Abstract. Climate change affects aquatic ecosystems altering temperature and precipitation patterns, and the rear edge of the distribution of cold-water species is especially sensitive to them. The main goal was to predict in detail how change in air temperature and precipitation will affect streamflow, the thermal habitat of a cold-water fish (brown trout, *Salmo trutta*
15 Linnaeus 1758), and their synergistic relationships at the rear edge of its natural distribution. 31 sites in 14 mountain rivers and streams were studied in Central Spain. Models at several sites were built using regression trees for streamflow, and a non-linear regression method for stream temperature. Nine global climate models simulations for the RCP4.5 and RCP8.5 (Representative Concentration Pathways) scenarios were downscaled to a local level. Significant streamflow reductions were predicted in all basins (max. -49 %) by the year 2099, showing seasonal differences between them. The stream temperature
20 models showed relationships between models parameters, geology and hydrologic responses. Temperature was sensitive to the streamflow in one set of streams, and summer reductions contributed to additional stream temperature increases (max. 3.6°C), although the most deep-aquifer dependent sites better resisted warming. The predicted increase in water temperature reached up to 4.0°C. Temperature and streamflow changes will cause a shift of the rear edge of the species distribution. However, geology conditioned the extent of this shift. Approaches like these should be useful in planning the prevention and
25 mitigation of negative effects of climate change by differentiating areas based on the risk level and viability of fish populations.

1 Introduction

Water temperature primarily influences the physical, chemical and biological processes in rivers and streams (Caissie, 2006; Webb *et al.*, 2008) and, subsequently, the organisms that live completely or partially in the water. Temperature is a major
30 trait of the ecological niche of poikilotherm species (e.g., Magnuson and Destasio, 1997; Angilletta, 2009) and a key factor

in fish energy balance, affecting the rate of food intake, metabolic rate and growth performance (Forseth *et al.*, 2009; Elliott and Elliott, 2010; Elliott and Allonby, 2013). It is also involved in many other physiological functions such as blood and reproductive maturation (Jeffries *et al.*, 2012), reproductive timing (Warren *et al.*, 2012), gametogenesis (Lahnsteiner and Leitner, 2013), cardiac function (Vornanen *et al.*, 2014), gene expression (White *et al.*, 2012; Meshcheryakova *et al.*, 2016),
5 ecological relationships (Hein *et al.*, 2013; Fey and Herren, 2014), and fish behaviour (Colchen *et al.*, 2016).

Natural patterns of water temperature and streamflow are profoundly linked with climatic variables (Caissie, 2006; Webb *et al.*, 2008). Stream temperature is strongly correlated to air temperature (Mohseni and Stefan, 1999), but streamflow has a complex relationship with precipitation (McCuen, 1998; Gordon *et al.*, 2004). In addition, temperature influences the precipitation type (rainfall or snowfall) and snowmelt occurrence, and inversely, river discharge is also a main explanatory
10 factor of water temperature for some river systems (Neumann *et al.*, 2003; van Vliet *et al.*, 2011; Toffolon and Piccolroaz, 2015). Furthermore, geology affects surface water temperature by means of the groundwater discharges (Caissie, 2006), influencing the aquifer deep (shallow or deep) and the water's residence time (Kurylyk *et al.*, 2013; Snyder *et al.*, 2015).

Climate change is already affecting aquatic ecosystems altering temperature and precipitation patterns. Stream temperature increases have been documented for the last decades throughout the globe, in Europe (e.g., Orr *et al.*, 2015), Asia (e.g., Chen
15 *et al.*, 2016), America (e.g., Kaushal *et al.*, 2010) and Australia (e.g., Chessman, 2009). Flow regimes are also being influenced by changes in precipitation, although those trends vary by climatic region (IPCC, 2013; Morán-Tejeda *et al.*, 2014). The predictions of the International Panel of Climate Change (IPCC, 2013) suggest that these alterations will continue throughout the XXI century and it will have consequences on the freshwater fish distribution (e.g., Comte *et al.*, 2013; Ruiz-Navarro *et al.*, 2016). This alteration may especially affect cold-water fish, which have been shown to be very sensitive to
20 climate warming (Williams *et al.*, 2015; Santiago *et al.*, 2016). For example, among salmonids, DeWeber and Wagner, (2015) found temperature to be the most important determinant of the occurrence probability of the brook trout, *Salvelinus fontinalis* (Mitchill, 1814).

The rear edge of the distribution (*sensu* Hampe and Petit, 2005) of a cold-water species is especially sensitive to changes in temperature in addition to reductions in the available habitable volume (i.e., streamflow). The impact of water temperature
25 on the distribution of salmonid fishes is well documented (e.g., Beer and Anderson, 2013; Eby *et al.*, 2014); however, the combined effects of temperature rise and streamflow decay remain relatively unexamined; with some exceptions, e.g. Wenger *et al.*, (2011) or Muñoz-Mas *et al.*, (2016). Jonsson and Jonsson (2009) predicted that expected effects of climate change on water temperatures and streamflow will have implications for migration, ontogeny, growth and life-history traits of Atlantic salmon, *Salmo salar* Linnaeus, 1758, and brown trout, *Salmo trutta* Linnaeus, 1758. Thus, investigation of these
30 habitat variables in the context of several climate scenarios should help scientists to assess the magnitude of these changes on the suitable range and life history.

The objective of this study was to predict how and to what extent the availability of suitable habitat for the brown trout, a sensitive cold-water species, will change within its current natural distribution under the new climate scenarios through the study of the changes in streamflow and temperature and their interaction. To this end hydrologic simulation with M5 models

5 trees coupled with non-linear water temperature models at the daily time step were feed with a fine grained downscaling of the air temperature and precipitation predicted for the most recent climate change scenarios (IPCC, 2013). It is hypothesized that the flow regime and geological nature of the basin influences the thermal regime of rivers and streams; thus, the effects of basin geology on the temperature models and on the changes in thermal regimes were studied. Finally, the alterations of trout thermal habitat were assessed by studying the violation of the tolerance temperature thresholds of the brown trout.

2. Materials and methods

10 The logical framework followed is summarized in Fig. 1. First, more recent daily general climate models at local resolutions were downscaled. Then, the obtained local climate models were applied to create streamflow and temperature models. The results are daily values that might be useful for the assessment of hydrological resources and the changes in water quality and aquatic communities based on the changes in resources availability. As noted, this study is focused on fish habitat suitability and availability.

The procedure yielded results in the form of continuous time series, but they are presented for two time horizons: year 2050 (H-2050) and year 2099 (H-2099). The values for these horizons are the results' average of the decades 2041-2050 and 2090-2099, respectively.

15

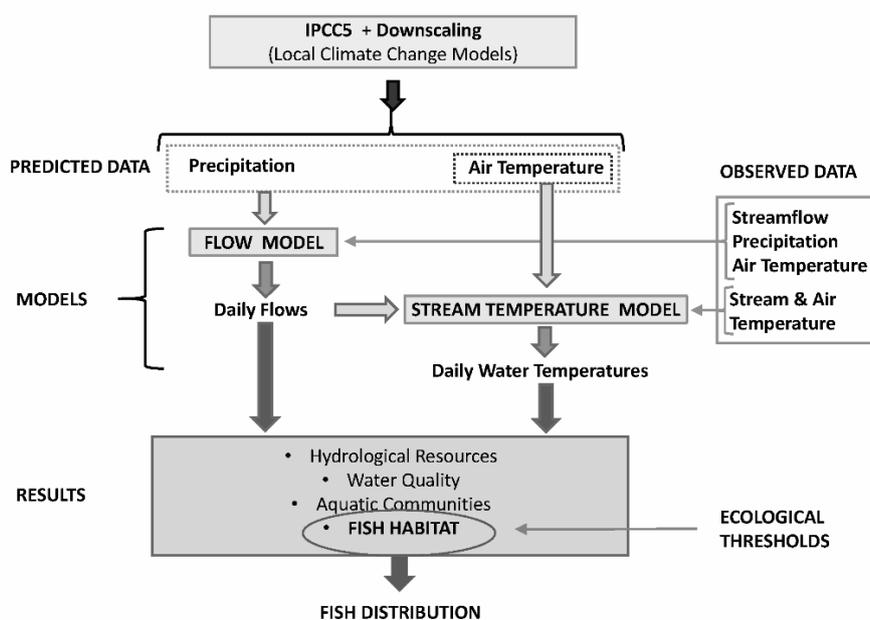

Figure 1. Logical framework of the study.

2.1 Study sites

A total of 31 sites at 14 mountain rivers and streams inhabited by brown trout was chosen with the aim of encompassing a diverse array of geological and hydrological conditions in the centre of Spain (between 39°53' N and 41°21' N latitudes): the Tormes River and its tributaries the Barbellido River, Gredos Gorge and the Aravalle River (Duero basin), Cega River, Pirón River (Pirón is a tributary of the Cega River, in the larger Duero basin), Lozoya River, Tagus River, Gallo River, Cabrillas (Tagus basin), Ebrón River, Vallanca River (Vallanca is a tributary of the Ebrón River, in the Turia basin), Palancia River and Villahermosa River (Fig. 2). Major components of geology lithologically characterize the mountain sites in the Duero and Lozoya basins as igneous, altitudinally lower sites in the Duero basin are detrital (Cenozoic), and the eastern basins (Tagus, Gallo, Cabrillas, Ebrón, Vallanca, Palancia and Villahermosa) are characterized as mainly carbonated (Mesozoic).
The geological characterization was retrieved from the Lithological Map of Spain (IGME, 2015) (Table 1).

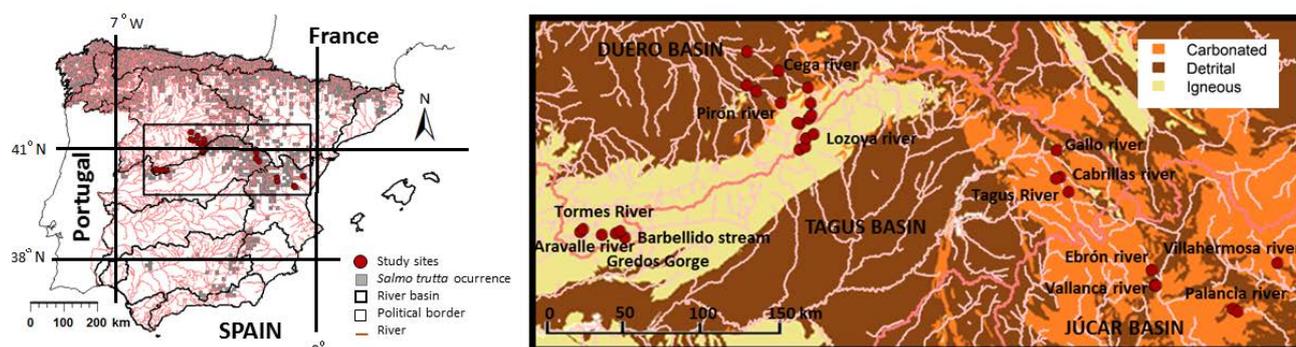

Figure 2 River network and location of the study sites (temperature data loggers), with details regarding lithology. The grid depicts the actual brown trout occurrence in Spain.

Land use is mainly forest in all study site basins (CORINE Land Cover 2006 [European Environmental Agency, 2007]). Only the lower basins of the downstream sites on the Cega and Pirón rivers are mosaics of forest and croplands, whereas the uppermost sites within the Tormes River basin (Barbellido and Gredos Gorge) lie above the current tree line. Land use change scenarios were assumed to not be probable. The studied reaches are not effectively regulated (only small weirs or natural obstacles exist). One large dam lies on the Pirón River (Torrecaballeros Dam; capacity: 0.324 hm³; maximum depth: 26 m; and altitude: 1390 m a.s.l.), but it does not significantly alter the temporal streamflow pattern (Santiago *et al.*, 2013). Hydrological data characterized the streamflow regimes as extreme winter/early spring (groups 13 and 14 in the classification of Haines *et al.*, [1988]). However, hydrographs show a west to east smoothing gradient (Fig. 3). Smoothing is associated with carbonated geology, whereas greater seasonality is associated with igneous and detrital geology.

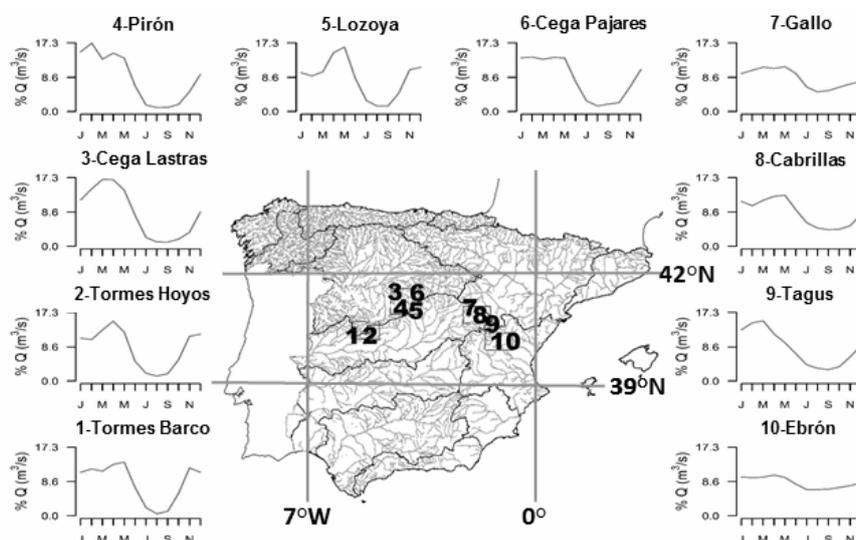

Figure 3. River regime patterns for the different gauging stations. Flows are expressed as percentages of the mean annual flow, and months are ordered from January to December.

5 2.2 Data collection

In each study site, water temperature was registered every two hours using 31 Hobo® Water Temperature Pro v2 (Onset®) and Vemco® Minilog data loggers located at several sites along the studied rivers (Table 1). Meteorological data were obtained from 9 thermometric and 15 pluviometric stations of the Spanish Meteorological Agency (AEMET) network, and 10 gauging stations (from the Water Administrations' official network) and were considered to model running flows. The closest AEMET-thermometric stations to the stream temperature monitoring sites with at least 30 years between 1955 and the present were selected. The selected pluviometric stations were those located within the target river basin and upstream of the corresponding gauging station (Table 2).

2.3 Climate change modelling and downscaling

Data from nine global climate models associated with the 5th Coupled Model Intercomparison Project were used, namely: BCC-CSM1-1; CanESM2; CNRM-CM5; GFDL -ESM2 M; HADGEM2-CC; MIROC-ESM-CHEM; MPI-ESM-MR; MRI-CGCM3; NorESM1-M (Santiago *et al.*, 2016) which provided daily data to simulate future climate change corresponding to the Representative Concentration Pathways RCP4.5 (stable scenario) and RCP8.5 (more increasing CO₂ scenario) established in Taylor *et al.* (2009) and used in the 5th Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2013). An array of nine general climate models was used to avoid bias due to the particular assumptions and features of each model, (Kurylyk *et al.*, 2013). Historical simulations (XX century) were used to control the quality of the procedure and to compare the magnitude of the predicted changes.

Pourmokhtarian *et al.* (2016) remark the importance of the use of fine downscaling techniques; thus, a two-step analogue statistical method (Ribalaygua *et al.*, 2013) was used to downscale the daily climatic data: the maximum and minimum air temperatures and the precipitation for each station and for each day. For both air temperature and precipitation, the procedure begins with an analogue stratification (Zorita and von Storch, 1999) in which the n days most similar to each problem day to be downscaled are selected using four different meteorological large-scale fields as predictors: (1) the speed and (2) direction of the geostrophic wind at 1000 hPa and (3) the speed and (4) direction of the geostrophic wind at 500 hPa. In a second step, the temperature determination was obtained using a multiple linear regression analysis using the selected n of most analogous days. This was performed for each station and for each problem day, as well as for maximum and minimum temperatures. The linear regression uses forward and backward stepwise selections of the predictors to select only the predictive variables for that particular case. For precipitation, a group of m problem days (the whole days of a month were used) were downscaled together: ‘preliminary precipitation amount’ averaging the rain amount of its n most analogous days was obtained for each problem day. Thus, the m problem days from the highest to the lowest ‘preliminary precipitation amount’ could be sorted. For assigning the final amount of rain, each one of the amounts of rain of the $m \times n$ analogous days was taken. Then those $m \times n$ amounts of rain were sorted, and then those amounts were clustered in m groups. Every quantity was then assigned, orderly, to the m days previously sorted by the ‘preliminary precipitation amount’. Further details of the methodology are described in Ribalaygua *et al.* (2013).

A systematic error is obtained when comparing the simulated data from the climate models with the observed data, inherently associated with every downscaling methodology and every climate model (both of which usually introduce bias into the data). To correct this systematic error, the future climate projections were corrected according to a parametric quantile-quantile method (Monjo *et al.*, 2014), performed by comparing the observed and simulated Empirical Cumulative Distribution Functions (ECDF) and linking them by the ECDF of the downscaled European Centre for Medium-Range Weather Forecasts ERA-40 reanalysis daily data (Uppala *et al.*, 2005).

As a result, for each climate change scenario, daily maximum and minimum temperatures (used to infer the mean temperature) and precipitation were obtained for each climate model which were used as input to simulate the runoff and water temperature under these climate change scenarios.

2.4 Hydrological modelling

The prospective prediction of the runoff flows was performed with data-driven hydrological models developed with the M5 algorithm (Quinlan, 1992). M5 has been demonstrated to be proficient to model daily streamflow (Solomatine and Dulal, 2003; Taghi Sattari *et al.*, 2013), even in studies involving climate change (Muñoz-Mas *et al.*, 2016). The M5 algorithm is a tree-like recursive partitioning technique, similar to Classification and Regression Trees (CARTs) (Breiman *et al.*, 1984) or Random Forests (RF) (Breiman, 2001). Recursive partition iteratively divides the input space into smaller subspaces, usually maximising the homogeneity of the child nodes. This partitioning typically begins with the most discriminant split and proceeds to the least one and is applied in a hierarchical fashion to each of the new branches of the tree until the maximum

number of allowed partitions or any other constraint is achieved (Veza et al. 2015). However, instead of assigning a single value or category to each terminal nodes (i.e., leaf), M5 fits a multi-linear regression model (Quinlan 1992). Consequently, the ultimate tree becomes a piecewise multi-linear model, which can be seen as a committee of linear models with each member specialized in particular subsets of the input space (Taghi Sattari *et al.*, 2013). Based on the multi-linear models at
5 the leaves, M5 allows extrapolation, in contrast with other machine learning techniques that have demonstrated a poor or null capacity to do so (Hettiarachchi *et al.*, 2005).

The M5-based hydrological models were developed in R (R Core Team, 2015) with the Cubist package (Kuhn *et al.*, 2014). One single M model tree was trained for each gauging station and predictions were supported by the nearest observation (i.e., neighbours = 1) to reduce the potential prediction of unreliable flows. Finally, M5 was allowed to decide the ultimate
10 number of leaves in the model tree (i.e., the number of models in which the input space is eventually divided).

Following previous studies, the hydrological models were trained using daily, monthly and quarterly data lags of historical rainfall and temperature data as input variables (Solomatine and Dulal, 2003; Taghi Sattari *et al.*, 2013; Muñoz-Mas *et al.*, 2016). These three groups of variables were intended to reflect the causes of peak, normal and base flows. The study encompassed several rivers that may present different hydrologic behaviours; therefore, the starting set of input variables
15 was larger than that used in other studies (Solomatine and Dulal, 2003; Taghi Sattari *et al.*, 2013; Muñoz-Mas *et al.*, 2016). Daily variables included the precipitation and temperature from the current day to the 15th previous day (16 variables in total). The monthly variables were calculated using the moving average for the 12 previous months (12 variables in total), and the quarterly data were calculated from the moving average for the current month to the 24th previous month (8 variables in total). Consequently, daily variables overlapped with the current month variable, and the first four quarterly variables
20 overlapped with the monthly data. Thus, 72 variables were used (36 each for temperature and precipitation).

The whole set of input variables may be relevant for some river systems, although it may cause M5 to overfit the data in others. Therefore, unlike previous studies that used smaller input variable sets (Muñoz-Mas *et al.*, 2016), the ultimate variable subset was optimized following the forward stepwise approach (Kittler, 1978). This greedy approach relies on iteratively adding inputs while performance on the test data set improves and stopping as soon the performance degrades.
25 However, this approach may cause consideration of unrelated variable sets (i.e., disjoint rainfall and temperature variable periods). To address such potential inconsistency, the optimization began by testing the rainfall-related variables and only tested the temperature variables for lags coinciding with those rainfall-related variables selected. No precaution was taken regarding correlation among inputs (Solomatine personal communication), and the forward stepwise approach sought the maximization of the Nash-Sutcliffe Efficiency (NSE) index (feasible range from $-\infty$ to 1; Nash and Sutcliffe [1970]) in a
30 fivefold cross-validation as indicated in Borra and Di Ciaccio (2010). Following previous studies (Fukuda *et al.*, 2013; Muñoz-Mas *et al.*, 2016), once the optimal variable set was determined, single M5 models trees were developed to perform the prospective prediction of the flow rate under the climate change scenarios.

Daily data were analysed monthly and seasonally using the following statistics: minimum flow (Q_{\min}), 10th-percentile flow (Q_{10}), mean flow (Q_{mean}), and maximum flow (Q_{\max}). Annual runoff and days of zero-flow were also examined.

To assess the significance of the streamflow trends throughout the century, Sen's slope was used (Trend package of R (Pohlert, 2016); p-value ≤ 0.05) with horizons H-2050 and H-2099.

Finally, the variation of the patterns of the monthly mean streamflow was studied by means of cluster analysis of the change rate of the normalized monthly mean streamflow at H-2050 and H-2099, for the RCP4.5 and RCP8.5 scenarios (Ward
 5 Hierarchical Clustering – cluster package of R [Maechler, 2013]).

2.5 Stream temperature modelling

Daily Mean Stream Temperature (DMST) was used because it better reflects the average conditions that fish (particularly trout) will experience for an extended period of time (Santiago *et al.*, 2016) and also it averaged daily fluctuation in the radiation and heat fluxes.

10 A non-linear regressive model was used to determine DMST from Daily Mean Air Temperature (DMAT). The Mohseni *et al.* (1998) regressive logistic model was preferred to machine-learning models such as classification and regression trees (De'ath and Fabricius, 2000) and random forests (Breiman, 2001) because parameters in the former have physic significance and higher transferability (Wenger and Olden, 2012). Thus, models described temperature behaviour adjusting a sigmoid curve to the data affecting the trend of the higher water temperatures, which present an attenuated gradient due to the
 15 evaporative water-cooling, being more reliable than linear regressions (Mohseni and Stefan, 1999). At the same time, prediction on air temperature will overpass the actual temperature range thus models which assure transferability as non-machine learning should be preferred (Wenger and Olden, 2012). The Mohseni *et al.* (1998) model was modified by Santiago *et al.* (2016) to include the trajectory of temperature to improve its performance when daily temperature is modelled (Term 1 in Eq. [1]). In the modified model T_s is DMST, T_a is DMAT, μ is the minimum stream temperature (given in °C), α is the maximum stream temperature (°C), β represents air temperature at which the rate of change of the stream temperature with respect to air temperature is maximum (°C), γ (°C⁻¹) is the value of the rate of change at β , and λ is a coefficient (dimensionless) representing the resistance of DMST to change with respect to 1-day variation in DMAT (ΔT_a). Negative values of λ are due to the resistance to temperature change and, thus, must be subtracted from the expected temperature: the more resistant the stream is to temperature change, the closer λ is to zero. The less resistant to change, the
 25 more negative λ is.

$$T_s = \underbrace{\mu + \frac{\alpha - \mu}{1 + e^{\gamma(\beta - T_a)}}}_{\text{Term 1}} + \lambda(\Delta T_a) + \underbrace{\frac{\omega}{1 + e^{\delta(\tau - Q)}}}_{\text{Term 2}} \quad (1)$$

In addition, the model was further modified by introducing the daily mean flow (Q) through a logistic function with three
 30 parameters (Term 2 in Eq. [1]): ω is the maximum observable variation in temperature due to the flow difference (given in °C), τ represents the flow value at which the rate of change of the stream temperature with respect to the flow is maximum (m³·s⁻¹), and δ (m⁻³·s) is this maximum rate at τ .

A blockwise non-parametric bootstrap regression (Liu and Singh, 1992) was used to estimate the parameters of both the modified Mohseni models (with and without streamflow), and residual normality and non-autocorrelation were checked with Shapiro test and Durbin-Watson test, as well the 7 day-lag PACF (Partial Autocorrelation Function) were obtained. Calculations were performed using R. A 95 % confidence interval was calculated for each parameter. Bayesian information criterion (BIC) and Akaike information criterion (AIC) were used to test the eight-parameter models against the five-parameter models.

The parameter μ was allowed to be less than zero in the modelling process even though this is the freezing temperature. Thus, the function would truncate at the freezing point. The relationship between the thermal amplitude $\alpha-\mu$ and the indicator of thermal stability λ was studied using the Pearson correlation.

Geology is determinant of the residence time of deep-groundwater in the aquifer (Chilton, 1996), and residence time influences the discharge temperature. To explore the relationships between thermal regimes and geology, a stratified study of both the geology classes of the parameter values was completed by means of a t-test with Bonferroni correction (p-value < 0.05). In the same sense, increments of the annual averages of the daily mean (ΔT_{mean}), minimum (ΔT_{min}) and maximum (ΔT_{max}) stream temperatures were calculated and studied by geological classes.

The variation of the patterns of the monthly mean stream temperature was studied by means of cluster analysis of the temperature increments at H-2050 and H-2099, for the RCP4.5 and RCP8.5 scenarios (Ward Hierarchical Clustering – cluster package of R [Maechler, 2013]).

2.6 Thermal habitat changes

Several tolerance temperatures have been described for brown trout (Elliott *et al.*, 1995; Forseth *et al.*, 2009; Elliott and Elliott, 2010). The elected threshold for this study was the occurrence of DMST above 18.7°C for seven or more consecutive days because it has proven to be the most realistic value to represent the realized thermal niche (Santiago *et al.*, 2016). The minimum period of 7 consecutive days is usually the established time for determining thermal tolerance (Elliott and Elliott, 2010), and when this period is exceeded, the death risk increases harshly. The use daily mean rather than daily maximum is better to reflect the average conditions that trout must experience for an extended period. In addition, studying DMST for 7 consecutive days above the threshold because is the more accurate option (Santiago *et al.*, 2016).

Once DMST was modelled, the frequency of events of 7 or more consecutive days above the threshold per year (Times Above the Threshold, $TAT_{\geq 7}$), the total Days Above the Threshold per year (DAT), and the Maximum Consecutive Days Above the Threshold per year (MCDAT) were calculated for the whole period of 2015-2099.

To assess the general trend in thermal habitat alterations at the middle (H-2050) and the end of the century (H-2099), the $TAT_{\geq 7}$, DAT and MCDAT were calculated at each sampling site for each climate change scenario and compared with current conditions. In this way, the sampling sites spread to a wide range of geological and hydrological conditions in three main basins.

The sampling sites distribution at Cega, Pirón and Lozoya streams allowed us to study the relation between the annual average of DMST and altitude, and a high correlation was detected ($R^2 = 0.986, 0.985$ and 0.881 , respectively). A digital elevation model (at a 5-m resolution, obtained from LIDAR, IGN [National Geographic Institute of the Spanish Government]) was used to perform an altitudinal interpolation of the model parameters to determine the water temperature
5 along the stream continuum to simulate the climate change scenarios' effects, and then to obtain the percentage of stream/river length lost for trout. ArcGis® 10.1 (by ESRI®) was used to manage the DEM.

3 Results

3.1 Climate change

Under the climate change scenarios, all the meteorological stations experience important increases in temperature (DMAT)
10 through the century, and this trend proved to be more pronounced in the RCP8.5 scenario. The main changes will occur in summer, and to a lesser extent, in winter (annual trends in Fig. 4; seasonal results per location in Fig. S1 to S24 [Supplementary Material 1]). The temperature variations run parallel in both scenarios until mid-century, when the RCP8.5 scenario predict a similar trend and the increases become smaller in the RCP4.5 scenario: the annual change in temperatures for the RCP4.5 fluctuates between 2°C and 2.5°C at mid-century ($3\text{-}4^\circ\text{C}$ in summer) and between 2.5°C and 3.5°C at the end
15 of the century ($3.5\text{-}4.5^\circ\text{C}$ in summer), and the annual change for the RCP8.5 is between 2°C and 3°C at mid-century ($3.5\text{-}4.5^\circ\text{C}$ in summer) and between 5°C and 7°C at the end of the century ($7\text{-}8^\circ\text{C}$ in summer).

In absolute terms ($\text{mm}\cdot\text{day}^{-1}$), annual precipitation fluctuates around the no-change value (zero) (Fig. 4), but seasonal trends differ (Fig. S1). The changes in precipitation are mainly small, but large changes are detected at some sites, especially in autumn, with important precipitation decreases in the RCP8.5 scenario. For the same time scale, RCP4.5 returns to the
20 current values at the end of the century. In relative terms (%), the changes are also small but sufficiently significant to be considered: there is an annual change in the RCP4.5 from 0 to -15% at mid-century (0 to -20% for the October-March period) and 10 to -10% at the end of the century (10 to -10% for the October-March period), and there is an annual change in the RCP8.5 from 10 to -10% at mid-century (0 to -20% for the October-March period) and 0 to -20% at the end of the century (0 to -20% for the October-March period).

25 Daily mean air temperatures of the ensemble models for each meteorological station are shown in the Supplementary Material 2 (Dataset S1).

3.2 Hydrological regimes

The hydrological models performed well—all of them achieved NSE values above 0.7 with the exception of Tormes-Hoyos (NSE=0.673); nonetheless, each model was constituted by different variable sets (Table S1 [Supplementary Material 3]).
30 Fig. 5 shows plots of the monthly Q_{mean} results of the simulations for RCP4.5 and RCP8.5 scenarios at H-2050 and H-2099. Predicted daily mean streamflow from the climate change models ensemble is in the Supplementary Material 4 (Dataset S2)

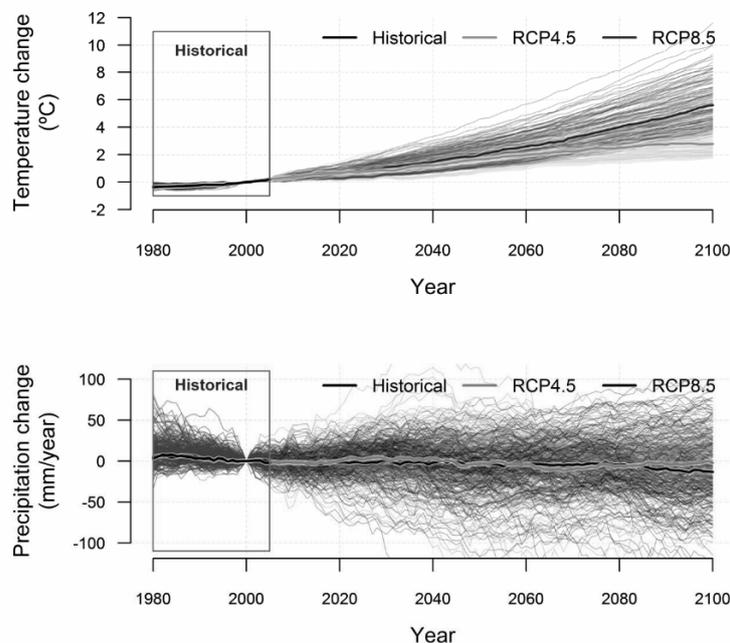

Figure 4. Climate change increments of mean air temperature and total annual precipitation for the nine general climate models and the two climate change scenarios for the all the studied meteorological stations.

5 3.2.1 RCP4.5 scenario

Statistically significant changes are rare at H-2050, with the exception of Cega-Lastras and Lozoya (Table 3, Fig. 5). At H-2099, changes are less pronounced, but the significance is higher (Table 3, Fig. 5). The only significant annual runoff reductions at H-2050 occur at two stations (Lozoya and Tagus), with significant losses at 7 sites at H-2099 (Tormes-Barco, Cega-Lastras, Pirón, Gallo, Cabrillas). The Lozoya and Tagus stations do not increase their annual runoff losses between H-2050 and H-2099. Changes in Q_{mean} are less significant in winter. The significant decrease in Q_{min} and Q_{10} at Cega-Lastras at H-2050 occurs throughout the year, whereas at H-2099, this decrease occurs mainly in spring and summer; this is also true in the Q_{mean} case. The most significant changes in Q_{mean} at H-2050 occur at the Lozoya station, whereas the changes are more general at Lozoya and in the upper Tagus basin (Gallo, Cabrillas and Tagus stations) at H-2099. Significant changes (decreases) in Q_{max} are only found at the same stations. At H-2099, the number of days with zero-flow increase is only significant at the Cega-Lastras station.

3.2.2 RCP8.5 scenario

The most significant results occur at Cega-Lastras y Lozoya at H-2050 (Table 3, Fig. 5). At H-2099, the streamflow losses increase and become significant, even given the seasonal flow increases at some gauging stations (Ebrón and both stations

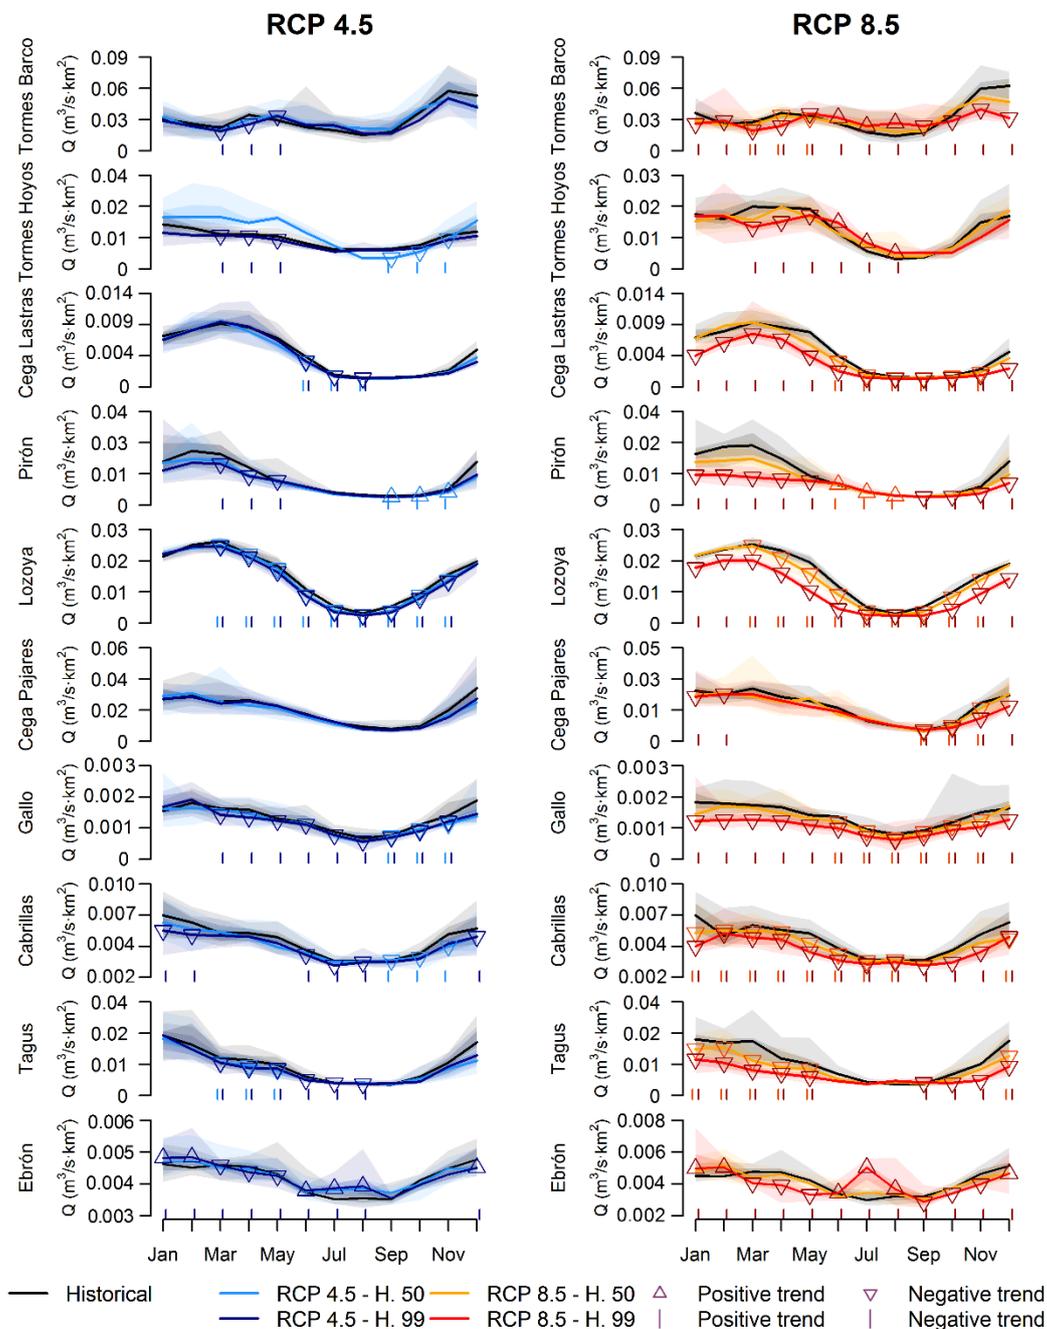

Figure 5. Predicted monthly mean specific-flow at H-2050 and H-2099 for the RCP4.5 and RCP8.5 scenarios. Shaded area indicates the decadal fluctuation. Triangles show significant negative or positive trend (Sen's slope $p \leq 0.05$) indicated by the ticks beneath each plot.

on the Tormes River) (Table 3, Fig. 5). Significant annual runoff reductions at H-2050 occur at 5 stations (Lozoya and Tagus, as in RCP4.5, and Cega-Lastras, Gallo and Cabrillas), increasing the occurrence of significant losses to 9 of the 10 sites at H-2099 (all stations except Ebrón). Changes in Q_{mean} are less significant in winter at H-2050, but they are very important at H-2099. The significant decreases in Q_{min} and Q_{10} at Cega-Lastras at H-2050 occur throughout the year (except for autumn for Q_{min}), as at H-2099. The stations with substantial decreases in all variables at H-2099 are Lozoya, Cega-Lastras, Pirón, Tagus, Gallo and Cabrillas, with fewer decreases at Cega-Pajares and both Tormes gauging stations. The number of days with zero-flow increase is significant for both horizons only at the Cega-Lastras and Pirón stations and is significant at only H-2099 at the Gallo station.

3.2.3 Geographical pattern

10 The current streamflow patterns, strongly modulated by geology, will experience a progressive increase of the influence of climate change that is reflected in the differences among the clustered sites (Fig. 6).

In the RCP4.5 scenario at H-2099 the clustering is very weak (agglomerative coefficient: 0.56) and heterogeneous. At H-2050, the clustering yields a geographical change pattern; however, in spite of the distance, Ebrón station is aggregated to Tormes stations because the similarity of the hydrological response (a.c.: 0.73).

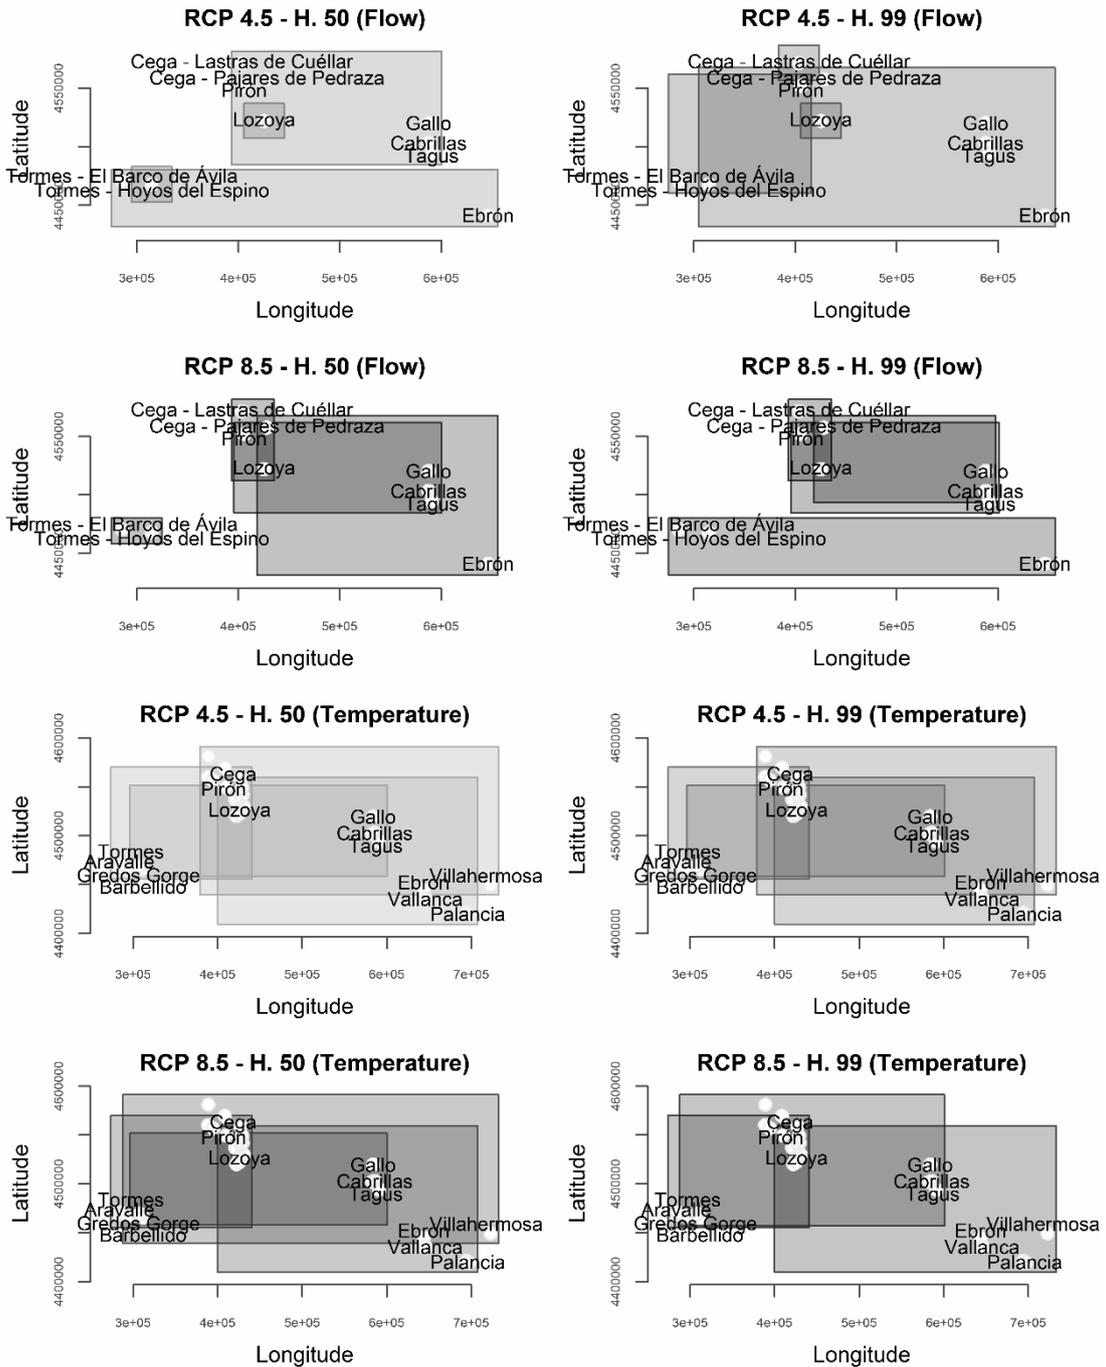

15 The agglomerative coefficient (0.61) for clustering in the RCP8.5 scenario at H-2050 is weak, with the only recognizable pattern grouping the stations that will lose more flow throughout the year. The most important changes will be produced in the RCP8.5 scenario at H-2099 (a.c.: 0.72). Cega-Lastras and Lozoya form the group of the most heavily affected sites by flow reductions; one of them is in the Duero basin, and the other in the Tagus basin, but they are geographically not far from one other. Another group share with the former the generalized losses excepting at summer. The remaining group can be
 20 disaggregated in two other: one with the stations located at Tormes basin and Ebrón which show significant losses at spring and autumn, and increases at summer, and the second group showing homogeneous but no so heavy losses. In this cluster the geologic component is attenuated.

In general, streamflow losses will increase throughout the century but not consistently in all the sites. At the most western (Tormes) and eastern (Ebrón) stations, flow values will increase again at H-2099 after decreasing in the fifties. Lozoya will
 25 suffer the most substantial flow losses, followed by Pirón and Cega-Lastras, Tagus and Gallo, and Cabrillas.

3.3 Stream temperature

3.3.1 Model parameter behaviour and general trends

In accordance with the BIC and the AIC calculated for each temperature model, the inclusion of the running flow improves model performance in 12 out of 31 study cases. In the other 19 cases, the five parameters model was used (Table 4). In cases
 30 in which no improvement occurs with the model that included streamflow effect, at times, no convergence of values is observed in the regression process, and at other times, the obtained values do not improve the results as the streamflow

5 **Figure 6.** Study sites clustered by the predicted change ratios of the monthly mean streamflow (gauging stations) and by the predicted increase of the monthly mean temperature ($^{\circ}\text{C}$, at water temperature recording sites) at H-2050 and H-2099 for the RCP4.5 and RCP8.5 scenarios. Axes show geographic position (UTM coordinates).

component is virtually zero. The calculated parameters are shown in Table 5, and daily mean stream temperatures from the climate change models are in the Supplementary Material 5 (Dataset S3).

For the entire sample ($n=31$), Pearson correlation between thermal amplitude ($\alpha-\mu$) and λ is significant (-0.832 ; $p<0.0001$).

5 As the thermal amplitude increased, λ become more negative (less resistance). As the thermal amplitude decreases, λ approaches zero (more resistance).

By the end of the XXI century, the predicted average increase in the mean annual stream temperature among the sites is 1.1°C for the RCP4.5 scenario simulations (range 0.3 - 1.6°C) and 2.7°C for the RCP8.5 (range 0.8 - 4.0°C). Annual maximum average temperature increases are predicted to be 0.8°C for the RCP4.5 (range 0.1 - 1.5°C) and 1.6°C for the RCP8.5 (range
 10 0.2 - 3.0°C), and annual minimum average temperature increases are 1.0°C (range 0.4 - 1.8°C) and 2.7°C (range 1.1 - 4.5°C), respectively. The most important increases are predicted to occur in winter, with summer experiencing lesser increases.

3.3.2 Temperature and geological nature

Thermal amplitude is higher at igneous ($\bar{\alpha}-\bar{\mu}= 20.38^{\circ}\text{C}$) than at carbonated sites ($\bar{\alpha}-\bar{\mu}= 13.07^{\circ}\text{C}$). β values are higher at igneous ($\bar{\beta}= 12.71^{\circ}\text{C}$) than at carbonated sites ($\bar{\beta}= 7.80^{\circ}\text{C}$), and λ is significantly higher ($\bar{\lambda}= -0.140$) at carbonated than at
 15 igneous ($\bar{\lambda}= -0.292$) and at quaternary-detrital sites ($\bar{\lambda}= -0.305$) (Fig. 7). All of these differences are significant.

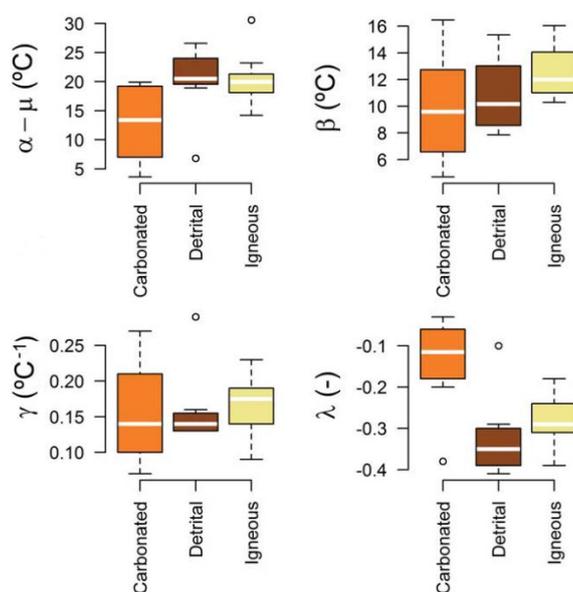

Figure 7. Distributions of the stream-temperature model parameters values ($\alpha-\mu$, β , γ and λ) in relation to lithology. Differences were tested by mean of Student's t with Bonferroni correction ($p<0.05$).

- Among the 8-parameter models ($n=12$), significant differences are also found among lithological classes for ω and τ . In both cases, ω and τ values were higher at carbonated ($\bar{\omega}= 0.96^{\circ}\text{C}$; $\bar{\tau}= 3.640 \text{ m}^3 \cdot \text{s}^{-1}$) than at igneous ($\bar{\omega}= -2.12^{\circ}\text{C}$; $\bar{\tau}= 0.345 \text{ m}^3 \cdot \text{s}^{-1}$) sites.
- 5 In RCP4.5 scenario, ΔT_{\min} at quaternary-detrital sites behaves significantly different than in carbonated and igneous sites. This difference is only found between quaternary-detrital and carbonated sites in RCP8.5 scenario. ΔT_{mean} exhibits significant differences between the carbonated and igneous and quaternary detrital sites, in both scenarios. All of these results are common at H-2050 and H-2099. Finally, at H-2050, significant differences are found between ΔT_{\max} in carbonated and igneous sites in both scenarios and, while this occurs in the same way at H-2099 in RCP4.5 scenario, the
- 10 differences are also significant between carbonated and quaternary-detrital sites in RCP8.5 scenario (Fig. 8).

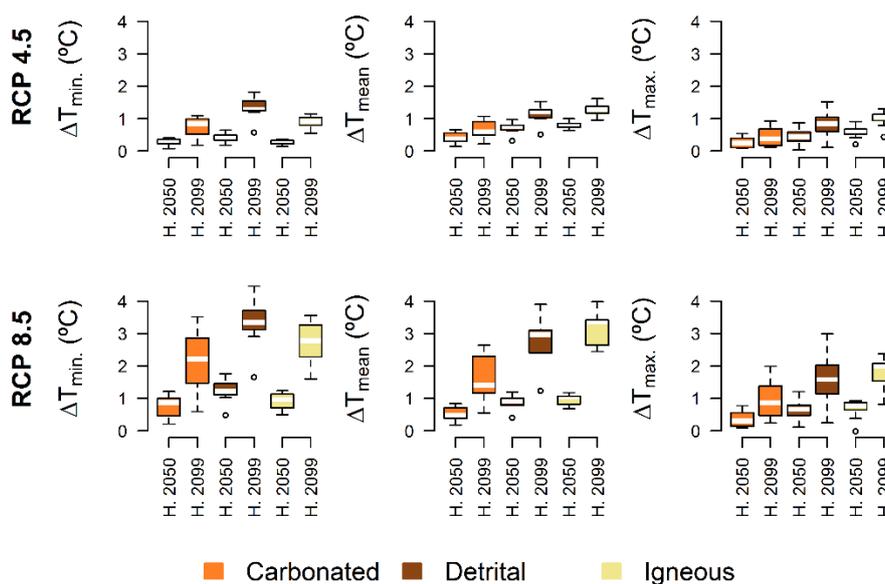

Figure 8. Distributions of ΔT_{\min} , ΔT_{mean} and ΔT_{\max} in relation to lithology for the climate change scenarios RCP4.5 and RCP8.5 at H-2050 and H-2099. Time of reference: simulated period 2010-2019.

- 15 The results of the cluster analysis of the monthly mean stream temperature of sites show highly homogeneous groups between the different combinations of horizons and scenarios, being the thermal response of the rivers and streams very linked to geology. The carbonated sites from Cabrillas stream to the East and Pirón 3 (under the strong influence of a calcareous spring) form a group of sites that shows low thermal amplitude and in which lambda is closest to zero. In the
- 20 other extreme, a group mainly formed by granitic sites (Lozoya and Tormes basins, and various sites in the detrital basin of

Cega-Pirón basin) shows higher thermal amplitude and lower values of lambda than the former group. All other sites have intermediate values of both, thermal amplitude and resistance.

3.3.3 Effect of streamflow reduction on stream temperature

The effect of streamflow change on temperature is analysed at the following sites: Tormes 2, Tormes 3, Pirón 1, Cega 1, 5 Lozoya 1 to 4, Cabrillas, Ebrón 1 and Vallanca 1 and 2. These are the sites in which the 8-parameter model improves upon the 5-parameter model. In all cases, stream temperature differences between the five and eight parameter models are found, and summer flow reduction led to an increase in stream temperature, increasing DAT, $TAT \geq 7$ and MCDAT. Among these cases, the threshold is only surpassed in Lozoya and Tormes, increasing the thermal habitat loss. In Cega 1, Cabrillas and Ebrón, α is below the thermal threshold, and in Pirón 1, the temperature increase is not sufficient to exceed the threshold. 10 The differences between the annual maximum stream temperatures for both models at H-2050 and H-2099 imply increases up to 3.6°C in Tormes 2, with smaller increases in Tormes 3 (2.5°C) and the Lozoya sites (0.9°C to 1.7°C). Because of the improved model, increases in the maxima of 1.1°C in Cega and 1.4°C in Pirón are observed. At the Ebrón, Vallanca and Cabrillas sites, the increases in the maxima are smaller (0.01°C to 0.3°C).

3.3.4 Effect of climate change on brown trout thermal habitat

15 In the predictions at H-2050, the 18.7°C threshold ($TAT \geq 7$) is violated at 8 sites in the RCP4.5 scenario and 6 sites in the RCP8.5 scenario. In the climate change simulations for the end of the XXI century (2099 horizon), the threshold is violated at 8 sites in the RCP4.5 scenario and 13 sites in the RCP8.5 scenario. These violations imply the loss of thermal habitat for brown trout.

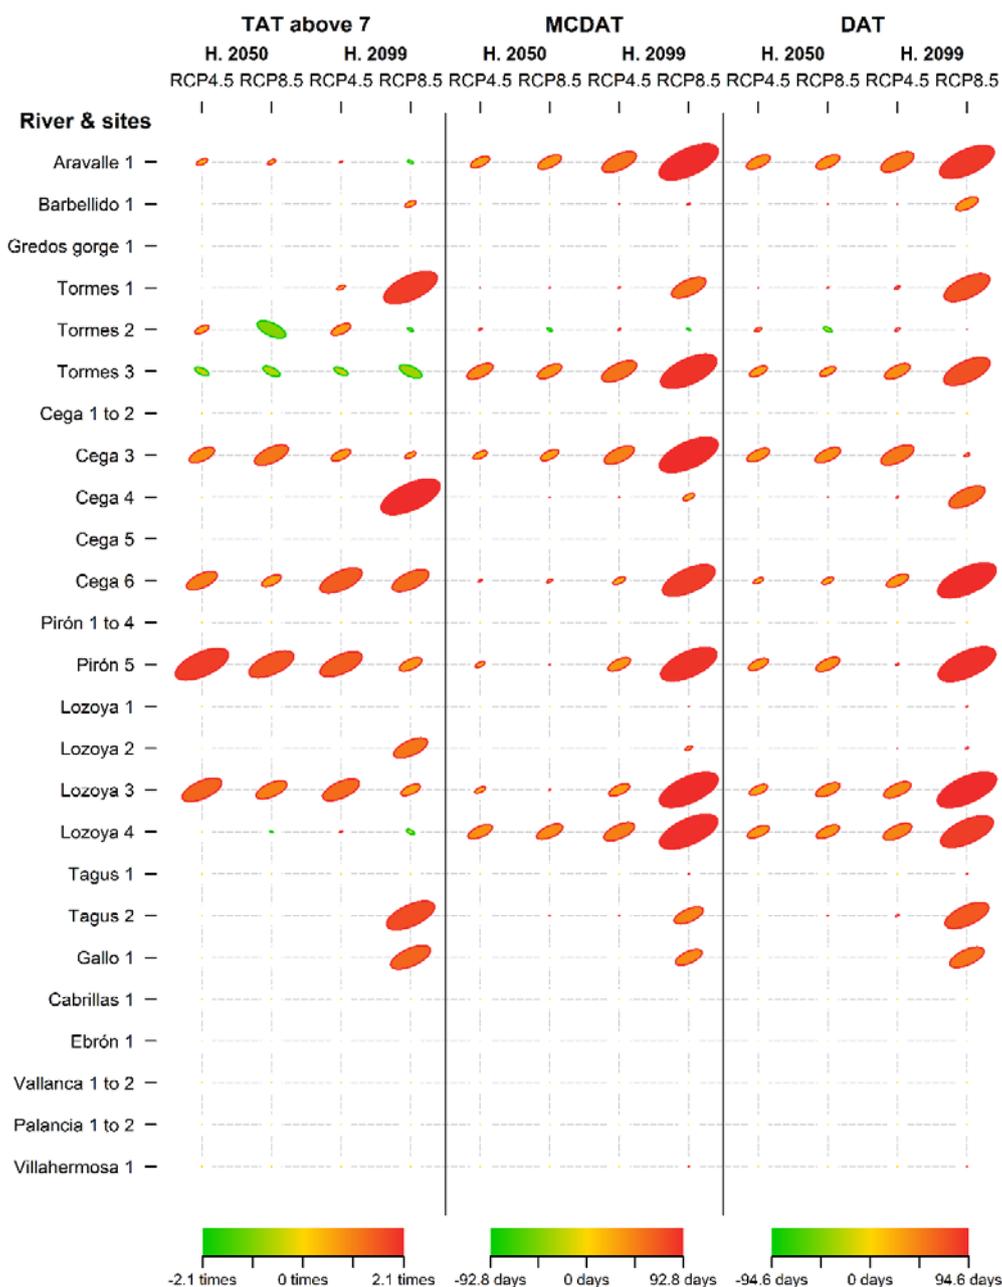

By the end of the century (H-2099), the most significant increases in $TAT \geq 7$ (Fig. 9) occur in Cega 6, Pirón 5 and Lozoya 3 20 in the RCP4.5 scenario and in Tormes 1, Cega 4, Cega 6, Lozoya 2, Gallo and Tagus-Poveda in the RCP8.5 scenario. The most significant increases in MCDAT (Fig. 9) are in Tormes 3, Aravalle, Lozoya 3, Lozoya 4, Cega 3, Cega 6 and Pirón 5 in RCP4.5 and in the same sites plus Gallo and Tagus-Poveda in RCP8.5. MCDAT is greater than 100 days in Tormes 3 (118.3), Aravalle (110.1), Lozoya 4 (110.6) and Cega 3 (105.6) in the RCP8.5 scenario. The pattern in DAT (Fig. 9) is similar to that of MCDAT, surpassing 91 days (a quarter of the total days in a year) in Tormes 3 (125.6), Aravalle (117.2), 25 Lozoya 3 (101.1), Lozoya 4 (116.2), Cega 3 (111.8), Cega 6 (94.9) and Pirón 5 (107.1) in RCP8.5. All of them surpass 37 days in RCP4.5.

At mid-century (H-2050), the main changes in the RCP8.5 scenario are comparable to those in RCP4.5 at the end of the century. The trend in the RCP4.5 scenario is slower warming beginning at mid-century, whereas the warming accelerates in RCP8.5.

30 The continuous modelling of water temperature in the Cega, Pirón and Lozoya streams show important losses of thermal habitat, affecting up to 56 %, 11 % and 66 % of the stream length, respectively. In the Cega and Pirón rivers, the loss is referred the total main channel length inhabited by the trout (98 and 77 km at Cega and Pirón, respectively). In Lozoya, the

length lost is the reach (20 km) located upstream of the Pinilla reservoir, which disconnects the reaches of the Lozoya upstream and downstream of the dam.

5 Figure 9. Increases of TAT ≥ 7 (times above the threshold during 7 or more consecutive days), MCDAT (maximum consecutive days above the threshold) and DAT (days –total per annum– above the threshold) from the present to H-2050 and H-2099 for RCP4.5 and RCP8.5.

4 Discussion and conclusions

4.1 Climate change

Results from the 5th Assessment Report of the Intergovernmental Panel on Climate Change and its annexed Atlas of Global and Regional Climate Projections (IPCC, 2013) for the Mediterranean area suggest that droughts are not likely to increase in the near future. However, air temperature is expected to rise, subsequently increasing evapotranspiration. Our downscaled results predict greater temperature increments than did the IPCC (2013), which can produce more relevant ecological consequences (Magnuson and Destasio, 1997; Angilletta, 2009). In the Mediterranean area, regional studies have used coarser resolution, which may be appropriate for their goals (e.g., Thuiller *et al.*, 2006). However, they can fail when more local predictions are needed. Thus, fine downscaling techniques as applied in this study must be used when a finer prediction resolution is needed.

4.2 Streamflow

Worldwide, abundant information is available regarding the impact of recent climate change on streamflow regimes (e.g., Luce and Holden 2009; Leppi *et al.*, 2012) and, more specifically, in our study area (e.g., Ceballos-Barbancho *et al.*, 2007; Lorenzo-Lacruz *et al.*, 2012; Morán-Tejeda *et al.*, 2014), but detailed predictions are uncommon (e.g., Thodsen, 2007). At the regional level, a reduction in water resources is expected at the Mediterranean area (IPCC, 2013). Milly *et al.* (2005) predicted a 10-30 % decrease in runoff in Southern Europe in 2050. In another global scale study, van Vliet *et al.* (2013) predicted a decrease in the mean flows of greater than 25 % in the Iberian Peninsula area by the end the century (2071-2100), using averages for both the SRES A2 and B1 scenarios (Nakicenovic *et al.*, 2000). Our results predict that mean flow will be similar to that value (-23 %, range: 0-49 %), although the emissions scenarios in this study are more severe (more increasing CO₂ scenario) than in previous studies.

The predictions for the RCP4.5 scenario show changes ranging from non-significant to significant flow reductions of up to 17 %. In the RCP8.5 scenario, significant predictions of reduction were more generalized, ranging up to 49 % of the annual streamflow losses. Our results also suggest a relevant increment in the number of days with zero-flow for some stations in the detrital area in this scenario (RCP8.5). The most sensitive variable was Q_{\min} , which showed significant declines at a larger number of sites. The predicted changes are compatible with those obtained in previous studies, although they were done for a greater scale (as cited: Milly *et al.*, 2005; van Vliet *et al.*, 2013). Apparent differences between the streamflow reductions in this study and the former (with lower flow reductions in the present study) might be because the former predictions were for the whole region (Iberian Peninsula), whereas ours are focused in mountain reaches; the scale of focus is likely also important. First, the climate and then geologic features are determinant for the hydrologic response (Raghunath,

2006). Variations respect the initial patterns seem very local. The strongest aggregations still show the geologic and geographic components.

Brown trout is a sensitive species to changes in discharge patterns because high intensity floods during the incubation and emergence periods may limit recruitment (Lobón-Cerviá and Rincón, 2004; Junker *et al.*, 2014). In the Iberian Peninsula, extreme discharges during winter are expected to increase (Rojas *et al.*, 2012) and, therefore, negatively affect trout recruitment. Thus, the predicted changes in the hydrological regime can subject brown trout populations to greater stochasticity, which may occasionally drive some populations to insuperable bottlenecks. Trout is a polytypic species and might have adaptable phenology and rather high intra-population variability in its life history traits that might allow a resilient response to variation in habitat features (Gortázar *et al.*, 2007; Larios-López *et al.*, 2015), especially in the marginal ranges (Ayllón *et al.*, 2016). However, despite these strong evolutionary responses, the current combination of warming and streamflow reduction scenarios is likely to exceed the capacity of many populations to adapt to new conditions (Ayllón *et al.*, 2016). Consistently with regional predictions (Rojas *et al.* 2012; Garner *et al.*, 2015), significant flow reductions are expected during summertime in most of the studied rivers and streams at the end of the century, and this may mean, in turn, the reduction of available habitat for trout (Muñoz-Mas *et al.*, 2016). The increase of extreme droughts involving absolute water depletion in certain reaches of the streams may be critical for some trout populations.

4.3 Stream temperature

Bustillo *et al.* (2013) recommended the assessment of the impacts of climate change on river temperatures using regression-based methods that rely on logistic approximations of *equilibrium temperatures* (Edinger *et al.*, 1968), which are at least as robust as the most refined classical heat balance models. Because our models are based on this argument, the stream temperature models developed in this study were found to be robust.

However, we also looked for relationships between thermal regime and other environmental variables in addition to air temperature and streamflow, such as geology. Bogan *et al.* (2003) showed that water temperatures were uniquely controlled by climate in only 26 % of 596 studied stream reaches. Groundwater, wastewater and reservoir releases influenced water temperature in the remaining 74 % of the cases. Loinaz *et al.* (2013) quantified the influence of groundwater discharge in the temperature variations in the Silver Creek Basin (Idaho, USA), and they conclude that a 10 % reduction in the groundwater flow can cause an increase of over 0.3°C and 1.5°C in the average and maximum temperatures, respectively. Our studied reaches did not suffer influences from wastewater or reservoir releases (with the exception of the Torrecaballeros Dam on the Pirón River). Kurylyk *et al.* (2015) showed that the temperature of shallow groundwater influences the thermal regimes of groundwater-dominated streams and rivers. Since groundwater is strongly influenced by geology, we can expect it to be a good indicator of the thermal response, as shown here. The parameters of the models accurately described the thermal performance of the study sites, and we found significant relations among parameters, geology and hydrologic response. Thermal amplitude ($\alpha\text{-}\mu$) and temperature at maximum change rate (β) were lower, and the resistance parameter (λ) was closer to zero, in basins with highly buffered aquifers (mainly carbonated) than in the others, especially in igneous basins.

Arismendi *et al.* (2014) concluded that regression models based on air temperature can be inadequate for projecting future stream temperatures because they are only surrogates for air temperature. In this study, we show that parameters of both the Mohseni model and our modification integrate the information of other variables, such as geology or flow regime. The parameter values could change with changes in geology (for instance), but these changes could be modelled by studying the behaviour of the parameters. The dynamics of parameters is a new research front, especially their asymptotic behaviour, because these models may less accurately predict extreme temperature events (Arismendi *et al.*, 2014). However, this may affect our study only if the value of the asymptote lies below the tested thresholds of fish tolerance. This can occur in highly buffered thermal regimes as the deep-groundwater very dependent streams. Thus, the limitation of ignoring the effect of climate warming on groundwater (subsurface water and deep water) must not be forgotten. Thermal sensitivity of shallow groundwater is different between the short-term (e.g., seasonal) and the long-term (e.g., multi-decadal), and the relationship between air and water temperature is not necessarily representative of that. This variability must be taken into account to not underestimate the climate warming effects (Kurylyk *et al.*, 2015). New research must be done to solve this limitation of the used model by integrate this criterion in the parametrization. Since a fine solution could need prohibitive methods (Kurylyk *et al.*, 2015) losing the advantages that make attractive the model (input data easy to get), a compromise between improved precision and increased cost must be met.

Regressive models are substantially site specific compared to deterministic approaches (Arismendi *et al.*, 2014). However, parameters of these regressive approaches are still physically meaningful, and need a lower amount of variables that can limit its feasibility in areas where data are scarce. Consequently, the value of this type of model is its applicability to a large number of sites where the only available data are for air temperature (and precipitation and streamflow to a lesser extent). Our results show that predictions are improved when streamflow is included in the water temperature model, especially in the periods when low flow and high temperatures are coincident, as is often true in temperate rivers and streams (Arismendi *et al.*, 2012). Some rivers show no sensitivity to the introduction of streamflow in the model, which must not necessarily be due to the lack of influence of flow on the water temperature but rather to its minor relevance compared to other sources of noise.

In the group of streams that showed sensitivity to the introduction of streamflow into the temperature model, differences between the stream temperatures estimated by the two models (with and without streamflow) were important in granitic basins, and summer flow reductions further increased stream temperatures. Other studies highlight the influence of streamflow on water temperature (e.g., regulated rivers: Sinokrot and Gulliver, 2000; groundwater discharge influence: Loinaz *et al.*, 2013; and natural, regulated and snowmelt-fed rivers: Toffolon and Piccolroaz, 2015). When this occurs, peak flows must be modelled separately (Toth *et al.*, 2000; Solomatine and Xue, 2004). Therefore, further development of our model should include the effect of these rainfall peak flow events.

The predicted increase in water temperature will be important at most of the study sites. Annual mean variation rates will increase with time. Stewart *et al.* (2015) predict an increase by 1-2°C by mid-century in the 80 % of stream lengths in Wisconsin and by 1-3°C by late-century in 99 %, with a significant loss of suitable areas for cold-water fishes. The results of

Stewart *et al.* (2015) are not different from ours except that we expect greater increases at the end of the period (up to 4°C). Our results are also compatible with those by van Vliet *et al.* (2013), who predicted a temperature increase >2°C in the Iberian Peninsula area by the end of the century; however, our results are more specific and precise. In this sense, Muñoz-Mas *et al.* (2016) also obtained similar results to ours in one river in Central Spain at the mid-century (daily mean flow
5 reductions between 20–29 % and daily mean stream temperature increases up to 0.8°C). However, we predict that minima are more sensitive to climate warming than maxima.

The predicted increase in winter temperatures can affect the sessile phases of trout: i.e., eggs and larvae. These phases are very sensitive to temperature changes because it affects their physiology and because their durations are temperature dependent (e.g., Lobón-Cerviá and Mortensen, 2005; Lahnsteiner and Leitner, 2013). Thus, changes in the duration of the
10 incubation and yolk sac absorption can affect the emergence time and, in turn, the sensitivity to hydrological regime alterations (Sánchez-Hernández and Nunn, 2016). An increase in temperature can also reduce hatchling survival (Elliott and Elliott, 2010). In accordance with the herein presented results, the predicted synergy of streamflow reductions and water temperature increases will cause substantial losses of suitable fish habitat, especially for cold-water fishes such as brown trout (Muñoz-Mas *et al.*, 2016).

15 The increases in threshold violations were important in our simulations. The duration of warm events (temperature above the threshold) increased by up to three months at the end of the century in the most pessimistic scenario (RCP8.5). A continuous analysis of the whole-river response should be conducted to allow a spatially explicit prediction and to identify of reaches where thermal refugia are likely to remain. However, our results suggest that trout will not survive in these reaches because the existence of thermal refugia will be improbable or insufficient. In the Cega, Pirón and Lozoya rivers, losses of thermal
20 habitat will be important and could jeopardize the viability of the trout population. Behavioural thermoregulatory tactics are common in fish (Reynolds and Casterlin, 1979; Goyer *et al.*, 2014); for instance, some species perform short excursions (<60 min in experiments with brook char, *S. fontinalis*) that could be a common thermoregulatory behaviour adopted by cold freshwater fish species to sustain their body temperature below a critical temperature threshold, enabling them to exploit resources in an unfavourable thermal environment (Pépin *et al.*, 2015). Brown trout can use pool bottoms during daylight
25 hours to avoid the warmer and less oxygenated surface waters in thermal refugia (Elliott, 2000). Nevertheless, if the warm events became too long, the thermal refugia could become completely insufficient, thus compromising fish survival (Brewitt and Danner, 2014; Daigle, *et al.*, 2014).

4.4 The brown trout distribution

According to our results, streamflow reductions synergistically contribute to the loss of thermal habitat by increasing daily
30 mean stream temperature. It is especially relevant in summer in the Mediterranean area, when warmest temperatures and minimum flows usually occur. The existence of thermal refugia is an alternative to fish survival and the probability for a water body to become a thermal refugium is highly geologically dependent. In our simulations, the most deep-aquifer

dependent sites (Mesozoic-calcareous basins) will better resist warming. The habitat retraction at the rear edge of the actual distribution of brown trout is deduced to be geologically mediated.

The mountains of Central and Southeast Spain hold a rear edge of the brown trout native distribution (Kottelat and Freyhof, 2007). Fragmentation and disconnection of populations by newly formed thermal barriers may aggravate the already
5 significant losses of thermal habitat by reducing the viability of populations and increasing the extinction risk. Thus, the rear edge of the trout population in the Iberian Peninsula might be shifted to the northern mountains to varying extents depending on relevant mesological features, such as geology. The calcareous mountains of Northern Spain could be a refuge for trout by combining both issues: favourable geology and a relatively more humid climate. Caused by this differential response, the western portion of the Iberian range (plutonic, less buffered) will eventually experience more frequent local temperature-
10 driven extinction events, thus producing a greater shift northward, than in the Eastern Iberian end (calcareous, highly buffered) of this range, which will remain more resilient to these local extinction events. However, the predicted streamflow reductions may act synergistically, reducing the physical space, and this may jeopardize the less thermally exposed populations. In the Iberian Peninsula, stream temperatures will raise less in the central and northern mountains than in the central plateau, and less in karstic than in granitic mountains. At the same time, the Mediterranean facade is expected to be
15 more sensitive to warming and streamflow reductions than the Atlantic facade. Thus, brown trout populations in karstic mountains in Northern Spain (Cantabrian Mountains and calcareous parts of Pyrenees) are better able to resist the climate warming than eastern populations in the granitic portion of Pyrenees (Santiago 2017). The same may occur in other parts of Southern Europe. Probably, the less pronounced thermal response of rivers and streams in the karstic areas will allow a better persistence of the brown trout population, although it would be also linked to changes in streamflow regimes.

20 Studying the great European basins, Lassalle and Rochard (2009) predicted brown trout “to lose all its suitable basins in the southern part of its distribution area (Black Sea, the Mediterranean, the Iberian Peninsula and the South of France), but likely to continue being abundant in northern basins”. Almodóvar *et al.* (2011) estimated that brown trout will be eradicated of almost the entire stream length of the studied basins in North Spain, and Filipe *et al.* (2013) estimated in 57 % the expected loss of the studied reaches at the Ebro basin (Northeast Spain). Our study shows important thermal habitat reduction, yet not
25 so dramatic, of Iberian brown trout populations in mountain areas: the number of used General Climate Models, the reliability of the downscaling procedure, the resolution of the stream temperature and streamflow models, and the method to study the threshold imply a substantial improvement of the detail (Santiago *et al.*, 2016) over previous work. It is reasonable to infer that many mountain streams appear poised to be refugia for cold-water biodiversity this century (Isaak *et al.*, 2016). Approaches such as ours should be useful in planning the prevention and mitigation of the negative effects of climate change
30 on freshwater fish species in the rear edge of their distribution. A differentiation of areas based on risk level and viability is necessary to set management goals. Our results show that trout persistence requires a study of both temperature and streamflow dynamics at fine spatial and temporal scales. Managers need easy-to-use tools to simulate the expected impacts and the management options to address them, and the methods and results we provide could be a reliable way of doing so.

Acknowledgments: We are grateful to the Consejería de Medio Ambiente y O.T. of the Government of Castilla y León, especially to Mariano Anchuelo, Fabián Mateo and the forest ranger team of Navafría. Also, we are in debt with the Sierra of Guadarrama National Park staff, and especially with Juan Bielva and Ángel Rubio for the temperature data of Lozoya stream. Juan Diego Alcaraz is the author of the temperature data of the Ebrón basin. The World Climate Research Programme's Working Group on Coupled Modelling is responsible for the 5th Coupled Model Intercomparison Project (CMIP5), and we thank the climate modelling groups for producing and making available their model output. Climate change study was partially funded by the Ministerio de Agricultura, Alimentación y Medio Ambiente of Spain through the Fundación para la Investigación del Clima (<http://www.ficlima.org/>), by the European Union, DG for Environment (DURERO Project. C1.3913442), by the Ministerio de Economía y Competitividad of Spain (IMPADAPT project CGL2013-48424-C2-1-R) and FEDER funds.

Table 1. Description of the data logger (thermograph) sites, specifying given name, UTM-coordinates (Europe WGS89), altitude (m above the sea level), code of the nearest temperature meteorological station with suitable time series for this study (AEMET: Spanish Meteorological Agency), orthogonal distance between the data logger and the meteorological station, number of recorded days for stream temperature and characteristic geological nature of the data logger site (the latter was obtained from ITGE, 2000). Bold letters indicate sites associated to the gauging stations.

Sites	UTM-X	UTM-Y	altitude (m a.s.l.)	AEMET code	distance to AEMET station (km)	recording days	geological nature
