providing annual closure information (Figure 7). Given that passive microwave-based soil moisture retrievals are available at substantially-
5 finer spatial resolution than gravity-based retrievals of S , this opens up the strong possibility of using microwave-based surface soil moisture retrievals to downscale gravity-based dS/dt retrievals (Figure 8).

The retrieval of the microwave-based dS_{PM}/dt proxy is based on two - somewhat *ad hoc* - assumptions expressed in (4-6) which claim that: 1) $d\theta_{PM}/dt$ obtained via (4) has a linear underlying relationship with dS/dt and 2) the constant of proportionality in the relationship can be derived via variance matching between microwave and
10 gravity-based estimates of dS/dt . These assumptions are directly supported by empirical results presented in Figures 5 and 6. Nevertheless, it should be stressed that theoretical support for (4-6) is still quite weak, and it is relatively easy to imagine cases in which these assumptions would be expected to fail (see Section 5). Therefore, additional validation work over a wider variety of conditions is certainly warranted. Likewise, an objective inter-
15 comparison between this approach and earlier downscaling approaches based on higher-resolution land surface model output (e.g., Reager et al. 2015; Wan et al. 2015) is warranted.

In addition to isolating potential value in microwave-based dS_{PM}/dt estimates, water balance results presented here also provide added confidence regarding our ability to capture annual variations in dS/dt via (1) and flux observations. In particular, both annual dS_{GR}/dt and dS_{PM}/dt estimates exhibit a statistically-significant correlation against independent annual $P-Q-E_T$ values with the medium-scale basins examined here (Figure 7). Terrestrial E_T ,
20 in particular, is commonly perceived to represent a weak link in the characterization of (1). However, based on results presented here, it appears that ALEXI-based E_T products over CONUS are now sufficiently accurate (at least in a relative inter-annual sense) for annual E_T estimates to be used as a viable constraint to infer the accuracy of other water budget components. This is a marked improvement over the calculation of E_T as a balance residual and opens the door to the fuller use of (1) as a diagnostic tool for various water balance products.

5 **Figure 2.** Annual time series of $P-Q-E_T$ (black) and gravity-based dS_{GR}/dt (red) estimates for each of the large-scale basins listed in Table 1.

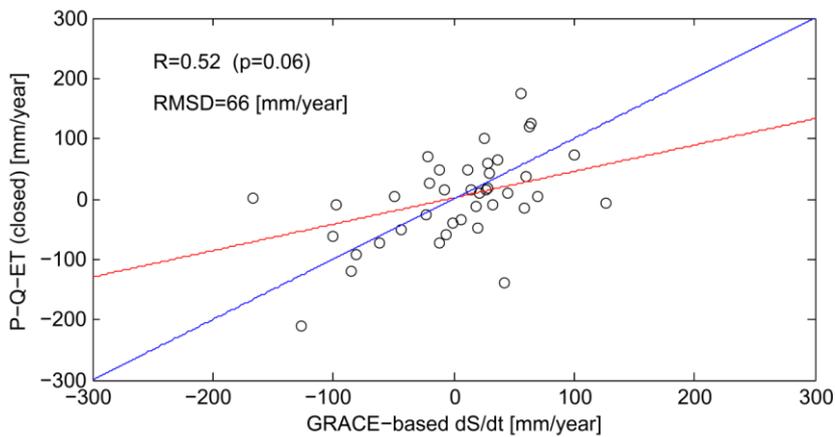

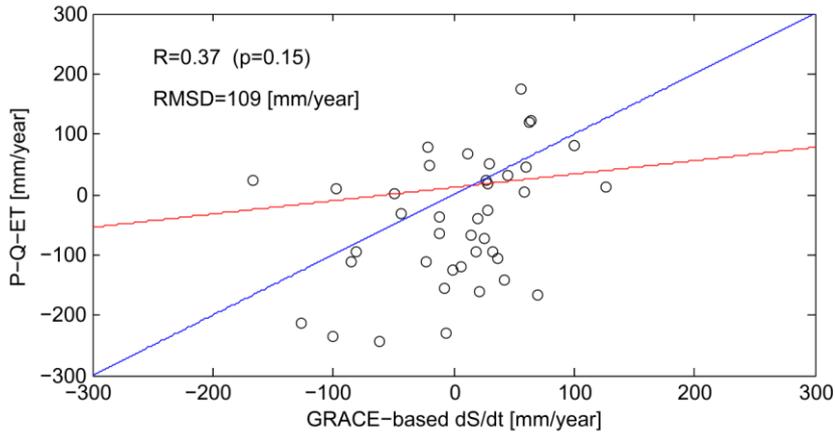

Figure 3. (a) Relationship between annual $P-Q-E_T$ and gravity-based dS_{GR}/dt within each of the large-scale basins listed in Table 1. (b) Same, except that annual $P-Q-E_T$ time series for each basin have been closed (i.e., modified to sum to zero over the 8-year data record). The blue line is a one-to-one line and red line is the least-squares linear fit.

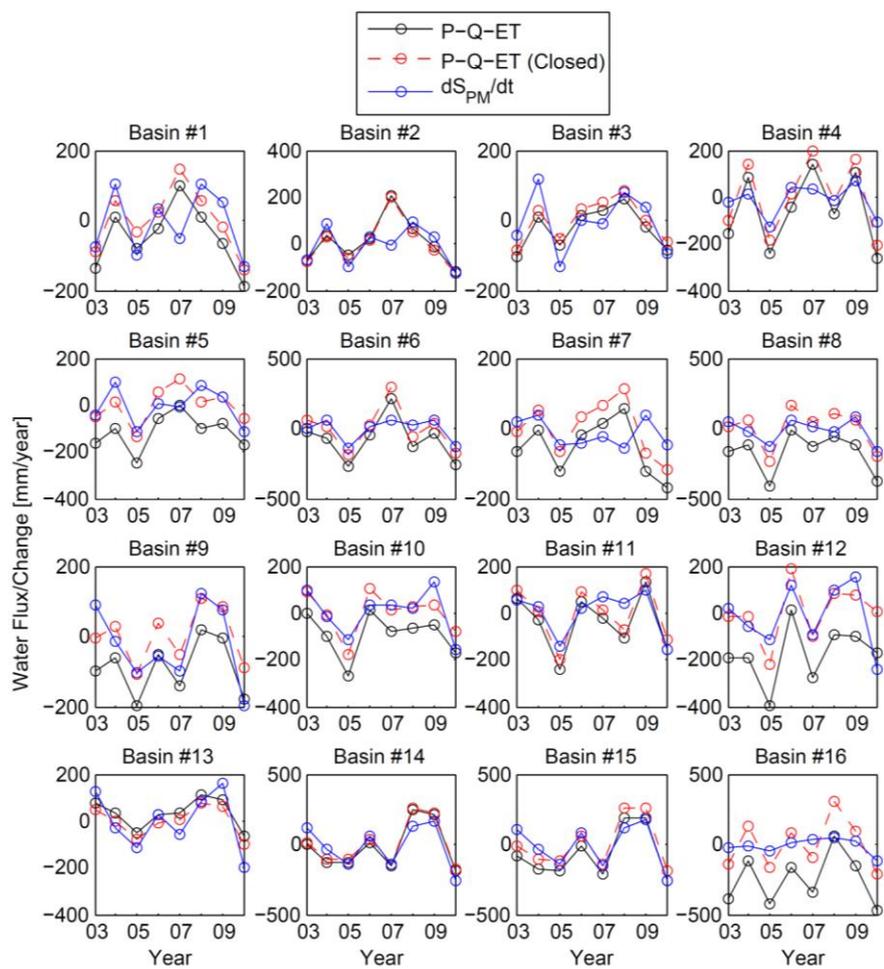

Figure 4. For the 16 medium-scale basins listed in Table 2, the annual time series of raw $P-Q-E_T$ (solid black line) and $P-Q-E_T$ obtained by assuming flux closure over the 8-year period of record (dashed red line). Values of the microwave-based dS_{PM}/dt proxy are also plotted (solid blue line).

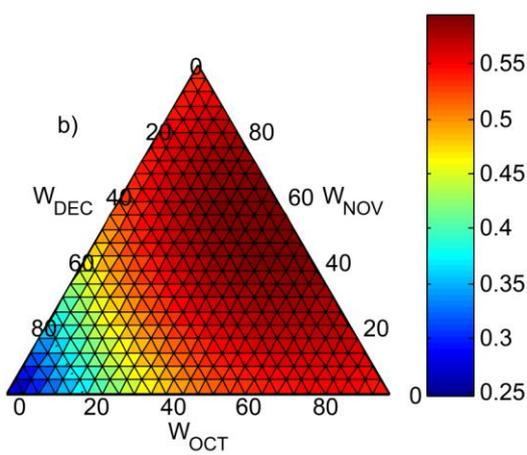

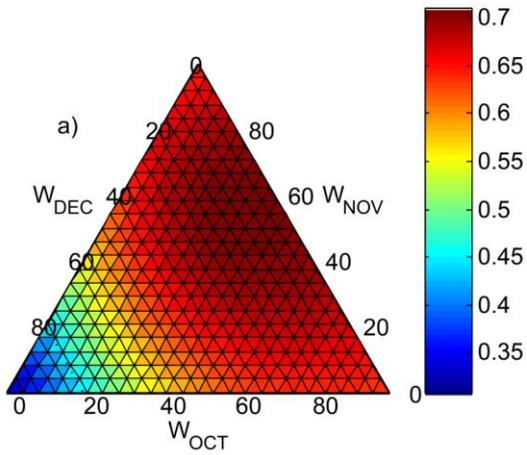

Figure 5. The impact of monthly weighting factors in (4) on the sampled correlation between: a) $d\theta_{PM}/dt$ and $P-Q-E_T$ and b) $d\theta_{PM}/dt$ and dS_{CR}/dt .

5

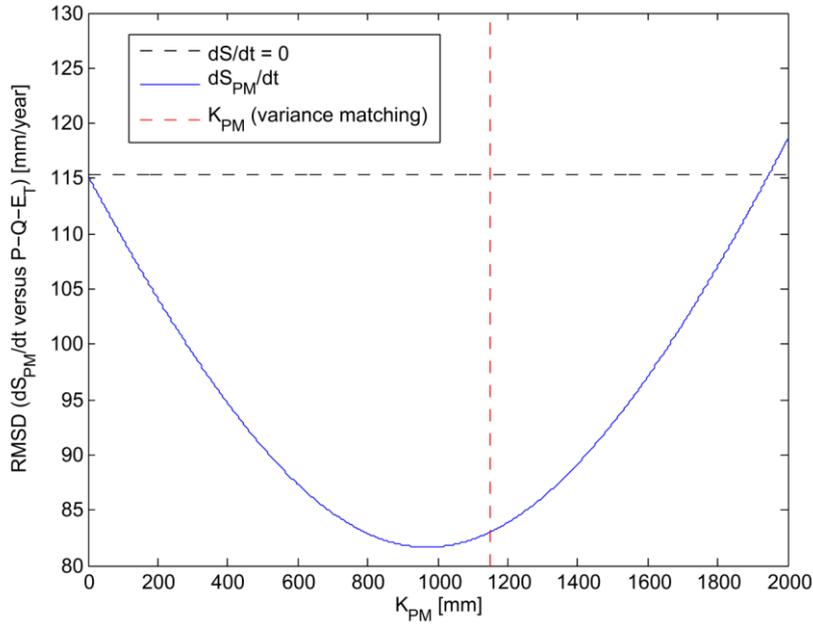

Figure 6. The impact of K_{PM} in (5) on the RMSD between dS_{PM}/dt and $P-Q-E_T$. Also plotted is the standard deviation of $P-Q-E_T$ (i.e., the RMSD incurred by neglecting annual dS/dt) and the value of K_{PM} defined by the variance matching approach in (6).

10

15

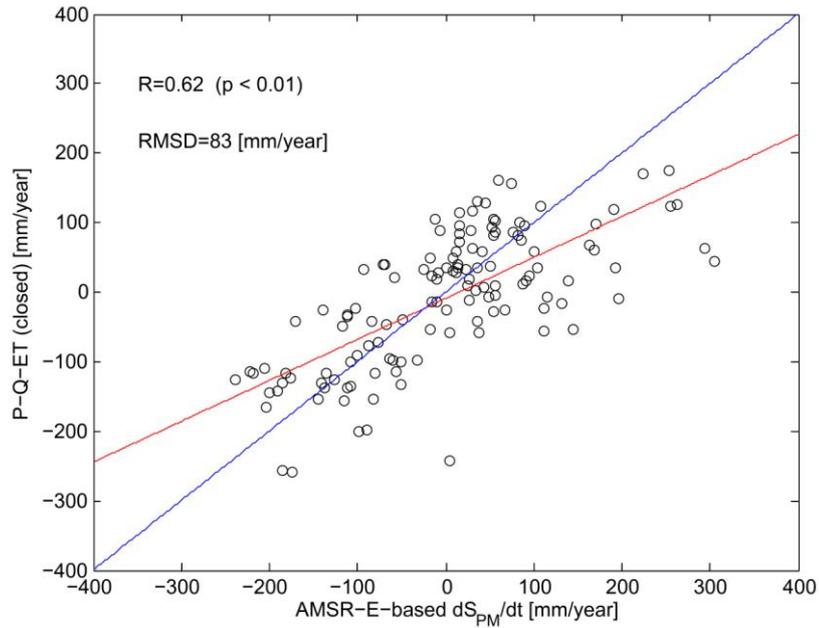

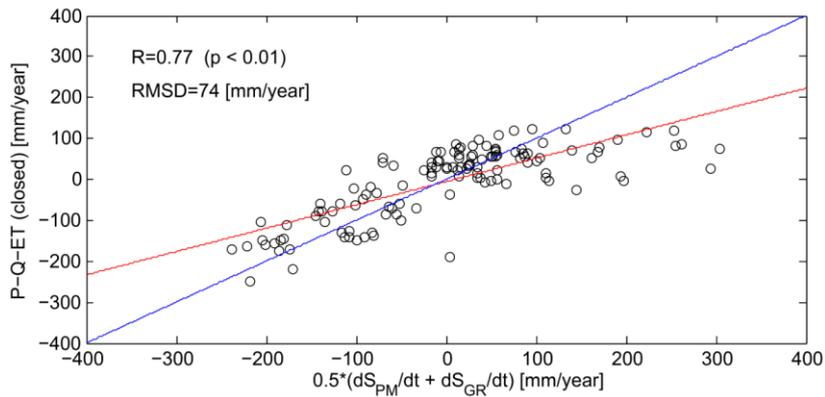

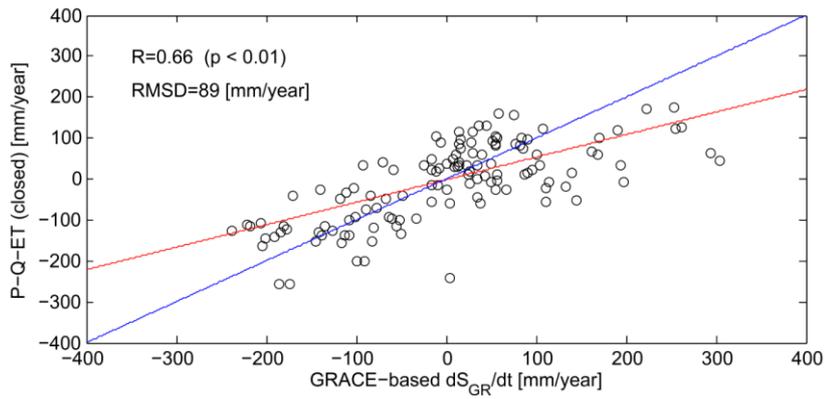

Figure 7. Relationship between annual $P-Q-E_T$ (closed over the 9-year time series) and the microwave-based dS_{PM}/dt proxy within each of the 16 medium-scale basins listed in Table 1. The blue line is a one-to-one line and
 10 red line is the least-squares linear fit.

5

Figure 8. a) Relationship between annual $P-Q-E_T$ (with 8-year closure) and gravity-based dS_{GR}/dt estimates within each of the 16 medium-scale basins listed in Table 1. Part b) is the same as a) except for correlation against the simple average of dS_{PM}/dt and dS_{GR}/dt . The blue line is a one-to-one line and red line is the least-squares linear fit.

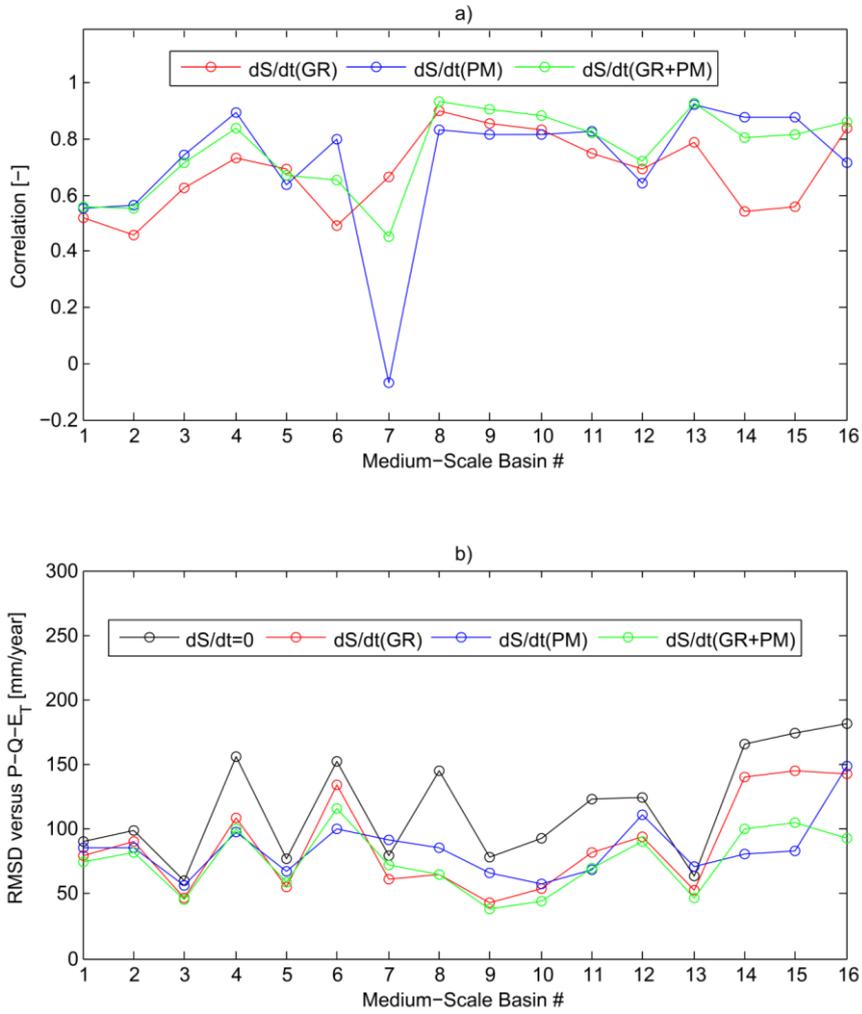

Figure 9. For the 16 medium-scale basins listed in Table 1: a) the linear correlation between annual $P-Q-E_T$ and various annual dS/dt estimates and b) the RMSD between $P-Q-E_T$ and various dS/dt estimates. Basins are ordered from drier to wetter (from left to right) and basin numbering corresponds to listing in Figure 2.
