Abstract

Recent flood dynamics of the Mekong Delta have raised concerns about an increased flood risk downstream in the Vietnamese Mekong Delta. Accelerated high dike building on the floodplains of the upper delta to allow triple cropping of rice has been linked to higher river levels in the downstream city of Can Tho. This paper assesses the hydraulic impacts of upstream dike construction on the flood hazard downstream in the Vietnamese Mekong Delta. We combined the existing one-dimensional (1D) Mekong Delta hydrodynamic model with a quasi-two dimensional (2D) approach. First we calibrated and validated the model using flood data

from 2011 and 2013. We then applied the model to explore the downstream water dynamics under various scenarios of high dike construction in An Giang Province and the Long Xuyen Quadrangle. Calculations of water balances allowed us to trace the propagation and distribution of flood volumes over the delta under the different scenarios. Model results indicate that extensive construction of high dikes on the upstream floodplains has had limited effect on peak river levels downstream in Can Tho. Instead, the model shows that the impacts dike construction, in terms of peak river levels, are concentrated and amplified in the upstream reaches of the delta. According to our water balance analysis, river levels in Can Tho have remained relatively stable, as greater volumes of floodwater have been diverted away from the Long Xuyen Quadrangle than the retention volume lost due to dike construction. Our findings expand on previous work on the impacts of water control infrastructure on flood risk and floodwater regimes across the delta.

Keywords: dike, flood dynamics, floodplain, Long Xuyen Quadrangle, Mekong Delta, hydrodynamic modelling

1. Introduction

The Vietnamese Mekong Delta (VMD) is popularly known as the rice bowl of Vietnam, as it provides about half of the nation's food volume (Käkönen, 2008). The delta owes much of its agricultural productivity to seasonal flooding, though severe flood years have dire consequences for local populations. Severe flooding is relatively frequent too, having occurred, for example, in 2000, 2001, 2002 and 2011. In general, while extreme flooding poses a threat to people and properties, the benefits of small to medium floods outweigh the disadvantages. In particular, the fertile sediment and fish conveyed by the floodwaters help create an optimal environment for agricultural livelihoods (Käkönen, 2008; Hung, 2012). Tri et al. (2013) and Marchand et al. (2014) calculated that the seasonal floods transport some 160 million tons of

fluvial sediment annually. Lu et al. (2014) estimated 67 million tons per year. Some 1.86 tons of fish, worth US $2.6 billion, were supplied by the floods in 2000. Flooding also improves soil quality by flushing fields, which reduces acidity and agrochemical residues, while contributing to wetland protection and biodiversity conservation (Howie, 2011; Danh and Mushtaq, 2011; Hung, 2012). Historically the Vietnamese have adapted their farming systems to exploit the benefits of flooding (Wesselink et al., 2015; Ngan et al., 2017). One example is cultivation of floating rice (*lua mua*) which grows in sync with rising floodwaters and is often combined with fishing (Käkönen, 2008).

Vietnam's *doi moi* economic reform policy, introduced in 1986, and the nation's resolve to become self-sufficient in rice set the VMD on a new socio-economic development path (Kingdom of the Netherlands, 2011; Toan, 2011). First and foremost, the policy gave rise to progressive intensification of rice cultivation (Sebesvari et al., 2012). Beginning with the Long Xuyen Quadrangle (LXQ) and Plain of Reeds, low dikes and irrigation and drainage canals were developed to enable cultivation of two rice crops before a delayed mid-August flood. In 1996, the land reclamation and flood protection program entered a new phase, with residents increasingly resettled to flood-protected villages (Danh and Mushtaq, 2011) and the first large-scale flood control infrastructures built. Construction of high dikes with compartments for rice cultivation continued unabated during the ensuing decades. The agricultural fields thus created were effectively cut off from natural flooding, allowing farmers to cultivate three rice crops annually.

Today, great expanses of the VMD floodplains are covered by intensively cultivated rice fields enclosed by low dikes or high dikes. This intensified land use, however, has coincided with an increased flood risk downstream in the delta, around the city of Can Tho. Comparing water levels in 2011 with those in 2000, lower water levels were observed upstream in the more recent year, with higher levels measured downstream. At the upstream station of

Tan Chau, for example, water levels in 2011 were 0.63 m lower than in 2000 (4.27 m versus 4.90 m). Yet, water levels at the downstream Can Tho station were 0.36 m higher in 2011 than in 2000 (2.15 m versus 1.79 m). This suggests a relationship between the proliferation of dike construction on the floodplains, particularly high dikes, and higher water levels and flood risk downstream.

Several studies have concluded that the flood risk in the VMD delta has increased over time. Numerous reasons have been proposed, such as climate change, sea level rise, hydropower projects, land subsidence and local rainfall. Wassmann et al. (2004) concluded based on a hydraulic model that the higher water levels in the delta were caused by sea level rise in association with climate change. Fujihara et al. (2015) investigated the impacts of upstream runoff, sea level rise and land subsidence on flood levels. They found that flood depths would be significantly increased in 19 tide-dominated areas, and that land subsidence and sea level rise would worsen inundation. Lauri et al. (2012) and Hoang et al. (2016) explored potential impacts of climate change and reservoir management scenarios on the future hydrology of the Mekong River. Numerous authors have considered the effects of climate change and sea level rise on flood propagation, inundated area and sediment transport (Apel et al., 2012; Hung, 201b; Quang et al., 2012; Manh et al., 2014).

Some studies have honed in on the effects of infrastructure development on VMD flood levels. Hoa et al. (2008) used the HydroGIS hydrodynamic model to evaluate the effects of the infrastructural changes from 1996 to 2004 on floodwater levels and flood protection efficacy. They concluded that infrastructure works, such as dredging canals, raising embankments and upgrading roads, likely mitigated the overall extent of flooding but increased flood depth by 20 to 30 cm in some regions near and between embankment systems. Using the Mike 11 hydrodynamic model, Duong et al. (2014) simulated the water-level impacts of dike construction for the floodwater conditions experienced in 2000 and 2011. Using 2000 flood

conditions in combination with the river network and infrastructure system of 2011, they found 13 cm higher water levels at Chau Doc and 5 cm higher Tien River levels at Can Tho. A scenario simulating the 2011 flood volumes with the 2000 river network and infrastructure system showed 8 cm lower water levels at Can Tho. Their simulations, however, could not determine how floodwaters would be distributed. Moreover, Dung et al. (2011) noted deficiencies in the model's representation of the dike system in Vietnam.

Dikes and other water control infrastructures prevent floodwaters from entering agricultural fields. They may therefore increase floodwater flows downstream. Indeed, although floodwater volumes were less in 2011 than in 2000, the water levels observed downstream were higher in 2011 than in 2000 (Duong et al., 2014). Marchand et al. (2014) proposed that the higher downstream river levels observed during the 2011 floods could be due to the construction of higher dikes. Fujihara et al. (2015) pointed out the need for more research to understand the impacts of high dike construction. Despite the rapid expansion of high dike systems for triple rice cultivation in the upper Mekong Delta, few modelling studies have as yet assessed the implications of such dikes for floodwater regimes[1]. Additionally, most previous studies have focused on changes in peak water levels, based on monitoring data or model results. No study has as yet analyzed the distribution of floodwaters and changes therein. However, water distribution analyses are essential for understanding how floodwaters may spread and where the impacted locations corresponding changes in water volumes are under different dike construction scenarios.

The study presented in this paper aimed to fill these knowledge gaps by using 1D and quasi2D modelling to test the hypothesis that large-scale high dike construction reduces the

---

[1] defined as "the prevailing characteristics and distribution of flood pulses and variability within and across years, is controlled by geography, geology, climate, and human modifications and drives physical and ecological processes within floodplain ecosystems, affecting the diversity, abundance, and communities of species" (Whipple et al., 2017).

1   flood retention capacity of the floodplains and increases water levels and the corresponding

2   flood risk downstream. We first examined the impacts of dike construction on flood dynamics,

3   focusing particularly on changes in river levels and the spatial distribution of floods on the

4   VMD floodplains. We then developed and calibrated a hydrodynamic model for the entire

5   VMD to simulate flooding under different dike construction scenarios. Using the simulation

6   results we calculated water balances to identify and quantify changes in flood dynamics. The

7   modelling results enabled us to analyze changes in flood patterns and river levels across the

8   VMD due to dike construction. Finally, we analyze and discuss some of the accompanying

9   uncertainties, closing with a number of conclusions.

10   **2. Study area**

11   The Mekong Delta covers some 5 million ha, extending down from Kratie in Cambodia through

12   the VMD to the Gulf of Thailand and South China Sea. At Chaktomuk, its main river, the

13   Mekong, meets the Tonlé Sap River, which in the wet and dry season, respectively, adds and

14   abstracts water to and from the more northern Tonlé Sap Lake. Under Phnom Penh, the Mekong

15   again divides, entering Vietnam in two branches: the Mekong River (called the Tien River in

16   Vietnam) and the Bassac River (called the Hau River in Vietnam) (Manh et al., 2014; Kummu

17   et al., 2014).

18   Located in the North Pacific monsoon climate (Tamura et al., 2010; Manh et al., 2014),

19   the Mekong Delta is strongly impacted by both flooding upstream and the tidal flows of the

20   Gulf of Thailand and South China Sea. Flooding occurs in the wet season, from July/August to

21   November/December, beginning when the annual average discharge at Kratie exceeds 13,600

22   m^3s^{-1} (Manh et al., 2014). At Tan Chau, on the Cambodia–Vietnam border, the Tien River

23   carries about 80% of the floodwaters (equivalent to 20,500–25,500 m^3s^{-1}), whereas 20%

24   (equivalent to 6,500–7,660 m^3s^{-1} at Chau Doc) is transported by the Hau River (Tri, 2012).

1   South of Vam Nao, the water volumes of the two rivers become more balanced, owing to

2   interconnecting tributaries. Due to the delta's flat, low-lying topography (its average elevation

3   is just 0.8 m above mean sea level) and the impact of tidal regimes (Hung, 2012), the annual

4   floods inundate 1.2 to 1.9 million ha of the delta (Hoa et al., 2008; Kingdom of the

5   Netherlands and the Socialist Republic of Vietnam, 2013). In a severe flood season, water

6   depths reach up to 3 m, affecting the lives of more than 2 million residents. Tidal movements

7   make understanding floodwater flows and distribution even more complex.

8   The LXQ and Plain of Reeds floodplains, due to their huge water retention capacity,

9   play a key role in moderating peak floods. Floodwaters originate from the two main rivers and

10   overland from Cambodia. As the aim of this study is to examine the effects of water control

11   infrastructure on floodwater levels and distribution, we focused on the LXQ, as it has undergone

12   the most extensive development of high dikes during the past decades. Most agricultural areas

13   on the LXQ floodplains are protected by low dikes or high dikes. Low dikes allow floodwaters

14   to overflow into the fields after the harvest of the second crop in mid-August. High dikes

15   prevent floods year-round, enabling cultivation of a third rice crop (Howie, 2011). This has

16   made the LXQ one of the VMD's highest productivity rice areas (Quang et al., 2012). The LXQ

17   encompasses parts of three provinces: a large part of An Giang and Kien Giang provinces and

18   a small part of Can Tho Province (see also Figure 1). The LXQ has 0.49 million ha of

19   floodplains, located on the northern delta, west of the Hau River. Between the river and the

20   dense network of canals that has long been a feature of this region, numerous dikes have been

21   built, some topped by roads. Statistics from the Department of Agricultural and Rural

22   Development show an enormous increase in the area protected by high dikes in An Giang

23   Province, from 2,591 ha in 1998 to 87,909 ha in 2009 (Kien, 2013). In Kien Giang Province,

24   most agricultural areas are protected by low dikes. There are very few dikes in Can Tho

25   Province.

1 **[Figure 1]**

2 ## 3. Methodology

3 ### 3.1. Model setup and data preparation

4 We developed a one-dimensional (1D) hydrodynamic model using the Mike 11 software

5 developed by the Danish Hydraulic Institute (DHI). This is an implicit finite difference model

6 for 1D unsteady flow computation. In addition, it can be applied to a quasi-two dimensional

7 (quasi2D) flow simulation appropriate for detailed modelling of rivers, including special

8 treatment of floodplains, road overtopping, culverts, gate openings and weirs (Doulgeris et al.,

9 2012). The modelling procedure allows use of kinematic, diffusive or fully dynamic, vertically

10 integrated equations for conservation of continuity and momentum (the Saint Venant equations)

11 to solve complex flow and mass transport problems (Patro et al., 2009; Dung et al., 2011; Manh

12 et al., 2014).

13 We developed our model to represent the river network and floodplains of the Mekong

14 Delta. Appendix 1 (A1) presents the equations and computational components. Data on the

15 Mekong Delta river network and physical properties were derived from the Southern Institute

16 for Water Resources Research (SIWRR). The hydrodynamic module included in Mike 11 was

17 applied to simulate flow dynamics and inundations. We incorporated four main components:

18 (i) the river network, (ii) boundary conditions, (iii) cross section and (iv) a set of other

19 parameters. Although rainfall accounted for only a small percentage of surface water inflows,

20 we nonetheless included it in the model using the Rainfall Runoff (RR) module.

21 The 2011 river network was imputed into the model based on available data. The area

22 of interest – from Kratie and the Tonlé Sap Lake in Cambodia to the river mouths in Vietnam

23 – encompassed 5 million ha, 4,084 river branches and 21,235 computational nodes (Figure A2

1 in the Appendix). For the canal and water control infrastructure network, sluice gates (14), weirs

2 (2,246) and control structures (2,657) were identified, representing the infrastructure system.

3 Sluice gates regulate water flows to larger areas. Weirs regulate flows into and out of

4 agricultural fields. The control structures considered were reservoirs, which prevent water

5 overflow at a specific sill level.

6   Boundary conditions for the model were set using discharges and water levels observed

7 in 2011 and 2013. All daily data were provided by the National Centre for Hydro-

8 Meteorological Forecasting (NCHMF) and SIWRR. Discharges from six stations were imputed

9 for the upstream boundary conditions, while the downstream boundary conditions were

10 provided by water levels measured by nine tide gauges near the coast. Upstream, the discharge

11 at Kratie was the most important boundary input for drawing the main flood hydrograph to

12 simulate discharges and water levels downstream for the VMD.

13   We embedded 13,000 cross sections into the model. These described the topography of

14 the rivers and branches. Cross-section data were collected from various sources. Data

15 concerning the major streams were very reliable, as these measurements were produced and

16 regularly updated by national projects. For the branches, bathymetric data were used for most

17 cross sections, though this process meant that accuracy was likely lower. These cross sections

18 had, however, been tested in various SIWRR projects.

19   Our set of other parameters included river roughness, wind effects and various

20 components derived from DHI (2011). These described the physics of the Mekong Delta.

21 Among them, the river roughness coefficient was the most important and sensitive parameter.

22 River roughness was represented in the model as Manning coefficients, which we initially

23 estimated based on published values corresponding to particular types of rivers and canals

24 (Chow, 1959; Fabio et al., 2010; Dung et al., 2011). First, referring to Chow (1959), we set the

1 Manning coefficients as 0.020 (irrigation channel, straight, on hard-packed smooth sand), 0.025

2 (earth channel excavated in alluvial silt soil, with deposits of sand on the bottom and grass

3 growth) and 0.033 (natural channel, somewhat irregular side slopes, very little variation in cross

4 section). These were used for all rivers and branches in the three initial model runs to identify

5 changes in water levels and discharges of the main rivers. Second, we calibrated the model by

6 modifying these numbers for the branches in the more coastal areas. After model fitness was

7 satisfactory for the stations near the coast, we defined a range of Manning coefficients (0.024–

8 0.017) for the Tien and the Hau rivers. Rivers in the Cambodia part of the delta were given a

9 range of 0.1–0.05, whereas a range of 0.03–0.025 was selected for the rivers and canals on the

10 VMD floodplains. These parameters were optimized during the calibration process.

11   Daily rainfall data was derived from 37 meteorological stations (28 in Vietnam and 9 in

12 Cambodia). Thiessen polygons were used to describe the contribution of surface water flows to

13 river and canal discharge. In the model, we divided the Mekong Delta into 120 sub-regions,

14 with data from rainfall gauges for each. The rainfall discharge had to be calibrated using the

15 Rainfall Runoff (RR) module provided with the Mike 11 NAM before it could be used for the

16 hydraulic model simulations.

17 **3.2. Calibration and validation**

18 The flood model had to be calibrated and validated to ensure reliable performance. For

19 calibration, we used the severe flood year of 2011. To validate the model, we used data from

20 the 2013 flood season. These two years were selected because the river and infrastructure

21 network, land uses and dike locations were similar in both years. The Nash–Sutcliffe efficiency

22 (NSE) and correlation coefficients were used to check the model's goodness-of-fit for the

23 calibration and validation periods. The NSE is one of the most commonly used efficiency

24 criteria in hydrology. It measures how much of the variability observed is explained by the

simulation. A perfect simulation has an NSE of 1 (Ritter and Muñoz-Carpena, 2013). The

correlation coefficient (R^2) expresses the linear relationship between observed and simulated

values.

For the calibration and validation periods, we used hourly discharge and water level

time series from 15 gauging stations, including 11 stations along the Tien and Hau rivers and 4

stations on the floodplains (Figure 1). We selected these stations because (i) the objective of

our study was to explore the water level dynamics in the main streams and LXQ and (ii)

observational data were available from each.

In addition to calibration and validation for the 2011 and 2013 data, we assessed model

performance for the 2000 flood hydrograph. Using flow data from 2000, including discharge at

Kratie and water levels at nine tide gauges, we ran the model assuming the 2011 river network

and land use system. Model outputs were compared to maximum river flows in the Hau River.

3.3. Modelling for the floodplains

To simulate the hydraulic dynamics of the floodplains, the quasi2D approach was combined

with 1D modelling. In the quasi2D model, the floodplains were described as a network of

fictitious river branches and spillovers with the main rivers. This approach had several

advantages: (i) transferring some of the benefits of 2D flow calculations and flow directions to

the 1D hydrological model; (ii) saving computation time because less input data was needed;

and (iii) reliable model representation of physical processes (Karl-Erich et al., 2008; Soumendra

et al., 2010).

We used different approaches to model the floodplains in Cambodia and in Vietnam. The

Cambodian floodplains without channels and dikes were simulated by wide cross sections using

the 1D method. For the LXQ, we applied the quasi2D approach to formulate the hydrodynamic

interactions between the floodplains and rivers under various dike construction scenarios. Although the Plain of Reeds itself was not a focus of this research, we included it in the model with the dikes as constructed in 2011, to better understand the hydraulic interactions between the Tien and Hau rivers via the Vam Nao River and tributaries. The LXQ floodplains are characterized by a dense network of dikes and channels, producing multitudes of compartmentalized fields for agriculture.

Our model has 554 dike compartments represent for the floodplains of the VMD. Our modelling approach for simulating the interaction between rivers and floodplain is to consider that each dike compartment is a flood cell. It means each flood cell is specifically defined and isolated geographical area as a rectangle surrounded by real dikes and channels. This approach, from Dung et al. (2011), is illustrated in Figure A2 in the Appendix. In the figure, each compartment was considered as a flood cell and modelled as a fictitious river branch with a low and wide cross section, as extracted from a SRTM digital elevation model (Shuttle Radar Topography Mission DEM, 90 m x 90 m resolution). These data also help model estimate each cell volume. The control structures linked these fictitious river branches to real channels. Weirs represented dikes and overflows. Dike height was adjusted by changing the sill level of the control structures. By using this approach, floodwater could flow in and out the flood cells, depending on the height of dikes as the sill level of the control structures.

3.4. Dike construction scenarios

Various dike construction and land use scenarios were developed to explore the impacts of dikes on flood dynamics (Figure 2). The first scenario (S1) provided a baseline to explore flood dynamics without the impact of high dikes[2]. All of the high dikes were therefore removed from

---

[2] High dikes are usually built at a height of 2.0–2.5 m, in places where maximum flood depths are less than 1.5 m, to completely prevent floodwater from entering the fields (Tran and Weger, 2017)

1   the model in this scenario. Without the high dike compartments, water discharge is freely

2   distributed over the LXQ and throughout the canals along the Hau River. The second scenario

3   (S2) represents the dike infrastructure and land use conditions of 2011. Here, more than half of

4   the total agricultural area in An Giang Province is set off by high dikes, with the remaining

5   areas protected by low dikes. Kien Giang Province had only low dikes in 2011. The third

6   scenario (S3) depicts a system in which high dikes protect the entire An Giang Province. The

7   fourth scenario (S4) represents a system with high dikes across the entire LXQ.

8   **[Figure 2]**

9   **3.5. Water balance calculation**

10   To understand why and where the water movements on the floodplains cause changes in

11   downstream flows, we calculated water balances for each scenario. For the 1D hydrological

12   model representing the complex hydraulic situation of the Mekong Delta, all components in the

13   water balance equation were estimated. The water balance equation is as follows:

14   $\sum_{i=1}^{n} Q_{in}(t_i) - \sum_{i=1}^{n} Q_{out}(t_i) = (V - V_o)dt_i,$ (1)

15   where $\sum_{i=1}^{n} Q_{in}(t_i)$ is total inflows and $\sum_{i=1}^{n} Q_{out}(t_i)$ is total outflows to the LXQ, in cubic

16   meters per second (m^3s^{-1}), corresponding with the starting time t_1 (July) and ending time t_n

17   (December) of the flood simulations. V is the controlled volume and V_o is the initial volume, in

18   cubic meters (m^3).

19   From the output of the hydraulic model, we extracted discharge time series data from canals

20   along the closed boundaries of the LXQ to calculate flow volumes over the July to December

21   period. Inflows include the water fluxes along the Vinh Te Canal and along the Hau River.

22   Outflows were taken from the Cai San Canal and the canal along the Gulf of Thailand. The

23   water balance was also computed for the Hau River. Here, the water fluxes at Chau Doc and

1 the volume of the Tien River were input flows, while the output flows consisted of discharges

2 along the Hau River to the LXQ, through the Cai San Canal, and at the point on the Hau River

3 beyond the Cai San Canal. Rainfall volumes were calculated from the individual rainfall

4 simulation files.

5 **4. Results**

6 **4.1. Calibration and validation results**

7 Table 1 presents the calibration and validation results. Additionally, Figure 3 presents Q–Q

8 plots of the 2011 data for representative stations (the 2013 data shown in Figure A4 in the

9 Appendix). Our NSE and R^2 values computed for selected stations suggest generally very good

10 performance of the model, in ranges, respectively, of 0.79–0.97 and 0.89–0.98. The 2011

11 calibration period shows better performance than the 2013 validation period. This is expected,

12 as changes in infrastructure and dike network may have occurred between 2011 (calibration)

13 and 2013 (validation) which were not incorporated in the model. For example, the NSE of the

14 water level found in Chau Doc in 2013 is 0.79 compared to 0.92 in 2011. The My Thuan station

15 shows lower NSE values for both 2011 and 2013, but these values are still greater than 0.8. For

16 the stations located within the floodplains, good fitness was found in water levels (0.85–0.96);

17 unfortunately, discharge observation data were not available for those stations.

18 **[Table 1]**

19 **[Figure 3]**

20 Model performance was also judged as good considering the small difference between

21 the peak water levels produced by the simulation and those observed in 2011 and 2013 (Figure

22 4). However, the peak values simulated were in most cases lower than observed values. The

23 discrepancy was greater for 2000 than for 2011 and 2013. The simulation returned a slightly

1   lower peak river water level at Can Tho in 2000 (2.02 m) compared to 2011 (2.10 m). According

2   to observational data, however, the highest water level observed in Can Tho in 2000 was 1.79

3   m, whereas 2.15 m was observed in 2011.

4   This raises the question of whether the changes in river levels at Can Tho are primarily

5   attributable to changes in the floodplains and canal networks between 2000 and 2011, or to the

6   effect of the higher tidal movements observed in the estuaries of the Tien and Hau rivers. Tidal

7   flows in these estuaries were markedly higher in 2011 than in the peak flood year of 2000,

8   suggesting potential backwater curve effects (Table 2). However, the model results for 2000

9   (using the 2011 river and infrastructure network and the 2000 river level and tidal data)

10   compared to those for 2011 (2011 river and infrastructure network and 2011 water levels) show

11   just a modest increase of 0.08 m at Can Tho (Table 3). This suggests that the tidal backwater

12   effect seems to be limited. It is significantly smaller than the difference in water levels observed

13   between 2011 and 2000, which amounts to 0.36 m at Can Tho. This analysis suggests that the

14   tidal influence is approximately 0.08 m, while the effect of changes in the river and

15   infrastructure network and on the floodplains amounts to 0.28 m in terms of river levels at Can

16   Tho. Given that the total flood volume in 2011 was 30% less than in 2000 (283×10^9 m^3

17   compared to 402×10^9 m^3) the effect of changes in the river and infrastructure network and

18   floodplains appears relatively large.

19   **[Table 2]**

20   **[Table 3]**

21   **[Figure 4]**

22   Figure 4 shows a good fit between the simulated and observed peak water levels for the

23   floods in 2011 (calibration) and 2013 (validation). In the flood 2000, the fitness is low due to

24   the significant changes in physical topography such as river network and branches and river

25   cross-sections between the model setup of 2011 and the measured data in 2000.

4.2. Flood dynamics under the impact of dike construction

3 Simulation results indicate that if all high dikes were removed (S1), peak river levels would be

4 much lower, especially in the upper part of the Mekong Delta (Figure 5). Compared to the 2011

5 situation (S2), peak river levels would be reduced by 66 cm at Chau Doc and 31 cm lower at

6 Vam Nao if all high dikes were removed. At Can Tho, however, differences in peak river levels

7 were relatively small: removing all high dikes reduced peak levels in Can Tho by only about 4

8 cm. Within the LXQ, removal of all high dikes would result in relatively large increases in peak

9 water levels upstream (90, 40 and 50 cm at Xuan To, Tri Ton and Tan Hiep, respectively),

10 compared to downstream points (2 cm at Phung Hiep) (Figure 6). In the Vinh Te Canal, water

11 levels fall under a no high dike scenario (by 17.2–84.6 cm from upstream to downstream), but

12 they increase in the Cai San Canal (4.3–45.8 cm) and in the canal along the Gulf of Thailand

13 (fluctuating 1.0–34.1 cm along the canal) (Table 4).

14 The increases in river levels from high dike expansion in An Giang Province and the

15 LXQ (S3 and S4) show a similar pattern to S2 (dike infrastructure as in 2011) and S1 (no dikes).

16 The model presents very slight increases in river levels (2–3 cm upstream and 1 cm

17 downstream) from expansion of the high dikes (S3 and S4) compared the 2011 dike scenario

18 (S2) (Figure 5 and Figure 6). Overall, we found major differences only between the baseline

19 scenario (S1) and the high dike scenarios (S3 and S4).

20 Paired sample t tests indicate significant differences between simulated and

21 observational water level data for the different scenarios at upstream stations, but not for those

22 downstream ($p<0.05$) (see Table A1 in the Appendix).

23 **[Figure 5]**

24 **[Figure 6]**

1 **[Table 4]**

2 **4.3. Floods of 2000 and 2013**

3 To assess the impact of different floods on peak river levels, we ran our four scenarios with the

4 2000 and 2013 flood hydrographs, compared to the base runs for 2011. These simulations

5 resulted in upstream concentrations of water level increases for all of the three flood

6 hydrographs (Figure 7). The largest increases in river levels were found for the high dike

7 scenarios (S2, S3 and S4). These produced similar absolute increases in relation to the no dike

8 scenario (S1) under all three hydrographs. The suggestion here is that peak levels in the Hau

9 River are relatively independent of the amount of floodwater and flow regime, as water volumes

10 for the simulations differed quite starkly, from 402×10^9 m^3 (2000) to 283×10^9 m^3 (2011) and

11 236×10^9 m^3 (2013).

12 **[Figure 7]**

13 **4.4. Variability in upstream and downstream water levels**

14 Across the four scenarios and the three flood hydrographs, our model results indicate

15 pronounced increases in water levels in the upstream reaches, with levels remaining fairly

16 constant downstream (Figure 8). For scenarios S1 and S2 and the 2000, 2011 and 2013 flood

17 hydrographs, we calculated coefficients of variation (CV) for the water levels. At Chau Doc,

18 upstream, the CV was 0.47, diminishing to 0.07 downstream at Can Tho. Two explanations

19 may account for the limited variability found in water levels downstream: (i) use of tidal water

20 level data at the river estuary as a boundary condition for the model and (ii) the coast-to-

21 upstream direction of our model calibration procedure.

22 **[Figure 8]**

1   The tidal water level data at the estuary of the Mekong were influenced by the (peak)

2   river discharges in the years considered, with peak river flows particularly influencing river

3   mouth levels at high and low tide. Thus, our model's boundary conditions were not only set by

4   tidal movements, but also influenced by river discharges at the estuary mouth for the years

5   considered. In calibrating our model, we first set the roughness coefficients for the coastal area

6   to agree with recorded water levels before calibrating for river levels and discharges in the

7   upstream parts. This potentially reduced the variability in downstream water levels. Potential

8   biases of water level would be propagated toward the upstream reaches and outer edges of the

9   model.

10   On the other hand, the dissipation effect of a floodplain and river network as large as the

11   Mekong Delta is expected to yield relatively smaller change amplitudes in downstream water

12   levels, as changes are modulated across a large area. However, any further reduction in the

13   floodplain area and its dissipation capacity would be expected to produce a markedly increased

14   amplitude in downstream water levels.

15   **4.5. Water balance**

16   To further assess the model's simulation of the hydrodynamic characteristics of the Mekong

17   Delta, we conducted a water balance analysis on flood volumes for the LXQ. Compared to the

18   situation without high dikes (S1), the high dike scenarios (S2, S3 and S4) produced a reduction

19   of floodwaters flowing into the LXQ (Figure 9). The floodwater volume decreased from 18.4 x

20   10^9 m^3 to 12.7–11.8 x 10^9 m^3 along the Vinh Te Canal bordering Cambodia, and from 31.7 x

21   10^9 m^3 to 12.5–11.3 x 10^9 m^3 along the Hau River. With less water coming into the LXQ

22   floodplains, water draining into the Gulf of Thailand and the Cai San Canal was reduced

23   accordingly in the high dike scenarios (from 33.3 x 10^9 m^3 to 22.1–21.3 x 10^9 m^3, and from

24   16.6 x 10^9 m^3 to 2.4–2.6 x 10^9 m^3, respectively). The total reduction in flood volumes entering

1   the northwest corner of the Mekong Delta for simulation runs S2, S3 and S4 (2011 hydrograph)

2   amounted to 15 x 10^9 m^3 (Table 5). This is equivalent to a reduction greater than the estimated

3   flood retention capacity (13 x 10^9 m^3) of the entire LXQ (estimated as a flood depth of 3 m over

4   the entire 0.49 million ha floodplain). This explains why the high dike simulations (S2, S3 and

5   S4) return only minimal increases in river levels, despite the significant reduction of flood

6   retention capacity in the LXQ. In the model simulations, floodwaters are diverted away from

7   the floodplains.

8   The floodwater volumes reaching the LXQ diminish with large-scale high dike

9   construction, that is, in scenarios S2, S3 and S4, due to several factors. First, overflow from the

10   Cambodian floodplains into the Vinh Te Canal drops from 16.8 x 10^9 m^3 in the situation without

11   high dikes to 13.5–12.6 x 10^9 m^3 with high dikes. Second, floodwater from upstream in the Hau

12   River drops from 84.1 x 10^9 m^3 to 81.8–81.6 x 10^9 m^3. Finally, the volume of floodwater from

13   the Tien River flowing into the Hau decreases from 138 x 10^9 m^3 to 128.9–129.3x10^9 m^3.

14   Combined, these diverted floodwaters amount to a volume reduction of 15 x 10^9 m^3 (Table 5).

15   The high dike scenarios (S2, S3 and S4) also resulted in changes in flow directions of

16   the modelled flood streams and in volumes. As a consequence, there was only a slight increase

17   in flood volume in the downstream (estuary) reach of the Hau River. In the Vinh Te Canal, a

18   flood stream amounting to 1.6 x 10^9 m^3 drains toward the Gulf of Thailand in the no dike

19   scenario (S1, 2011). For the high dike scenarios (S2, S3 and S4, 2011), it reverses direction,

20   diverting 1.3–1.4 x 10^9 m^3 toward the Hau River. In the Cai San Canal, a flood stream

21   amounting to 4.26 x 10^9 m^3 flows into the Hau River, but under the impact of high dikes changes

22   direction, with a volume of 2.74–2.77 x 10^9 m^3 flowing toward the Gulf of Thailand. In the

23   downstream reaches of the Hau River the model returns just a slight increase in flood volume

24   (0.5–1.8 x 10^9 m^3; < 1%) for the high dike scenarios (S2, S3 and S4) compared to the no dike

25   scenario (S1). As the water balance analysis shows, this is caused by a diversion (rerouting) of

flood volumes away from the LXQ, so that the reduction of flood retention capacity due to expansion of high dikes has little impact on downstream water levels and flows. The reduction in the flood retention capacity of the LXQ (7–13 x 10^9 m^3, Table 5) is thus effectively (over) compensated for in the model runs by the reduction of 24–26 x 10^9 m^3 of flood volume entering the LXQ floodplains (Figure 9). However, this diversion of flood volumes to primarily the Plain of Reeds (+9 x 10^9 m^3) and the Cambodian floodplains (+6.7 x 10^9 m^3) cannot be verified at present due to data limitations in these areas.

[Figure 9]

[Table 5]

5. Discussion

Recent flood dynamics of the Mekong Delta have raised concerns about an increased flood risk downstream in the VMD. Some authors suggest that a greater flood risk downstream might be linked to the prevalence of high dikes on the upper VMD floodplains (Hoa et al., 2007; Duong et al., 2014; Marchand et al., 2014; Fujihara et al., 2015). Using a 1D hydrodynamic model combined with a quasi2D approach (following Dung et al., 2011), we quantified the impacts of extensive high dike construction on floodwater levels and flood risk across the VMD. Most hydrodynamic studies of the Mekong Delta have retrofitted modelled changes (e.g., dikes and canal network) to past flood events (e.g., flood levels and flood area data). Whereas good fits are generally reported between model outputs and recorded water levels, these studies are unable to explain how flood volumes are distributed over the delta. We therefore elaborate one of the new studies to explore the 1D with a quasi2D model advantage, considering potential hydraulic impacts of existing and planning dike construction scenarios on the flood regimes in the VMD. We fill knowledge gap by using water balance calculations to explain where floodwater delivers under the dike scenarios.

In our study, we calculated water balances for the flood scenarios and events considered, to provide insight on the spatial redistribution of flood volumes due to changes in dike prevalence. Our results show a clear impact of dike construction on floodwater levels in the Hau River. The high dike scenarios (S2, S3 and S4) produced a marked increase in peak river levels in the upstream reaches of the Hau River (+68 cm at Chau Doc), while minimal increases occurred downstream (+5 cm at Can Tho). A similar trend and effect was found on water levels in the canal network of the LXQ and western floodplains. The model showed that high dike construction would have a substantial impact (+100 cm) on water levels along the upstream boundary of the LXQ (i.e., at Xuan To). This was paired with a diminishment in water levels (–45 cm) within the dike-protected floodplains and a limited or no effect on the downstream floodplains of the LXQ and in Can Tho (i.e., at Phung Hiep). These results suggest that further expansion of high dikes in the LXQ would have little impact on peak water levels, as simulated in scenario S3 (a fully diked An Giang Province) and scenario S4 (a fully diked LXQ). Furthermore, only a fraction of the reported differences in water levels between the no dike scenario (S1) and the 2011 scenario (S2) could be attributed to changes in dike infrastructure. Compared to the dike condition in 2011 (scenario S2), additional expansion of dikes is thus expected to have only small additional impact on river levels. The greatest impact appears to have already occurred with the extent of dike construction in 2011.

Regarding the flood hydrographs and floodwater volumes examined, representing the flood conditions of 2000, 2011 and 2013, we found fairly limited effects of extensive dike construction on the water levels of the Hau River and canal network. Although total flood volumes differed markedly (402 x 10^9 m^3 in 2000, 283 x 10^9 m^3 in 2011 and 236 x 10^9 m^3 in 2013), impacts on peak levels in the Hau River were minimal in our simulation runs. The largest effects were found for the upstream reaches at Chau Doc, but these were a fraction of the impacts in scenarios S1 and S2. Both with further extension of high dikes (S2, S3 and S4) and

use of the different flood hydrographs (2000, 2011 and 2013), we found little change in peak water levels downstream in the Hau River (i.e., at Can Tho). The impacts of doubling the area of agricultural fields protected by high dikes (S2, S3 and S4) and increasing Mekong River discharge volumes (2011 compared with 2000) were absorbed elsewhere in the lower Mekong Delta, according to our model simulations.

These results are consistent with those of other authors making use of 1D hydrodynamic models with quasi2D approaches. Previous studies report water level increases of +60 to +100 cm concentrated in the upper reaches in the LXQ (Hoa et al., 2007; Duong et al., 2014; Fujihara et al., 2015) and limited increases (4–5 cm) downstream (Duong et al., 2014). Nonetheless, these large increases in water levels and flow velocities in the upper delta point to a heightened risk of bank erosion and catastrophic dike failures there (Hoa et al., 2007).

Our model performed well in the calibration (S2, 2011) and validation (S2, 2013) runs, in which the state of high dikes in 2011 was compared with the recorded water levels from gauging stations for the hydrographs of 2011 and 2013. Consistent with previous work, this suggests that our model setup and calibration were able to reproduce recorded water levels. Our simulation runs did not return a neat fit with the recorded water levels in the Hau River in the 2000 flood hydrograph (Figure 8). Upstream, our scenarios returned lower than recorded values, and downstream at Can Tho our values were slightly higher. In part, this may be attributable to changes in the river and canal network between 2000 and 2011 (e.g., additional dredging and excavation). These may have altered the hydraulic properties of the Hau River in ways not captured in our scenarios.

The major known change in this period, that is, expansion of high dikes (from <10,000 ha in 2000 to >140,000 ha in 2011 in An Giang Province alone), was captured in our no dikes scenario (S1). The recorded rise in water levels at Can Tho (from 1.79 m in 2000 to 2.15 m in

1 2011/2013) over this period can also be partly attributed to the siltation of the Hau River

2 (reported as Bassac estuary in Hoa et al., 2007). According to Hoa et al. (2007), progressive

3 siltation would lead to an increased backwater effect, as the discharge capacity of the river

4 would be gradually reduced with siltation, sea level rise and storm surges. This could potentially

5 raise water levels at Can Tho up to 100 cm (Hoa et al. 2007).

6   At the outset of our study, we expected expansion of high dikes to produce greater

7 discharges in the Hau River, resulting in a more pronounced backwater curve and higher water

8 levels at Can Tho, such as those reported at the peak of the 2011 floods. However, this was not

9 corroborated by our modelling results. Water levels at Can Tho were stable, the main changes

10 in water levels being upstream. The relative stability of the water level at Can Tho can only be

11 explained by a relative stability in discharge in the lower reaches of the Hau.

12   Our water balance analysis used the 2011 hydrograph for all of our scenarios to show

13 how water is redistributed over the delta in the various model simulations. According to the

14 scenario runs, the impacts of floodwater retention losses in the LXQ due to high dike

15 construction are concentrated in the upstream and eastern reaches of the delta, with minimal

16 impacts downstream in the Hau River and at Can Tho. The simulation runs further show

17 increases in floodwater volumes and flood risk to be redirected toward the Tien River and Plain

18 of Reeds, as well as the Cambodian floodplains. To be able to return fairly stable water levels

19 downstream in the Hau River (at Can Tho and the estuary mouth), reductions in flood retention

20 capacity of the LXQ (S2, S3 and S4) are compensated by reduced floodwater volumes entering

21 the system and the LXQ floodplains (Δ Storage LXQ = -7 to -13 x 10^9 m^3; ΔQ entering the

22 western delta = -15.8 x 10^9 m^3; and Δ Q entering the LXQ plain = -26 x 10^9 m^3). This enables

23 the model to return a relatively constant water level and floodwater volume (195 x 10^9 m^3 $\pm$

24 1%) downstream. Whereas this may be a function of the current model configuration, there are

at present no means of verification, as water level and discharge data are currently unavailable for these areas.

Some limitations need to be considered in our study. We could not fully validate the suggested reduced flood inflows to the Long Xuyen Quadrangle, and subsequent diversion of floodwaters to the Plain of Reeds and Cambodian floodplains, due to lack of monitoring data for these areas. Our model results regarding the spatial redistribution of floodwater volumes could have been influenced by the way we calibrated the model as well as the model uncertainty. The hydrodynamic model approach applied could also have influenced the accuracy of flood simulation and water balance equations. On a small scale, two-dimensional and three-dimensional hydrodynamic models (2D and 3D) are most suitable for simulating the flood dynamics of a complex floodplain. However, 2D and 3D models are at present difficult to apply to large areas, such as the Mekong Delta, due to the detailed data and computational capacity required (Soumendra et al., 2010; Dung et al., 2011). The aims of our study dictated a focus on a large part of the delta, as we were interested in the impacts of upstream water control measures on downstream river levels. Given the constraints in data and available model configurations, we combined the 1D model with a quasi2D approach. Our modelling results are in line with previous studies applying similar methods. Our water balance analysis suggests that it would be recommendable to invest in better and more comprehensive data availability, as well as additional computational capacity, to enable more in-depth study of floodwater movements on the delta through 2D and 3D modelling.

6. Conclusions

Development of extensive high dikes to enable triple rice cultivation in the upstream floodplains of the VMD has raised critical concerns about environmental impacts, especially changing water flows and downstream flood risk. We used a 1D-quasi2D modelling approach to assess

the impacts of four dike development scenarios on floodwater volumes and distributions on the delta, focusing on changes in peak water levels and the delta-wide water balance. Our study's main findings were three.

- *First*, expanded high dike construction in the upper Mekong Delta from 2000 to 2011 has had large hydraulic impact, demonstrated by significant increases in floodwater levels of up to +68 cm in the upper delta. Whereas dike expansion has substantially affected flood levels and distribution in the upper delta, impacts have been remarkably small in the downstream regions.

- *Second*, continued high dike construction over the period from 2000 is likely to increase the flood risk across the entire LXQ, as peak water levels there are set to rise up to an additional +100 cm.

- *Third*, dike construction has produced radical changes in the floodwater balance and distributions. High dikes have reduced the volumes of floodwater reaching the LXQ, in amounts in excess of the retention volume lost due to dike construction.

All in all, our results indicate substantial impacts of large-scale dike construction on peak flood levels, flood retention capacity and the delta-wide water balance in the Mekong Delta. Flood risk in the Mekong Delta will likely increase as a direct consequence of high dike construction, especially in view of the cumulative impacts of other factors, such as sea level rise, land subsidence and more extreme rainfall due to climate change. Any plans for future expansion of high dikes should therefore be subject to careful deliberation and detailed impact assessment. From a hydraulic modelling perspective, dike impact assessment should be conducted on a delta-wide scale and pay special attention to opportunities for model calibration and validation for the Cambodian floodplains and Plain of Reeds.

 TABLES

2 Table 1: Correlation coefficient and Nash–Sutcliffe efficiency of water levels (WL) and
3 discharges (Q) for 2011 (calibration) and 2013 (validation)

Location	Correlation coefficient R^2				Nash-Sutcliffe efficiency E			
	WL 2011	WL 2013	Q 2011	Q 2013	WL 2011	WL 2013	Q 2011	Q 2013
Tan Chau	0.97	0.96	0.97	0.95	0.94	0.90	0.88	0.94
Chau Doc	0.95	0.90	0.95	0.92	0.92	0.79	0.92	0.90
Vam Nao	0.98	0.94	0.96	0.94	0.91	0.93	0.90	0.92
Long Xuyen	0.96	0.93	-	-	0.92	0.92	-	-
Can Tho	0.97	0.98	0.95	0.96	0.97	0.97	0.92	0.90
Cao Lanh	0.97	0.94	-	-	0.93	0.94	-	-
My Thuan	0.97	0.94	0.89	0.91	0.94	0.83	0.80	0.86
Xuan To	0.91	0.90	-	-	0.85	0.87	-	-
Tri Ton	0.95	0.93	-	-	0.91	0.85	-	-
Tan Hiep	0.97	0.93	-	-	0.96	0.90	-	-
Phung Hiep	0.94	0.94	-	-	0.85	0.88	-	-

4 *(-) Missing data due to unavailability of observed discharge data from station.*

5 Table 2: Tidal water levels in numbers of hours above various thresholds, observed at the My

6 Thanh and Ben Trai stations in the 2000 and 2011 wet seasons (July to December).

Water level	Numbers of hours above threshold at My Thanh		Numbers of hours above threshold at Ben Trai	
	2000	2011	2000	2011
>1.5 m	95	424	31	102
>1.6 m	35	290	8	51
>1.7 m	7	198	0	23
>1.75 m	3	160	0	12
>1.85 m	1	104	0	0

8 Table 3: Changes in river level and origins at Can Tho, 2000 and 2011

WL at Can Tho	Model (m)	Observed (m)	Δ (m)	Flood volume of VMD (10^9 m^3)
2000	2.02[*]	1.79	-0.23	402
2011	2.10	2.15	+0.05	283
Δ (m)	**0.08**	0.36	**0.28**	

9 ** Model outcomes for 2000 were derived using the observed hydrograph and tidal water levels*

10 *of 2000 combined with the river network and floodplain characteristics of 2011.*

1 Table 4: Peak water levels under different dike construction scenarios in the boundary canals

2 of the Long Xuyen Quadrangle

Scenarios	S1 (m)	S2 (m)	S3 (m)	S4 (m)	S2–S1 (cm)	S3–S1 (cm)	S4–S1 (cm)
Vinh Te Canal							
(1) Km 0	3.40	4.18	4.20	4.22	*78.70*	*80.70*	*82.20*
(2) Km 17	3.08	3.92	3.97	4.03	*84.60*	*89.60*	*95.50*
(3) Km 31	2.39	3.01	3.31	3.64	*61.70*	*92.20*	*124.80*
(4) Km 42	2.77	2.95	3.01	3.61	*18.80*	*24.00*	*84.20*
(5) Km 54	2.81	2.98	3.04	3.62	*17.20*	*22.90*	*81.30*
Cai San Canal							
(1) Km 0	2.36	2.31	2.33	2.34	*−4.30*	*−2.80*	*−1.80*
(2) Km 10	2.23	1.98	2.00	2.01	*−25.20*	*−23.20*	*−21.50*

1 **A1 The Saint Venant equations and computational components**

2 The Saint Venant equations were formulated as follows (DHI, 2011).

3 Continuity equation:

4 $$\frac{\partial Q}{\partial t} + \frac{\partial A}{\partial t} = q$$

5 Momentum equation:

6 $$\frac{\partial Q}{\partial t} + \frac{\partial \left(\frac{\propto Q^2}{A}\right)}{\partial x} + gA\frac{\partial h}{\partial x} + \frac{gQ|Q|}{C^2 AR} = 0$$

7 Where

8 Q-discharge [m^3/s]

9 A-flow area [m^2]

10 q-the lateral inflow [m^2/s]

11 h-stage above datum [m]

12 C-Chezy resistance coefficient [m$^{1/2}$/s]

13 R-hydraulic or resistance radius [m]

14 ∝-momentum distribution coefficient

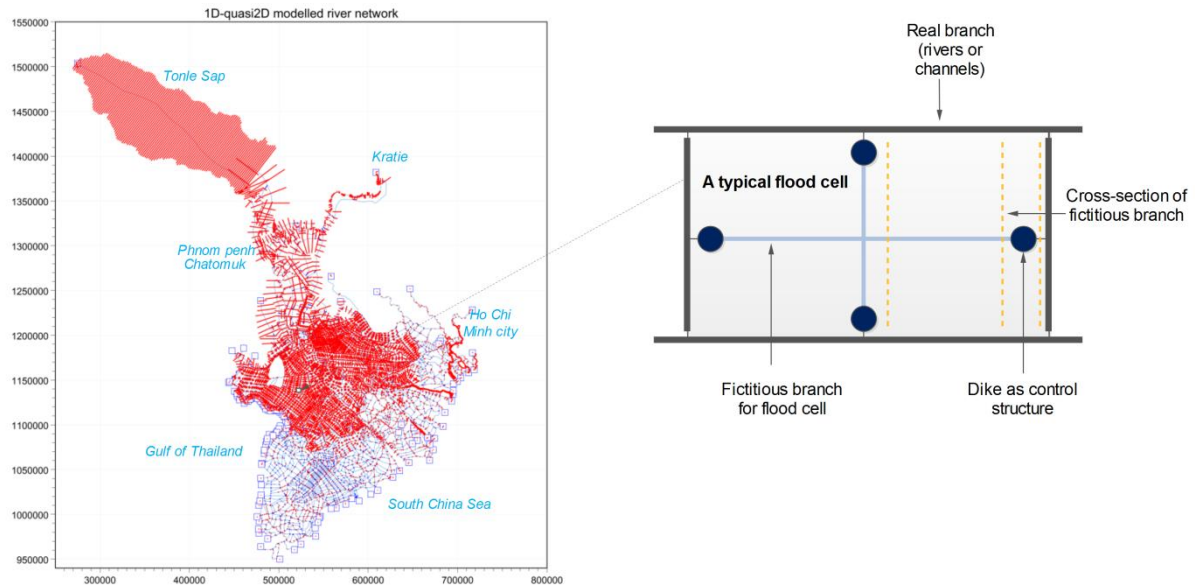
A2 The 1D-quasi2D modelled river network


Figure A2: The left figure describes the 1D-quasi2D modelled river network of the VMD and the right figure shows a representative typical floodplain compartment. The approach is from Dung et al. (2011).

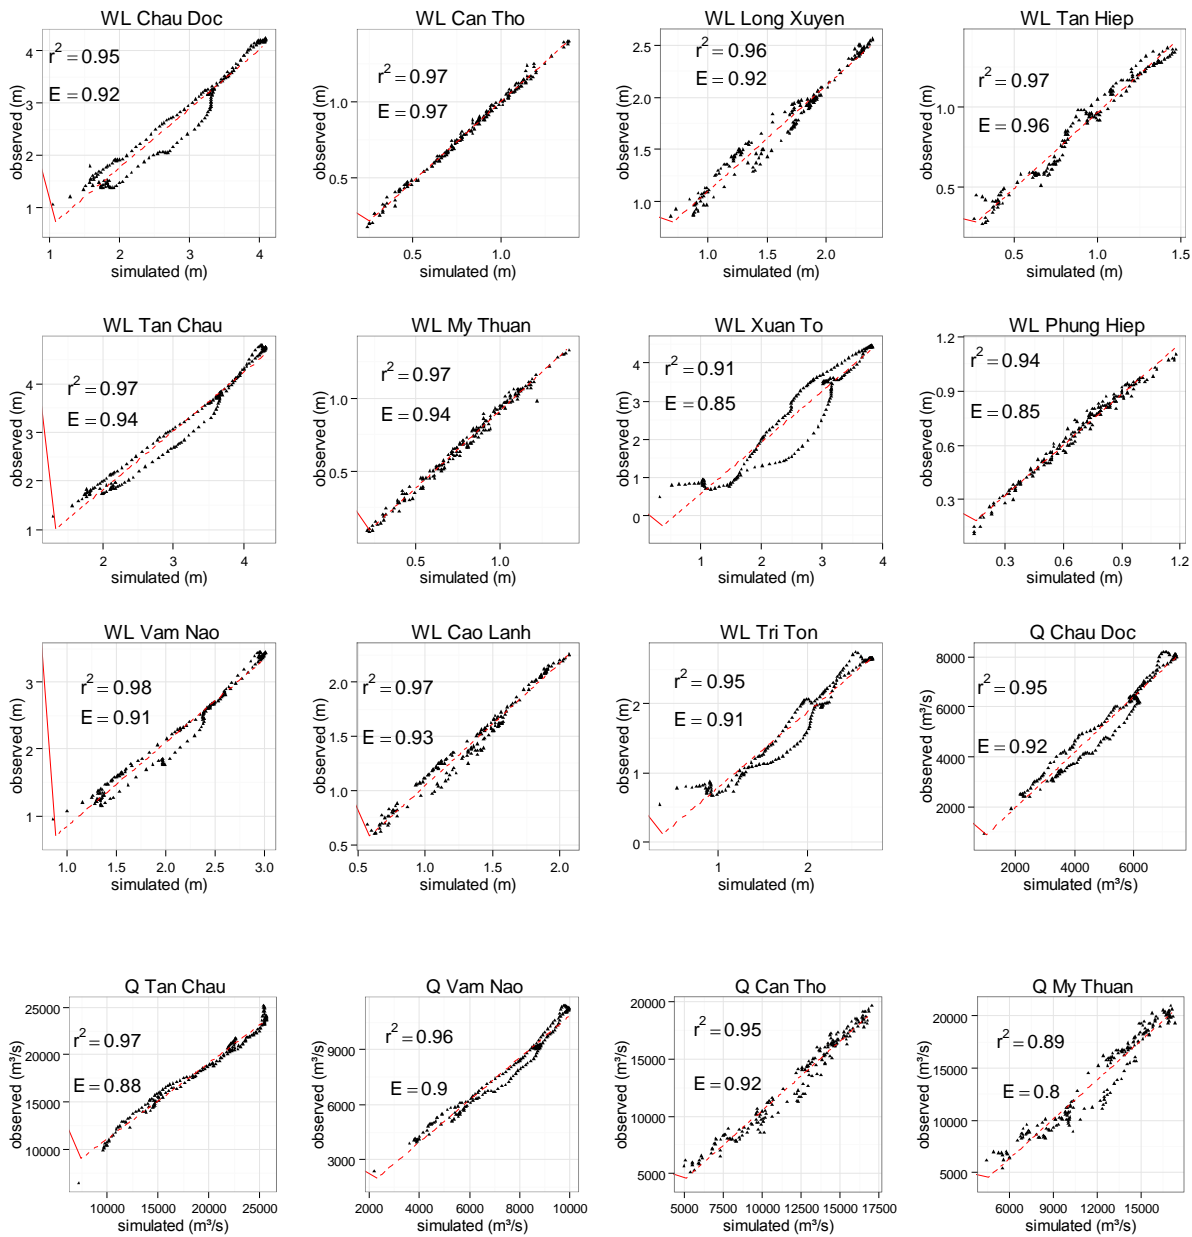
A3 Graphs of correlation and Nash–Sutcliffe efficiency


Figure A3: Graphs of correlation and Nash–Sutcliffe efficiency of daily simulated and observed flows in 2011 at all stations used for model calibration

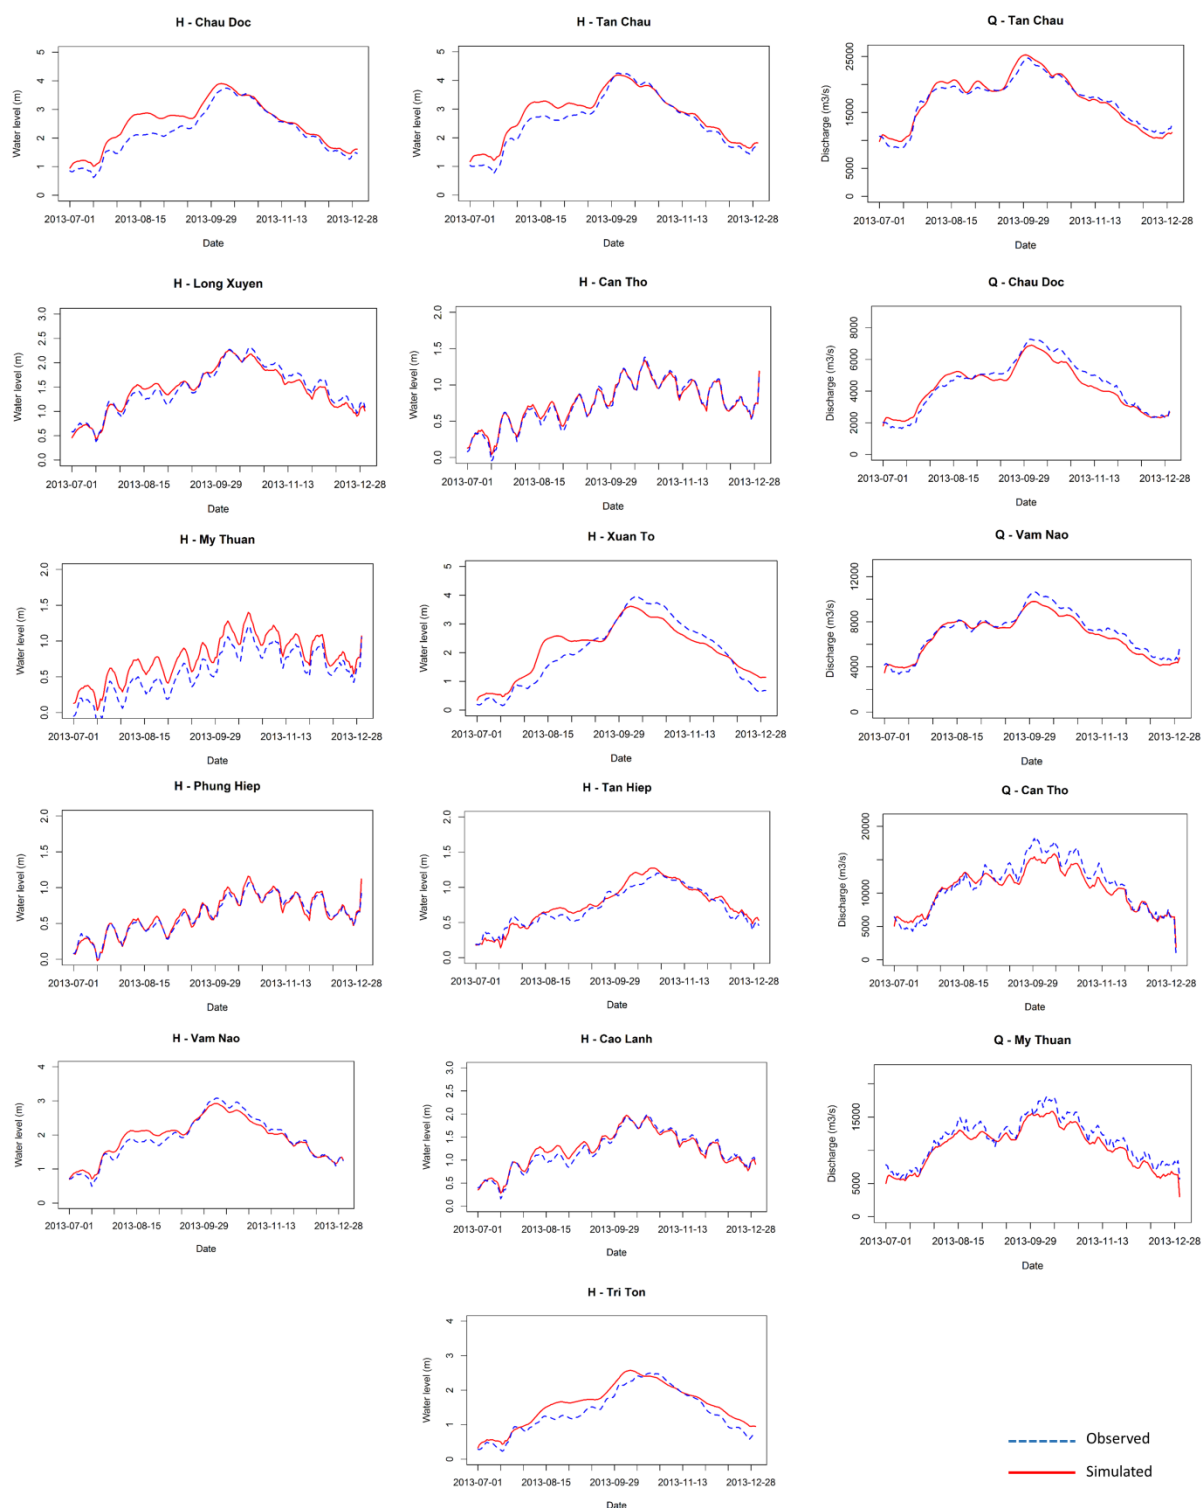
1 **A4 Time series of daily simulated and observed flows in 2013 at all stations used**

2 **for model calibration**


4 Figure A4: Time series of daily simulated and observed flows in 2013 at all stations used for model

5 calibration
