7 monitoring

8 **Abstract**

9 An in situ bioremediation experiment of a deep vadose zone (~40 m) contaminated
10 with a high concentration of perchlorate ($>25,000 \text{ mg L}^{-1}$) was conducted through a
11 full-scale field operation. Favorable environmental conditions for microbiological
12 reduction of perchlorate were sought by infiltrating an electron donor-enriched water
13 solution using drip irrigation underlying an airtight sealing liner. A vadose-zone
14 monitoring system (VMS) was used for real-time tracking of the percolation process,
15 the penetration depth of dissolved organic carbon (DOC), and the variation in
16 perchlorate concentration across the entire soil depth. The experimental conditions for
17 each infiltration event were adjusted according to insight gained from data obtained
18 by the VMS in previous stages. Continuous monitoring of the vadose zone indicated
19 that in the top 13 m of the cross section, perchlorate concentration is dramatically
20 reduced from thousands of milligrams per liter to near-detection limits with a
21 concurrent increase in chloride concentration. Nevertheless, in the deeper parts of the
22 vadose zone ($<17 \text{ m}$), perchlorate concentration increased, suggesting its mobilization
23 down through the cross section. Breakthrough of DOC and bromide at different

24 depths across the unsaturated zone showed limited migration capacity of biologically
25 consumable carbon and energy sources due to their enhanced biodegradation in the
26 upper soil layers. Nevertheless, the increased DOC concentration with concurrent
27 reduction in perchlorate and increase in the chloride-to-perchlorate ratio in the top 13
28 m indicate partial degradation of perchlorate in this zone. There was no evidence of
29 improved degradation conditions in the deeper parts where the initial concentrations
30 of perchlorate were significantly higher.

31 **1 Introduction**

32 In situ bioremediation of a contaminated unsaturated zone (also termed vadose zone)
33 depends mainly on the ability to control the hydrological, physical and chemical
34 conditions in the subsurface (Bombach et al., 2010; EPA, 2015; Höhener and Ponsin,
35 2014). Chemical and hydrological manipulations are primarily aimed at enhancing the
36 activity of specific indigenous degrading bacteria. The optimal conditions for specific
37 contaminants' degradation are usually determined in microcosm experiments, where
38 the preferred electron donor and acceptor for degradation can be controlled and
39 examined (Gal et al., 2008; Megharaj et al., 2011; Sagi-Ben Moshe et al., 2012). The
40 optimal degradation conditions, evaluated through laboratory experiments, usually
41 form the basis for selecting a strategy for in situ remediation in field-scale operations.
42 Nevertheless, implementation of desired biodegradation conditions in the deep vadose
43 zone through full-scale field setups requires control of the vadose zone
44 hydrogeochemical conditions. This is often achieved through either infiltration of
45 water enriched with electron donors or nutrients (Battey et al., 2007; EPA, 2004;
46 Frankel and Owsianiak, 2005), or injection of a gaseous mixture capable of promoting
47 optimal biogeochemical conditions for microbial pollutant degradation (Evans et al.,

48 2011; Evans and Trute, 2006). Due to the complex nature of flow and transport
49 processes in the unsaturated zone, application of water with specific chemical
50 conditions near land surface does not necessarily result in promoting the desired
51 geochemical and hydraulic conditions in deeper parts of the vadose zone (Allaire et
52 al., 2009; Flury and Wai, 2003; Jarvis, 2007; Rimon et al., 2011a). Therefore, in the
53 vadose zone, and particularly in its deeper parts, a proper understanding of the
54 transport process is key to the success of in situ remediation operations (Baram et al.,
55 2012a; Dahan et al., 2009; Kurtzman et al., 2016; Rimon et al., 2011a).

56 Assessment of water percolation and solute transport in the vadose zone is considered
57 a major challenge in hydrological sciences. It is often characterized by unstable flow
58 that is highly sensitive to hydraulic, chemical and microbial conditions (Bautersa et
59 al., 2000; Dahan et al., 2009; DiCarlo, 2007; Germann and al Hagrey, 2008; Hallett et
60 al., 2013; Rimon et al., 2011a; Sher et al., 2012; Stumpp et al., 2009). Moreover, the
61 chemical composition of the percolating water [e.g., dissolved organic carbon (DOC),
62 oxygen and nutrients] is subjected to frequent changes due to natural hydroclimatic
63 and biological cycles (Stumpp et al., 2009, 2012). Accordingly, contaminant
64 attenuation in the vadose zone is dependent on the complex hydrological, chemical
65 and biological states of the sediment. Continuous measurements of the hydrological
66 and chemical properties of the unsaturated zone may be achieved with a vadose-zone
67 monitoring system (VMS) (Dahan et al., 2009). The VMS provides high-resolution
68 measurements of variation in sediment water content (Dahan et al., 2008; Rimon et
69 al., 2007) and evolution of the pore water's chemical composition across the
70 unsaturated profile (Rimon et al., 2011a; Dahan et al., 2014; Turkeltaub et al., 2014,
71 2016).

72 Perchlorate is an environmental pollutant that is often associated with the explosives
73 manufacturing industry (Roote, 2001; Urbansky, 2002; Trumpolt et al., 2005). It is
74 mostly produced, and consequently released to the environment as ammonium
75 perchlorate. Its high solubility (220 g L^{-1}) and stability in aerobic environments makes
76 it very mobile and persistent in the subsurface (Motzer, 2001; Urbansky and Brown,
77 2003). Microbial reduction of perchlorate to harmless chloride and oxygen in the
78 unsaturated zone requires elevated water content, negative redox potential, available
79 electron donors and the presence of suitable indigenous bacteria (Coates and
80 Achenbach, 2004). In the vadose zone, natural attenuation and biodegradation of
81 perchlorate are considered very limited (Gal et al., 2009). Nevertheless, studies have
82 shown that perchlorate can be metabolized in unsaturated soil whenever reducing
83 conditions ($<110 \text{ mV}$) (Attaway and Smith, 1993; Shrouf and Parkin, 2006) are
84 achieved and an available electron donor is introduced (Tipton et al., 2003; Frankel
85 and Owsianiak, 2005; Nozawa-Inoue et al., 2005; Evans and Trute, 2006; Cai et al.,
86 2010).

87 Here, the efficiency of a remediation operation of a perchlorate-contaminated vadose
88 zone was assessed using a VMS, which provided continuous information on the
89 chemical composition of the vadose-zone pore water. Promotion of perchlorate-
90 degrading conditions in the vadose zone was based on infiltration of water enriched
91 with ethanol (as a source of electron donor) from land surface. Real-time information
92 on the depth of the enriched water's propagation, along with variations in the
93 concentrations of perchlorate, chloride and bromide (applied as a tracer), was used to
94 assess transport and degradation of perchlorate across the unsaturated profile. Water-
95 and ethanol-application strategies were adjusted in each flow phase to obtain real-time
96 feedback on the chemical and hydrological state of the vadose zone.

97 **2 Study site**

98 The study area is located in the central part of the Israeli coastal plain, east of the city
99 of Ramat Hasharon. The site is a former unlined earthen pond that was used to store
100 industrial wastewater for several decades. A hydrogeological survey conducted in the
101 study area revealed substantial perchlorate contamination in the vadose zone and
102 groundwater under the pond area (Gal et al., 2008, 2009). It was concluded that
103 percolation of untreated wastewater from the ponds had crossed the 40m thick vadose
104 zone and created a large perchlorate pollution plume in the underlying phreatic aquifer
105 with concentrations exceeding $1,000 \text{ mg L}^{-1}$. In the vadose zone, however, the
106 investigation revealed extreme perchlorate pollution, reaching concentrations
107 exceeding $2,000 \text{ mg kg}^{-1}$ dry soil (equivalent to $\sim 25,000 \text{ mg L}^{-1}$ in the sediment pore
108 water), along with high total salinity and chloride concentration exceeding $25,000 \text{ mg}$
109 L^{-1} . Because this area is under consideration for future urban development,
110 remediation of both the vadose zone and groundwater there is of major concern.

111 The stratigraphy of the area is characterized by Neogene and Pleistocene sediments,
112 mainly of sands and sandstones with interbedding of clay lenses (Gvirtzman, 2002).
113 The vadose zone lithological profile at the site was assessed again through a borehole
114 that was drilled at the pilot site in 2012 (Table 1, Fig. 1). Most of the profile is
115 composed of yellow and red sand layers with low clay content ($<5 \%$), with interbeds
116 of brown sand containing variable clay content of up to 11% . A single $\sim 1\text{m}$ thick clay
117 layer (27.5% clay content) was observed at a depth of 13.3 m . To improve infiltration
118 capacity in deep sections of the vadose zone during the remediation experiment, a
119 shallow clay layer with low permeability, known as “nazaz” (Singer, 2007), was
120 removed from a depth of $2.5\text{--}3 \text{ m}$ by excavation. The excavated area, $10 \times 30 \text{ m}$,

121 which was primarily assigned for the pilot infiltration experiment, was backfilled with
122 the sandy loam from the excavated site after removal of the 0.5m thick nazaz layer.
123 This layer is therefore presented in the profile as disturbed soil.

124 The climate in the area is characterized as subtropical Mediterranean with a hot and
125 dry summer from May to October and a colder wet winter from November to April.
126 The average air temperature on summer and winter days is 30 °C and 17 °C,
127 respectively. The average annual precipitation is 530 mm year⁻¹, mostly as rain
128 occurring mainly in four to seven rainy episodes during the winter season (IMS,
129 2011).

130 **3 Experimental setup**

131 **3.1 Vadose-zone monitoring setup**

132 Real-time characterization of flow and transport processes in the vadose zone, as well
133 as assessment of chemical transformation of the percolating water during the
134 remediation experiments were carried out with a VMS that was installed across the
135 entire unsaturated profile, from land surface to a depth of 37 m (Fig. 2). A detailed
136 description of the VMS, its structure, installation procedure and performance, can be
137 found in previous publications (Dahan et al., 2009; Rimon et al., 2011a) and in the
138 supplementary material. In particular, the VMS that was used at this site was
139 composed of a 44m long flexible polyurethane sleeve hosting 11 monitoring units
140 distributed along its length. Each monitoring unit included: (a) a flexible time-domain
141 reflectometer (FTDR) sensor for continuous measurement of variations in the
142 sediment water content (Dahan et al., 2008; Rimon et al., 2007), and (b) vadose-zone
143 sampling ports (VSPs), which enable frequent sampling of the vadose zone pore water
144 for chemical analysis (Baram et al., 2012a; Dahan et al., 2009; Rimon et al., 2011b;

145 Turkeltaub et al., 2016). The VMS flexible sleeve was installed in a 0.16m diameter
146 uncased borehole drilled slanted at a 55° angle (to the horizon) to a vertical depth of
147 37 m. In addition to the 11 monitoring units that were installed with the VMS, four
148 additional monitoring units were installed directly in the soil at depths of 0.5 m and
149 1.5 m. It should be noted that the slanted installation is preferred to ensure that
150 measurements carried out by each monitoring unit take place in separate undisturbed
151 sediment columns. In addition, the flexibility of the monitoring sleeve and its filling
152 with non-shrinking cement grout ensured complete sealing of the borehole void and
153 prevention of cross-contamination through preferential flow in the borehole.

154 **3.2 Field setup**

155 Water amended with ethanol as the electron donor for perchlorate-reducing bacteria
156 was infiltrated into the vadose zone through an area of 8 x 30 m at the pilot site using
157 a drip-irrigation system. Dripping lines with drippers having a nominal discharge rate
158 of 2.2 L h⁻¹ were set up in a 0.3 x 0.3 m spatial distribution to create fairly even water
159 distribution over the area. Accordingly, the total discharge rate of the irrigation
160 system was set to 5 m³ h⁻¹, which is equivalent to an infiltration rate of 0.02 m h⁻¹. To
161 promote anaerobic conditions in the unsaturated zone, a polyethylene liner covered
162 with soil was placed over the dripper system after its installation. Ethanol was
163 selected as the electron donor and carbon substrate because it is a natural, soluble
164 compound that is commonly used by perchlorate-reducing bacteria (Bardiya and Bae,
165 2011). Moreover, it eliminates the increased soil salinity associated with other
166 common sources of electron donors such as acetate (Gal et al., 2008).

167 **3.3 Infiltration experiments**

168 Three infiltration experiments with variable amounts of water and ethanol were
169 implemented at the pilot site over a period of 7 months. To trace the percolating water
170 across the unsaturated zone, bromide (as KBr) was added to the infiltrating water at
171 the early stages of the experiment. The infiltration rates, as well as the concentrations
172 and application sequence were assigned for each experiment with insight gained from
173 the previous experiment (Table 2). Accordingly, information obtained by the VMS on
174 depth propagation of the ethanol and tracer and variations in perchlorate and chloride
175 concentrations across the unsaturated zone during and after each infiltration
176 experiment were used to adjust the infiltration procedure in the following stage.

177 The first experiment (8 Aug 2010) consisted of infiltration of 50 m³ water (equivalent
178 to 210 mm) (Table 2). The first 6 m³ were applied as untraced fresh water with no
179 ethanol to wet the topsoil. This wetting stage is essential to promoting deep transport
180 and preventing accumulation of tracers and ethanol in the low-flow zone located on
181 the margins of the dripper's influential zone. Following the initial wetting phase, 0.4
182 m³ of bromide tracer solution (as KBr) at a concentration of 12.5 g L⁻¹ was applied,
183 followed by 1 m³ of water with 5 % ethanol. Immediately after the application of the
184 carbon and tracer solution, the rest of the water (42.6 m³) was applied to enhance
185 transport of the ethanol and tracers to deeper parts of the vadose zone.

186 After obtaining the results pertaining to the wetting process, as well as tracer and
187 ethanol migration in the vadose zone during the first infiltration experiment, a second
188 experiment was performed (1 Sep 2010). This experiment was conducted with 100 m³
189 of water (equivalent to 420 mm). Here the first 7 m³ of water was injected into the
190 topsoil as untraced fresh water, followed by 1 m³ of water with 5 % ethanol, and then
191 the rest of the water dose (92 m³). No tracers were used in this experiment. The

192 amount of water used after application of the ethanol was doubled to enhance
193 migration of the ethanol to deep sections of the unsaturated zone.

194 Results from the first two experiments indicated limited migration of tracer and
195 ethanol to deeper parts of the vadose zone. A third infiltration experiment was
196 therefore conducted 5 months later with increased discharge of 300 m³ (equivalent to
197 1250 mm). This experiment started with 24 m³ of untraced water followed by 0.4 m³
198 concentrated (50 %) ethanol solution. Then, the rest of the water (275.6 m³) was used
199 to push the ethanol down into the vadose zone. The large quantity of water applied
200 after the concentrated ethanol solution was designed to enhance quick migration of
201 the ethanol to deep parts of the vadose zone while minimizing its biodegradation in
202 the upper soil layers.

203 **3.4 Analytical procedure**

204 Perchlorate was analyzed with a perchlorate ion-selective electrode (ISE; Laboratory
205 Perchlorate Ion Electrode, Cole-Parmer, USA). All samples measured with the ISE
206 were adjusted by dilution to a concentration range of 10–100 mg L⁻¹. Duplicates were
207 frequently analyzed by injecting 25 µL sample into a Thermo Scientific™ Dionex™
208 ion chromatography system (ICS 5000) equipped with Ion Pac AS19 column
209 (detection limit of ±0.01 mg L⁻¹). Because results from the two methods were not
210 significantly different, most of the data reported here are from the perchlorate
211 electrode with a detection limit of 1 ppm. Bromide and chloride were analyzed by ion
212 chromatography with a detection limit of 30 ppb (Gal et al. 2008). Total organic
213 carbon (TOC) was analyzed to examine the success of delivering carbon to the vadose
214 zone. Because porewater samples from the vadose zone are obtained through the VSP,
215 which uses a porous ceramic interface (pore size < 2 µm), TOC values reflect DOC.

216 TOC was analyzed through a combustion TOC analyzer (Teledyne Tekmar, Apollo
217 9000) with a detection limit of 2 ppm. Ethanol concentration in the vadose zone pore
218 water was analyzed in a gas chromatograph (Varian, CP3800). Water samples (1.5
219 μL) were injected by autosampler. The FID and injector temperatures were set to 270
220 and 250 $^{\circ}\text{C}$, respectively. The GC oven temperature was first held at 50 $^{\circ}\text{C}$ for 1 min,
221 increased to 220 $^{\circ}\text{C}$ at a rate of 25 $^{\circ}\text{C min}^{-1}$, and then held for 4 min. The separation
222 was performed by Stabilwax[®] capillary column (60 m, 0.32 mm, 0.25 μm , Restek
223 Corporation, USA); helium was used as the carrier gas (1 mL min^{-1}). For
224 quantification, five external standards were used.

225 **4 Results and discussion**

226 All of the data obtained by the VMS are presented here as variations in measured
227 parameters with depth, as commonly done to describe depth profiles. However, to
228 ensure measurements under undisturbed vertical profiles, the VMS was installed in a
229 slanted orientation (Fig. 2 and supplementary material). Thus, each monitoring unit
230 faces an undisturbed profile that is shifted horizontally and vertically from the other
231 units. Accordingly, although the data are presented as depth profiles, they should be
232 regarded as individual points distributed across the 3D space of the vadose zone
233 (Dahan et al., 2007; Rimon et al., 2011a).

234 Prior to detailed discussion on the results a general outline of the rationale behind the
235 experimental setup will be presented here. Three infiltration experiments were
236 conducted with variable amounts of water, ethanol as electron donor, and bromide as
237 a tracer (all of which is presented above in chapter 3.3 *Infiltration experiment*).
238 Nevertheless, the experimental conditions in each experiment were set following the
239 results obtained from the previous stage. The first infiltration experiment was

240 conducted as a first trial to infiltrate ethanol-enriched water-solution into the
241 unsaturated zone. This experiment was also conducted with bromide as a tracer in
242 order to mark the water front propagation across the unsaturated zone. As will be
243 discussed further on, results the first infiltration experiment indicated that the
244 migration capacity of both ethanol and bromide across the unsaturated profile was
245 very limited. Accordingly a second infiltration experiment was conducted with a
246 double amount of water and the same amount and concentration of ethanol in order to
247 enhanced deep migration of the ethanol down the unsaturated zone. Following the
248 results from the first two experiments a third infiltration experiment was conducted
249 with larger water volumes and higher ethanol concentration in order to avoid quick
250 ethanol degradation in the shallow soil. all of which will be presented and discussed
251 below.

252 **4.1 Water percolation**

253 Temporal variations in the vadose zone water content provide a direct indication of
254 percolation processes in the vadose zone (Rimon et al., 2007; Dahan et al., 2008;
255 Turkeltaub et al., 2015). Each infiltration experiment launched a wetting wave that
256 propagated sequentially through the unsaturated zone (Fig. 3). Down-migration of the
257 wetting wave was expressed as a quick rise in water content followed by a recession
258 caused by water redistribution and drainage. Referring the wetting sequence in the
259 vadose zone to the infiltration events on land surface enabled a direct calculation of
260 the flow velocity across the unsaturated zone (Rimon et al., 2007; Dahan et al., 2008).
261 All three infiltration experiments produced wetting fronts that moved down the
262 vadose zone at a velocity of $\sim 0.18 \text{ m h}^{-1}$, even though the water volumes that were
263 used in each experiment were significantly different (50, 100 and 300 m^3).

264 Observations of regulated flow velocities at constant rates across the vadose zone
265 under variable surface hydraulic conditions have also been reported in other studies
266 (Dahan et al., 2008; Amiaz et al., 2011; Rimon et al., 2011a).

267 The high salinity of the deeper parts of the vadose zone (>13 m) (Fig. 1) limits the
268 reliability of the TDR technology for measuring water content at those depths (Nadler
269 et al., 1999). Therefore, variation in water content, as an indication of deep
270 percolation, is presented here only down to a depth of 11.2 m, where the salinity was
271 low enough to achieve reliable moisture measurements with the FTDR sensors.
272 Nevertheless, indications of deep percolation in the deeper layers (>13 m) are further
273 discussed through the variation in chemical composition of the percolating water
274 across the entire thickness of the unsaturated zone (40 m).

275 **4.2 Perchlorate transformation and mobilization**

276 Initial analysis of porewater samples from the vadose zone, prior to initiation of the
277 infiltration experiments, revealed very high concentrations of perchlorate and
278 chloride, both reaching maximum values of $\sim 22,500 \text{ mg L}^{-1}$ (Fig. 1), and total
279 dissolved solids (TDS) of $43,000 \text{ mg L}^{-1}$, at a depth of 21 m. Note that at this stage,
280 the concentrations of perchlorate and chloride are nearly identical throughout the
281 entire profile. These high concentrations, sampled by the VMS, are in accordance
282 with concentration profiles obtained previously in extracts of sediment samples (Gal
283 et al., 2009).

284 Frequent sampling of the vadose zone pore water showed dynamic variations in
285 perchlorate concentration during the percolation experiments. In the upper section of
286 the vadose zone (0–13 m), perchlorate concentrations decreased dramatically, from as
287 high as 9000 mg L^{-1} to below detection levels (Fig. 4). Such a reduction in

288 concentration in a relatively thick portion of the vadose zone (13 m) over the short
289 period of 10 months is clearly desirable and may even be considered a great success.
290 Nevertheless, closer inspection of the variations in perchlorate concentration in deep
291 parts of the vadose zone (17–40 m) showed an increase at most of the measurement
292 points (Fig. 5). Perchlorate concentration rose from 12,700 mg L⁻¹ to 27,400 mg L⁻¹ at
293 a depth of 17 m during the same period. A similar increase in concentration was also
294 found in deeper parts of the cross section at depths of 25, 28, and 36 m. Note that
295 during this period, an increase in perchlorate concentration was even observed in the
296 groundwater (represented at a depth of 41 m in Fig. 5). Obviously, the mixed trend in
297 variations of perchlorate concentration implies that transformation and mobilization
298 processes take place simultaneously. As such, the conditions for both biodegradation
299 and mobilization should be examined along with the variation in perchlorate
300 concentration.

301 **4.3 Electron donor availability**

302 Available organic carbon as an electron donor is crucial for perchlorate reduction. To
303 increase the concentration of DOC in the vadose zone, ethanol was mixed with the
304 percolating water during the early stage of each infiltration experiment. Analysis of
305 ethanol and DOC in the water samples from the vadose zone throughout the
306 experiment revealed a similar concentration pattern (1 g ethanol = 2 g DOC).
307 Therefore, we assume that the variation in DOC was due to transport of ethanol or
308 ethanol-degradation products with the percolating water.

309 During the first infiltration experiment, an increase in DOC above background levels
310 was observed only at shallow depths, down to 1.5 m (Fig. 6). No signs of increasing
311 DOC were observed in the deeper parts of the cross section at this stage. Twenty-three

312 days later, before initiation of the second infiltration experiment, DOC values had
313 dropped back down to background levels. This implies that the ethanol was
314 microbiologically consumed in the soil before it could be leached further down.

315 As a result of the limited transport of ethanol in the first infiltration experiment, a
316 second experiment was conducted with the same mass and concentration of ethanol.
317 However, it was flushed with double the amount of water to promote its quicker
318 migration to deeper layers (Fig. 4). In this experiment, no signs of increasing DOC
319 were observed at any depth. On the contrary, DOC level decreased to values below
320 background levels (Fig. 6). Obviously, the rate of ethanol metabolism in the soil
321 increased following the first experiment, where both water content of the sediment
322 and substrate required for efficient microbial activity increased. As a result, ethanol-
323 degradation efficiency in the topsoil (<0.5 m) was significantly enhanced.

324 To overcome the limitation of electron donor delivery through the shallow soils, a
325 third infiltration experiment was designed. In this experiment, the ethanol was
326 injected in a 0.4m³ high-concentration (50 %) pulse followed by a large volume of
327 water. Application of ethanol at a very high concentration was aimed at suppressing
328 its biological degradation in the shallow soil. The ethanol pulse was introduced after
329 application of 24 m³, the latter to provide high initial wetting conditions under the
330 ethanol front. Then the ethanol slug was pushed down with 276 m³ of water. At this
331 stage of the study, which was conducted 6 months after the previous one, a substantial
332 increase in DOC was observed in the entire top 13 m of the cross section (Fig. 6).
333 Obviously, an increase in DOC serving as electron donor is an essential prerequisite
334 for perchlorate degradation. Apparently, application of ethanol at a high
335 concentration, which inhibited its degradation in the upper layer, succeeded to drive

336 the ethanol all the way down to 13 m, just above the clay layer. Nevertheless, no signs
337 of DOC increase were observed below 13 m.

338 **4.4 Transport and degradation**

339 The mechanism controlling down-propagation of a non-conservative substance such
340 as ethanol may be elucidated by looking at the migration pattern of a conservative
341 tracer such as bromide. Bromide was injected with the percolating water in the early
342 stages of the first infiltration experiment. Results on bromide migration are presented
343 here only for the top 13 m, where the background concentrations prior to the initiation
344 of the infiltration experiment were below detection limits. Concentration profiles
345 during the infiltration experiments clearly demonstrated sequential progress of the
346 percolating water across the top 13 m of the unsaturated zone (Fig. 7). Mass balance
347 calculation of bromide on the basis of the concentration profiles (Fig. 7) and sediment
348 water content (Fig. 3) on various dates after the infiltration experiment resulted in
349 high recovery rates of 85–127 %. A comparison of the transport patterns of bromide
350 and DOC confirmed that biodegradable material such as ethanol is rapidly consumed
351 in the vadose zone.

352 An increase in chloride concentration in the vadose zone is usually attributed to
353 evaporation processes near land surface, a mechanism that is unlikely to occur in this
354 particular setup where the surface is isolated from the atmosphere. Accordingly,
355 variations in chloride concentration across the vadose zone may be attributed to
356 chloride mobilization with the percolating water and perchlorate reduction. Therefore,
357 degradation of perchlorate is expected to result in an increase in chloride mass.

358 Prior to the infiltration experiments, chloride-to-perchlorate ratios in the vadose zone
359 were very similar, exhibiting nearly identical profiles (Fig. 1) with equivalent

360 concentration proportions of 2.4–5.5 (Fig. 8). Following the infiltration experiment, a
361 significant increase in ionic ratios was observed in the top 13 m, while in the rest of
362 the profile—from a depth of 17 m to the water table, the concentration ratio of
363 chloride to perchlorate remained relatively unchanged. Obviously, since both
364 perchlorate and chloride are very soluble and mobile, infiltration water with a low
365 concentration of chloride ($\sim 100 \text{ mg L}^{-1}$) and zero perchlorate is also expected to result
366 in an increased chloride-to-perchlorate ratio, even if no perchlorate degradation takes
367 place. Since both chloride and perchlorate are very mobile and easily displaced with
368 the percolating water, quantification of the perchlorate-degradation rate with respect
369 to its down-leaching is not straightforward.

370 **5 Conclusions**

371 The infiltration experiments were primarily aimed at improving the environmental
372 conditions for perchlorate-reducing bacteria across the vadose zone. This included an
373 increase in water content along the soil profile and amendment of the electron donor.
374 The results, which were based on continuous monitoring of the entire vadose zone,
375 exhibited notable variation in the concentrations of perchlorate, DOC and other
376 solutes in the unsaturated zone. Increased concentrations of DOC with a concurrent
377 reduction in perchlorate concentration (from thousands to a few milligrams per liter)
378 and increased chloride-to-perchlorate ratio (from ~ 2.5 to ~ 300) in the upper 13 m
379 indicated that perchlorate is partially reduced in this part of the vadose zone. On the
380 other hand, no evidence of improved reducing conditions was observed in the deeper
381 parts, where the initial concentrations of perchlorate were significantly higher.
382 Nevertheless, since assessment of redox conditions in deep vadose zone is not yet

383 feasible, we can only rely on variations in the chemical composition to assess the
384 existence of degradative conditions.

385 The limited ability to deliver a soluble electron donor across a microbiologically
386 reactive medium, such as topsoil, is a major limiting factor for remediation of the
387 deep vadose zone through gravitational percolation of enriched solution. Note that
388 temporal variations in the concentrations of perchlorate, as well as other solutes, in the
389 deep parts of the vadose zone, i.e., under the clay layer at 14 m, indicate that the clay
390 layer does not play any role in limiting infiltration **capacity in terms of flow velocity**
391 **and fluxes**. Similar observations on the role of clay layers in infiltration in the
392 unsaturated zone have been reported in previous publications (Baram et al., 2012b,
393 2012c; Dahan et al., 2009; Rimon et al., 2007; Turkeltaub et al., 2015b).

394 The attempts to leach the ethanol down into the vadose zone with large quantities of
395 water inevitably drove down-leaching and displacement of the dissolved solutes,
396 including perchlorate. Although there were indications of partial degradation of
397 perchlorate in the upper part of the vadose zone, its downward displacement toward
398 the water table was evident from the sequential increase in perchlorate concentration
399 with depth (Fig. 5). It seems that the entire column of perchlorate mass was pushed
400 down by the percolating water toward the water table, which also resulted in an
401 increased concentration of perchlorate in the observation well, which was located
402 under the infiltration zone.

403 The study demonstrates that application of vadose-zone monitoring technology during
404 a remediation operation provides real-time information on the chemical and
405 hydrological state of the subsurface. Linking the temporal variation in the chemical

406 composition of the vadose zone pore water, sediment saturation degree and flow
407 velocities are vital for efficient management of remediation operations.

408 ***Author contribution:*** Ofer Dahan (PI, Vadose zone hydrology) design of the
409 experimental and monitoring setup. Idan Katz (MSc student) conducted the field
410 experiment and laboratory analysis. Zeev Ronen (PI, Microbiology) design the bio
411 treatment setup. Data analysis and manuscript preparation - all coauthors.

412 ***Competing interest:*** The authors declare that they have no conflict of interest.

413 ***Acknowledgments.*** The authors wish to express their appreciation to Israeli Water
414 Authority for project funding.
