23 **Abstract**

24 Land surface energy and water fluxes play an important role in land-atmosphere interactions,
25 especially for the climatic feedback effects driven by land use/land cover change (LULCC).
26 These have long been documented in model-based studies, but the performance of land surface
27 models in representing LULCC-induced responses has not been well investigated. In this study,
28 measurements from proximate paired (open versus forest) flux tower sites are used to represent
29 observed deforestation-induced changes in surface fluxes, which are compared with simulations
30 from the Community Land Model (CLM) and the Noah Multi-Parameterization (Noah-MP) land
31 model. Point-scale simulations suggest CLM can represent the observed diurnal and seasonal
32 changes in net radiation (R_{net}) and ground heat flux (G), but difficulties remain in the energy
33 partitioning between latent (LE) and sensible (H) heat flux. CLM does not capture the observed
34 decreased daytime LE , and overestimates the increased H during summer. These deficiencies are
35 mainly associated with models' greater biases over forest land-cover types and the
36 parameterization of soil evaporation. Global gridded simulations with CLM show uncertainties
37 in the estimation of LE and H at the grid level for regional and global simulations. Noah-MP
38 exhibits a similar ability to simulate the surface flux changes, but with larger biases in H , G , and
39 R_{net} change during late winter and early spring, which are related to a deficiency in estimating
40 albedo. Differences in meteorological conditions between paired sites is not a factor in these
41 results. Attention needs to be devoted to improving the representation of surface heat flux
42 processes in land models to increase confidence in LULCC simulations.

43

44

45 **1. Introduction**

46

47 Earth system models (ESMs) have long been used to investigate the climatic impacts of land
48 use/land cover change (LULCC) (cf. Pielke et al. 2011; Mahmood et al. 2014). Results from
49 sensitivity studies largely depend on the land surface model (LSM) that is coupled to the
50 atmospheric model within ESMs. In the context of the Land-Use and Climate, Identification of
51 Robust Impacts (LUCID) project, Pitman et al. (2009) found disagreement among the LSMs in
52 simulating the LULCC-induced changes in summer latent heat flux over the Northern
53 Hemisphere. de Noblet-Ducoudré et al. (2012) and Boiser et al. (2012) argued that the inter-
54 model spread of LULCC sensitivity (especially regarding the partitioning of available energy
55 between latent and sensible heat fluxes within the different land-cover types) highlights an
56 urgent need for a rigorous evaluation of LSMs. From Phase 5 of the Coupled Model Inter-
57 comparison Project (CMIP5), Brovkin et al. (2013) also found different climatic responses to
58 LULCC among the participating models, and the diverse responses are associated with different
59 parameterizations of land surface processes among ESMs. To deal with the uncertainties in
60 LULCC sensitivity among models, the Land Use Model Inter-comparison Project (LUMIP) has
61 been planned, with a goal to develop metrics and diagnostic protocols that quantify LSM
62 performance and related sensitivities with respect to LULCC (Lawrence et al. 2016).

63

64 However, a paucity of useful observations has hindered the assessment of the simulated impacts
65 of LULCC and limited the understanding of the discrepancies among models. In-situ and satellite
66 observations make it possible to quantify the impacts of LULCC on land surface variables.
67 Satellite-derived datasets have been used to explore the albedo, evapotranspiration (ET), and

68 land surface temperature changes due to historical LULCC (Boisier et al. 2013, 2014) and the
69 climatic effects of forest (Li et al. 2015).
70
71 Meanwhile, the development of FLUXNET (Baldocchi et al. 2001) enables the study of land
72 surface responses to different land-cover types based on paired field observations from
73 neighboring flux towers over forest and open land (Juang et al. 2007; Lee et al. 2011; Luyssaert
74 et al. 2014; Teuling et al. 2010; Williams et al. 2012). In terms of LSM evaluation, the paired site
75 observations have been mainly used to simulated impacts of LULCC on land surface temperature
76 (Chen and Dirmeyer 2016; Lejeune et al. 2016; Vanden Broucke et al. 2015). However, a more
77 fundamental question, “whether a model can well represent the observed LULCC-induced
78 changes in surface energy fluxes”, has not been thoroughly investigated, even though we know
79 that the turbulent fluxes are tightly associated with both energy and water exchange between the
80 land surface and atmosphere.

81

82 In this study, we evaluate the performance of the Community Land Model (CLM) version 4.5
83 and the Noah Multi-Parameterization (Noah-MP) LSM in simulating the impacts of LULCC on
84 surface energy fluxes based on observations from FLUXNET sites. CLM and Noah-MP
85 represent perhaps the two most readily available and widely used state-of-the-art community
86 land models developed in the U.S. CLM is chosen because, as the land component for
87 Community Earth System Model (CESM), it prioritizes the simulation of biogeophysical and
88 biogeochemical processes for climate applications (Oleson et al. 2013). Much effort has gone
89 into improving the representation of the land-atmosphere interactions among different biomes
90 (Bonan et al. 2011), and the model itself has been used for many LULCC sensitivity studies

91 (e.g., Chen and Dirmeyer 2016, 2017; Schultz et al. 2016; Lejeune et al. 2017; Lawrence et al.
92 2012). Noah-MP has found use mainly in shorter time-scale, limited area applications, such as
93 weather and hydrologic forecasting, and as a LSM run at very high resolution coupled to
94 mesoscale models (e.g., WRF-Hydro, Gochis et al. 2015). It is planned to become the LSM used
95 in global weather and seasonal forecasting applications at the National Centers for
96 Environmental Prediction (NCEP). Its performance over varying land cover types has direct
97 consequences for its use in forecast models.

98

99 The rest of this paper is structured as follows. Section 2 describes the datasets used in the study
100 and experimental design. Section 3 presents comparison between observations and model
101 simulations in surface latent and sensible heat flux, ground heat flux, and net radiation. Section 4
102 shows the uncertainties within the FLUXNET pairs and model simulations. Sections 5 and 6
103 include discussion and conclusions, respectively.

104

105 **2. Methodology**

106

107 *2.1 Observational data*

108

109 We use half-hourly observations from 24 selected pairs of flux sites from the FLUXNET2015
110 Tier 1 dataset (<http://fluxnet.fluxdata.org/data/fluxnet2015-dataset>) and 4 pairs from the
111 AmeriFlux dataset (Baldocchi et al. 2001). These observations include meteorological forcings
112 for the LSM, and surface flux measurements for model validation, which include latent heat flux
113 (LE), sensible heat flux (H), ground heat flux (G), and net radiation (R_{net}). All of these variables

114 have been gap-filled (Reichstein et al. 2005; Vuichard and Papale 2015). Table 1 shows the
115 variable names and gap-filling algorithms used in FLUXNET2015. Because there is no directly
116 measured humidity variable reported, which is needed as a meteorological forcing for the LSMs,
117 relative humidity is calculated based on the reported vapor pressure deficit and surface air
118 temperature (Equation 1-2).

$$e_s = 6.11 \exp\left(17.26938818 \frac{T_a}{237.3 + T_a}\right) \quad (1)$$

$$RH = \left(1 - \frac{VPD}{e_s}\right) \times 100 \quad (2)$$

119 in which T_a is air temperature (°C), e_s is saturation vapor pressure (hPa), VPD is vapor pressure
120 deficit (hPa), and RH is relative humidity (%). Additionally, for the turbulent flux measurements
121 over 18 pairs, FLUXNET2015 provides “corrected” fluxes based on an energy balance closure
122 correction factor, which is calculated for each half-hour as $(R_{net} - G) / (H + LE)$. More details
123 about the data processing can be found on the FLUXNET2015 website
124 (<http://fluxnet.fluxdata.org/data/fluxnet2015-dataset/data-processing/>).

125
126 To simulate local land cover change for each pair, one flux tower is located in forest (deciduous,
127 evergreen or mixed; broadleaf or needleleaf) and the other is in a nearby open land cover type
128 (grassland, cropland or open shrub). Figure 1 shows the locations of the paired sites. Their
129 general characteristics are listed in Table S1. The median linear distance between the paired sites
130 is 21.6 km, and the median elevation difference is 20.0 m. Because of their proximities, the
131 paired sites share similar atmospheric background conditions, however they are not identical
132 (Chen and Dirmeyer 2016). Below we show that the differences in meteorology are usually small
133 and not likely a dominant factor in simulated surface flux differences in most of the pairs. We

134 consider the differences (open minus forest) in observed surface fluxes to be representative of the
135 effects of LULCC (deforestation in this case).

136

137 *2.2 Model simulations*

138

139 We have run the offline version of CLM 4.5 and Noah-MP at the point-scale for individual sites.

140 The forcing data, described below, includes downwelling long-wave radiation (W/m^2),

141 downwelling short-wave radiation (W/m^2), air temperature (K), precipitation (mm/s), relative

142 humidity (%), surface pressure (Pa), and wind speed (m/s) at half-hourly time steps. The plant

143 functional type (PFT) in CLM for each site is identified based on its reported land cover type

144 (Table S1) with prescribed climatological satellite phenology (Lawrence and Chase, 2010).

145 Because of the focus on biogeophysical impacts of LULCC in this study, the biogeochemistry

146 Carbon-Nitrogen module has been disabled in our simulations. The initial conditions for each

147 site are generated by cycling through available atmospheric forcings for about 40 years until soil

148 moisture and temperature reach quasi-equilibrium.

149

150 The differences in simulated surface fluxes between the paired sites are compared against the

151 observations, so that the performance of CLM in representing LULCC-induced surface flux

152 changes can be evaluated. In the single-point simulations, two types of forcing data are used for

153 each site: 1) measurements at this site; 2) measurements at the neighboring paired site.

154 Consequently, three types of differences in simulated surface fluxes can be calculated: 1) the

155 difference derived from individual forcings; 2) the difference from identical “forest forcings”

156 (both of the paired sites use the same forcings measured at the forest site); 3) the difference from

157 identical “open forcings” (both of the paired sites use the same forcings measured at the open
158 sites). Such an experimental design can well eliminate the influence from the uncertainties of
159 forcing data and the difference in atmospheric background of the paired sites.

160
161 The ultimate goal of evaluating CLM’s performance at single-point scale is to assess its
162 capability to be used in global LULCC sensitivity simulations in both offline and coupled modes.
163 The paired sites are close enough that they are typically located within a single grid cell of
164 CESM. Moreover, the sub-grid heterogeneity of CLM allows the biogeophysical processes to be
165 calculated at the individual PFT level (15 PFTs available), and makes it possible to output
166 surface fluxes for individual land cover types. The paired sites can be presented as paired PFTs
167 within a single grid of CESM. They then share the same atmospheric forcings, and their
168 differences can be considered as the impacts of LULCC. It should be noted that the PFT-level
169 calculation is independent of the percentage of individual PFTs in the grid cell. Therefore, the
170 coverage of the PFTs in the shared grid cell does not influence the flux difference between the
171 paired PFTs in the global simulations.

172
173 We run CLM offline, globally driven by the CRUNCEP forcings from 1991 to 2010 (Viovy
174 2011) and present land cover conditions (Lawrence et al. 2012) at a horizontal resolution of
175 $0.9^{\circ} \times 1.25^{\circ}$. The paired PFTs are identified based on the locations and land cover types of the
176 FLUXNET paired sites, to ensure the single-point and global simulations are comparable.
177 Schultz et al. (2016) found the shared-soil-column configuration for vegetated land units in CLM
178 caused issues with PFT-level ground heat fluxes. They propose an individual-soil-column
179 scheme (PFTCOL) to better represent the PFT-level energy fluxes, so we also extract and

180 examine the output for the paired PFTs from the PFTCOL model configuration. Details about the
181 PFTCOL simulations can be found in Schultz et al. (2016). Additionally, a coupled simulation
182 with Community Atmosphere Model (CAM) has also been conducted. It shows very similar
183 results to the offline simulations, because the paired PFTs in a single model grid box always
184 share the same atmospheric forcings no matter if CLM is run offline or coupled with CAM.
185 Therefore, results from the coupled simulation are not included in this study.

186

187 Furthermore, we compare the performance of CLM with Noah-MP (Niu et al. 2011), which
188 serves as a participant model in Land Data Assimilation Systems (LDAS, Cai et al. 2014).
189 Single-point Noah-MP simulations are conducted in the same way as CLM simulations to ensure
190 their comparability. The monthly leaf area index (LAI) of each site is identical to the prescribed
191 satellite-based LAI in the corresponding CLM simulation. Table S2 shows selected options for
192 various physical processes in Noah-MP. Information about all model simulations is summarized
193 in Table 2.

194

195 **3. Surface energy fluxes and their changes**

196

197 First, we analyze the diurnal and seasonal cycles of surface energy fluxes and the LULCC-
198 induced changes. The diurnal cycle analysis is primarily focused on summer (DJF for the two
199 austral sites and JJA for the other sites). The seasonal cycle for the austral sites is shifted by 6
200 months to keep summer in the middle of the time series when comparing or compositing with the
201 Northern Hemisphere sites. The results shown below are composites averaged over all open (or
202 forest) sites or open-forest pairs. Not all sites have energy-balance corrected fluxes available;

203 exclusion of those sites shows very similar results for uncorrected fluxes to the average over all
204 sites (or pairs, not shown). There are also some pairs with relatively large changes in surface
205 fluxes. Exclusion of those pairs shows very consistent patterns with the results including all sites,
206 even though there is a slight influence on the magnitude of the changes (Figure S1). Therefore,
207 all sites are included in our analyses for each variable.

208

209 *3.1 Latent heat flux (LE)*

210

211 Figure 2a-b shows the diurnal cycle of *LE* averaged over all the open sites and forest sites during
212 summer. Compared with the observations without energy-balance correction, single-point CLM
213 simulations overestimate *LE* for the open sites with both their actual meteorological forcings and
214 the nearby forest forcings, but underestimate *LE* over the forest sites. The extracted PFT-level
215 output from the global simulations also exhibit similar biases. Relative to CLM, Noah-MP
216 simulations show better agreement with observations over the open sites, but a greater
217 underestimation over forest. The energy-balance correction tends to increase the values of *LE*.
218 Therefore, both CLM and Noah-MP have negative biases compared to the corrected fluxes
219 (except *LE_CORR_25* over the open sites).

220

221 Figure 2c shows the difference in the diurnal cycle of *LE* due to LULCC (deforestation). It
222 should be noted that there is a substantial spread among the pairs in model simulations and
223 especially observations, indicating the diverse geographical backgrounds and specific vegetation
224 changes of these paired sites. The observations suggest an overall lower summer daytime *LE*
225 over the open land compared to forest. In spite of the considerable spread among the energy-

226 balance corrected *LE* observations (Figure 2ab), the differences between the forest and open
227 lands show consistent signals. However, both CLM and Noah-MP single-point simulations fail to
228 represent the observed decreased daytime *LE* as a result of deforestation. The simulated *LE* over
229 the open land is usually slightly greater than the forest from 10:00 to 16:00 at local time. Such a
230 discrepancy may be attributed to the large underestimation of daytime forest *LE* in the models.
231 Meanwhile, simulations by different forcings of the paired sites show robust signals, implying
232 that the bias of the simulated *LE* sensitivity should not be attributed to the uncertainties of the
233 forcing data. For the CLM global simulations, the PFTCOL case exhibits a similar diurnal
234 pattern to the single-point simulations, while decreased daytime *LE* is found consistently only in
235 the PFT simulations. As CLM-PFT is less physically realistic than CLM-PFTCOL from a soil
236 hydrologic perspective, its superior performance needs further investigation.

237

238 To explore the mechanism of the *LE* changes within CLM, we examine the changes in the three
239 components of evapotranspiration; namely canopy evaporation, canopy transpiration, and ground
240 evaporation (Figure 3). Unfortunately, these separate components are not measured and cannot
241 be directly validated. The CLM, PFT and PFTCOL simulations show an agreement in decreased
242 canopy evaporation after deforestation with the greatest decrease during the early morning.

243 There also is an agreement in an overall decreased canopy transpiration, but CLM simulations do
244 not exhibit an obvious change during the morning when greatly decreased canopy transpiration
245 can be found in the PFT and PFTCOL simulations. The main discrepancy among model versions
246 is found in ground evaporation, which increases after deforestation in the CLM and PFTCOL
247 simulations. The increased ground evaporation has exceeded the decreased canopy evaporation
248 and transpiration, resulting in slightly increased *LE* (Figure 2c). Interestingly, the PFT

249 simulations, which have known issues with PFT-level ground heat flux (Schultz et al. 2016),
250 show decreased daytime ground evaporation. Along with decreased canopy evaporation,
251 transpiration, and ground evaporation, the total LE decreases sharply after deforestation in the
252 PFT simulations, which agrees better with the observations than other simulations (Figure 2c).
253 However, the decreased ground evaporation may be associated with a problematic soil-column
254 scheme at sub-grid scale, which undermines the credibility of the agreement between the
255 observations and PFT simulations.

256

257 Figure 4 shows the changes in monthly LE after deforestation across the annual cycle. There is
258 clear and consistent seasonality in the LE changes from the observations. The four types of
259 observations show decreased LE (up to -24.0 W/m^2) during local summer. There is little change
260 in LE in the uncorrected observations during the winter season. However, there is significantly
261 increased LE (up to $+17.9 \text{ W/m}^2$) in the energy-balance corrected observations in late winter and
262 early spring. Neither CLM nor Noah-MP capture the observed seasonality of LE change. As
263 found in the change in the diurnal cycle of the LE , the PFTCOL simulations exhibit a similar
264 pattern to the single-point simulations, while the PFT simulations show decreased LE throughout
265 the year with the maximum from May to August, and the best correlation ($R = 0.81$, $P < 0.01$)
266 with observations.

267

268 *3.2 Sensible heat flux (H)*

269

270 Figure 5a-b shows the diurnal cycle of H averaged over all open and forest sites during local
271 summer. Generally, the models overestimate H throughout the day, with the largest positive bias

272 during midday. Compared with the observations without energy-balance correction, the
273 overestimation can be up to 86.5 W/m^2 from CLM over the forest during noon and 46.4 W/m^2
274 over the open sites. The difference in H between the forest and open sites is shown in Figure 5c.
275 Robust signals are found among the four types of observations, so results from the energy-
276 balance corrected observations are not included hereafter, but are shown in Figure S2. Both
277 observations and models exhibit a clear diurnal pattern of change in H after deforestation – a
278 small nighttime increase and a large daytime decrease. Observations show a large spread among
279 the 28 pairs, which is much greater than that from the CLM simulations, indicating uncertainties
280 and variability among the observed fluxes and the robustness of simulated H sensitivity to
281 LULCC in the LSM. Compared with the observations, CLM shows a greater H decrease, which
282 is twice as much as in the observations. The overestimated H decrease may be related to the large
283 positive bias in H over the forest sites (Figure 5b). Additionally, the PFT simulations show the
284 largest H decrease, which may be associated with the ground heat issues in the shared-soil-
285 column scheme.

286

287 Seasonally, decreased H is found throughout the year after deforestation in both observations and
288 models (except for the same-forest-forcing CLM simulations in winter, Figure 6). The greatest
289 decrease is observed during spring, when both of the single-point CLM and PFTCOL
290 simulations show good agreement. However, CLM and Noah-MP simulations also show a large
291 decrease during summer, which has not been observed in the FLUXNET dataset. Again, the PFT
292 simulations show the greatest H decrease among the simulations and the largest bias compared
293 with the observations during the warm season.

294

295 Additionally, evaporative fraction (EF), which is defined as the ratio of LE to the available
296 energy ($LE+H$), is a useful diagnostic of the surface energy balance (Gentine et al. 2011).
297 Meanwhile, most of the correction methods to solve the imbalance issue of surface energy
298 budget assume the Bowen ratio for small- and large-scale eddies are similar or even equal
299 (Wilson et al. 2002; Foken 2008; Zhou and Wang 2016). Under such an assumption, EF can be
300 independent of energy closure issue, because EF is related to the Bowen ratio (B) as:

$$EF = (1 + B)^{-1} \quad (3)$$

301 Figure 7 shows the change in the diurnal (summer only) and seasonal cycle of EF due to LULCC
302 from forest to open land. During summer, there are small changes in observed daytime EF
303 (Figure 7a) because of the decreases in both LE and H . However, both CLM and Noah-MP show
304 increased daytime EF due to the decreased H and slightly increased LE after deforestation.
305 Seasonally, the models show year-around increased EF , however, which is not observed in
306 FLUXNET from June to September, further demonstrating the models' deficiencies in
307 representing energy partitioning during summer.

308

309 *3.3 Diurnal and seasonal cycle of ground heat flux (G) and net radiation (R_{net})*

310

311 Figure 8a shows the change in the diurnal cycle of G after deforestation. Both the observations
312 and models exhibit increased G during the day and decreased G during the night. However,
313 models overestimate the magnitude of the G change, and discrepancies also exist in the timing of
314 maximum change. The greatest increase in G is observed during early afternoon, while the
315 greatest increase in simulated G occurs at noon in CLM (single-point and PFTCOL) and during
316 morning in Noah-MP. Because G is strongly correlated with R_{net} (Santanello and Friedl 2003),

317 we examine the timing of maximum observed G and R_{net} during summer. There are some sites
318 showing about a 1-hour lag between maximum R_{net} and G (not shown). Therefore, the lag
319 between simulated and observed peaks in G change can be partially attributed to the uncertainties
320 in G measurements that are commonly estimated with heat flux plates installed at some depth
321 (e.g., 5~10 cm) below the surface (Wang and Bou-Zeid 2012), while the LSM simulated G is
322 calculated at the surface. Meanwhile, the G changes (in both the diurnal and seasonal cycle) in
323 the PFT simulations are further from the observations than the other simulations. Such
324 disagreement further confirms the issues with the sub-grid soil column scheme in CLM, which is
325 discussed in the following section. The changes in observed G also have a clear seasonal pattern
326 – an increase during the warm season and a decrease during the cold season (Figure 8b). This
327 seasonality is well captured by the CLM simulations (especially the simulations with identical
328 forcings for the paired sites) in both magnitude and timing, but not evident in Noah-MP
329 simulations.

330

331 After exploring the three flux components of the surface energy balance, it is worthwhile to
332 examine the change in R_{net} after deforestation. During summer, the observations show that R_{net}
333 slightly increases during the night, and decreases considerably (up to -65.7 W/m^2) during the
334 day, which can be attributed to the increased albedo after deforestation (Figure 9a). Decreased
335 daytime R_{net} is also found in the CLM simulations, but with a slightly smaller magnitude.
336 Seasonally, there is a good agreement between the observations and CLM simulations, showing
337 a large R_{net} decrease during spring and summer but a relatively small decrease during autumn and
338 winter (Figure 9b). The Noah-MP simulations are comparable to CLM, but with a notable
339 deficiency in simulating the R_{net} change during late winter and early spring.

340

341 4. Uncertainty Analysis

342

343 4.1 Uncertainties among the FLUXNET pairs

344

345 The results discussed above are based on composites averaged over all forest and open sites. It is
346 worthwhile to examine the uncertainties in surface flux changes among different paired sites.

347 Figure 10a shows the changes in summer daytime (8:00 ~ 16:00) LE from the observations and
348 model simulations across the 28 pairs. This time period is chosen because it is the time of
349 greatest differences in surface energy fluxes (Figure 2c, 5c, 7a, 8a). The observations show
350 decreased LE associated with deforestation over 23 pairs, among which the pairs of evergreen
351 needleleaf forest and open shrub (No. 16~25) exhibit consistent decreases and the pairs of
352 deciduous broadleaf forest and crops (No. 1~4) show the overall greatest decrease. However,
353 both CLM and Noah-MP show relatively weak increases over most of the pairs, which further
354 demonstrate their deficiency in simulating LE change. Additionally, for both CLM or Noah, the
355 choice of forcings does not exert much influence on the simulated change in summer daytime
356 LE .

357

358 The changes in R_{net} over individual pairs are shown in Figure 10b. There are 27 pairs (all except
359 number 21) showing decreased R_{net} after deforestation, with the greatest decreases over the pairs
360 of evergreen needleleaf forest and grassland. Both CLM and Noah-MP well captures the
361 observed decreases in R_{net} over most of the pairs.

362

363 It should be noted that pair 15 shows large LE and R_{net} changes in Figure 10. This pair consists of
364 a site over valley grassland and the other site over mountain evergreen needleleaf forest with
365 60.29 km separation and 1186 m elevation difference. There are significantly different air
366 temperature and downwelling longwave radiation measurements between the sites (Figure S3).
367 Such large differences in LE and R_{net} here are likely associated with the distinct although
368 proximate geographical sites. Even though the exclusion of this site does not make a significant
369 change to the composite analysis in section 3 (not shown), it may raise another question if the
370 simulated sensitivity of surface energy fluxes is associated with the inconsistencies of
371 atmospheric forcings of LSMs at the single pair level.

372

373 *4.2 Uncertainties within the forcings for LSMs*

374

375 Based on the composite analysis in section 3, we have found that the simulated changes in
376 surface energy fluxes with identical forcings (either from forest or open sites) are consistent with
377 the simulations with individual forcings, demonstrating that the overall sensitivities of surface
378 energy fluxes are robust among the choices of different forcings. In this sub-section, we explore
379 the uncertainties of the simulated surface flux changes due to the different forcings for individual
380 pairs, especially with the focus on the roles of separation and elevation difference in the
381 simulated sensitivity of surface energy fluxes.

382

383 Since we have simulations with identical forcings for the paired sites, the difference in surface
384 flux changes between “forest forcings” and “open forcings” can be considered as the simulated
385 sensitivity of surface energy fluxes to variation in the atmospheric forcings. Figure 11 shows the

386 relationship with separation and elevation difference for individual pairs. Overall, the flux
387 changes are not associated with the separation and elevation difference between the paired sites,
388 further confirming the robustness of simulated signals from paired-site simulations.
389 Nevertheless, some “outliers” are identified. In the CLM simulations, only pair 15 shows large
390 differences in LE and H change. However, pairs 3, 7, and 12 also exhibit large differences in
391 Noah-MP simulations. The uncertainties in pairs 12 and 15 may be attributed to their large
392 elevation differences. For pair 7 in Australia, Noah-MP shows greater sensitivity of H and R_{net} to
393 atmospheric forcings over the evergreen broadleaf forest than grassland (not shown), leading to
394 large differences in the surface flux changes. However, this is the only pair with evergreen
395 broadleaf forest, and its behavior in Noah-MP needs further investigation. Even though the pair 3
396 sites are close with small elevation difference, we found considerably different downwelling
397 shortwave and longwave radiation between the two sites (not shown), which may explain the
398 uncertainties in the Noah-MP simulations.

399

400 **5. Discussion**

401

402 This study has examined simulated changes in the surface energy budget in response to local
403 land cover change based on paired proximate FLUXNET sites with differing land cover. Our
404 results suggest that CLM well represents the observed changes in R_{net} and G ; but there remain
405 issues in simulating the energy partitioning between LE and H , which also further confirms the
406 large uncertainties in simulated ET responses to LULCC revealed in several recent studies (e.g.,
407 Pitman et al. 2009; Boisier et al. 2012, 2014; de Noblet-Ducoudré et al. 2012; Vanden Broucke
408 et al. 2015). Based on the observations, deforestation generally leads to a decrease in summer

409 daytime R_{net} , accompanied by decreased LE and H . On one hand, CLM captures the observed
410 signal of H change, but overestimates the decrease due to its large overestimation of H over the
411 forest. On the other hand, the model underestimates the LE over the forest, leading to an opposite
412 signal (a slight increase) of LE change comparing to the observations. Simulations in Noah-MP
413 show similar biases. Therefore, uncertainties in current LULCC sensitivity studies may persist
414 specifically in the representation of turbulent fluxes over forest land-cover types.

415

416 Scrutinizing the three components of ET suggests that the simulated increase in summer daytime
417 LE is mainly attributable to a large increase in ground evaporation, which counteracts the
418 decreased canopy evaporation and transpiration. This may raise another issue about the soil
419 resistance parameterization in CLM4.5. Previous studies indicate that the model generates
420 excessive ground evaporation when the canopy is sparse or absent (Swenson and Lawrence
421 2014; Tang et al. 2015). If there is overestimated ground evaporation over the open land, such a
422 bias can also contribute to the disagreement in the LULCC-induced ET changes. Swenson and
423 Lawrence (2014) have implemented a dry surface layer for the soil resistance parameterization to
424 solve this issue for the upcoming CLM5. An extension of the evaluation with CLM5 would be
425 useful to examine if the issue within the soil resistance parameterization is responsible for the
426 uncertainties in ET changes.

427

428 Besides the uncertainties in estimating turbulent fluxes over different land cover types, the
429 simulations show that differences in the meteorological forcings between nearby paired sites
430 seem to have little impact on the simulation of surface flux changes due to LULCC. Many
431 LSMs besides CLM employ a sub-grid tiling parameterization where multiple land surface types

432 exist within a single grid box, each maintaining a separate set of surface balances and returning a
433 weighted average set of fluxes to the atmosphere based on areal coverage of each surface type.
434 In this arrangement, each land surface type within a grid box receives the same meteorological
435 forcing from the overlying atmospheric model. It appears from our forcing-sensitivity studies
436 that this arrangement does not significantly impact the simulation of surface flux changes
437 associated with LULCC on the grid scale.

438

439 That said, the sub-grid comparison between different land cover types may yet be problematic
440 due to the shared soil column issue for vegetated land units in CLM (Schultz et al. 2016). Both
441 the single-point observations and simulations show significant differences in surface soil
442 moisture between most of the paired sites, even though no clear drying or wetting pattern is
443 found (Figure S4). The differences between the paired sites suggests that the shared soil column
444 for vegetated land in CLM may not well represent soil moisture and temperature at the sub-grid
445 scale, which may influence the simulations of land surface energy and water fluxes. We find an
446 unreasonably large change in PFT-level G between forest and open land especially for the
447 seasonal cycle in PFT simulations, while both observations, single-point and PFTCOL
448 simulations show a seasonal change with a very small range (within $\pm 3\text{W/m}^2$). As G is the
449 calculated as the residual of the surface energy budget in CLM (Oleson et al. 2013), this sub-grid
450 G issue may cast even more uncertainties on the calculation of LE and H at the PFT level, as well
451 as their aggregated values at the grid level for regional or global simulations. Therefore, caution
452 should be taken when examining the LULCC sensitivity which involves sub-grid PFT changes.

453

454 Compared with CLM, Noah-MP exhibits a similar ability to simulate surface flux changes,
455 except for a deficiency in simulating H and R_{net} changes during late winter and early spring. We
456 have examined the daytime albedo change after deforestation, calculated from available
457 shortwave radiation terms, from observations and model simulations during local late
458 winter/early spring (February ~ April, FMA) and summer (Figure 12). Both CLM and Noah-MP
459 agree with the observations during summer. However, Noah-MP does not capture the observed
460 albedo increase over nearly half of the pairs during late winter/early spring. Greater disagreement
461 is also found during the local winter season (DJF, not shown), suggesting a deficiency in
462 snowmelt timing or snow albedo sensitivity to LULCC, despite improvement in the snow surface
463 albedo simulations by implementation of the Canadian Land Surface Scheme (CLASS;
464 Verseghy, 1991) in Noah-MP (Niu et al. 2011).

465

466 Finally, it should be recognized that the observational data are not perfect. In particular, there
467 may be systematic biases or even trends in specific instruments that contribute to the perceived
468 differences between paired sites (e.g., site 3). Ideally, redundant instrumentation at sites, or in
469 this case the rotation of an extra set of instruments among nearby paired sites, could be used to
470 identify, quantify and account for significant systematic biases in measurements for suspicious
471 variables. Furthermore, footprints of the flux towers may bias the comparison of surface fluxes
472 between the open and forest sites (Baker et al. 2003; Griebel et al. 2016). In other words, the
473 observed differences between sites can only be partially attributed to LULCC because their
474 environmental conditions may also be different. As most of current studies using paired sites to
475 represent LULCC, we have assumed that the paired sites share the similar background
476 atmospheric conditions, and any observed differences in surface climate conditions can be

477 attributed to LULCC (e.g., Lejeune et al. 2017; Luysaert et al. 2014; Teuling et al. 2010;
478 Vanden Broucke et al 2015). Meanwhile, model simulations with the different forcings can
479 effectively examine the effects of the local environment of individual sites, because their
480 footprints can also be taken by the meteorological measurements. Our results show robust signals
481 of LULCC-induced changes in surface fluxes, implying that impacts of footprints at individual
482 sites are probably trivial.

483

484 **6. Conclusions**

485

486 This study has evaluated the performance of two state-of-the-art LSMs in simulating the
487 LULCC-induced changes in surface energy fluxes. Observations from 28 FLUXNET pairs (open
488 versus forest) are used to represent the observed flux changes following deforestation, which are
489 compared with the LSM simulations forced with meteorological data from the observation sites.
490 Diurnal and seasonal cycles of the flux changes have been investigated.

491

492 The single-point simulations in CLM and Noah-MP show the greatest bias in simulating *LE*
493 change. Significantly decreased daytime *LE* is observed during local summer, but not captured
494 by the models. The observed *LE* changes also exhibit an evident seasonality, which is not
495 represented in the model. The energy partitioning between *LE* and *H* might be a common issue
496 within the LSMs. Other studies have noted problems in the simulation of surface fluxes by
497 LSMs, including poor performance relative to non-physical statistical models (Best et al. 2015,
498 Haughton et al. 2016).

499

500 The sub-grid comparison from the global simulations in CLM yields unrealistic changes in G and
501 H when the soil column is shared among vegetated land units, even though there is a better
502 agreement in LE change with the observations. The individual-soil-column scheme improves the
503 representation of the PFT-level energy flux changes, but uncertainties still remain as with the
504 point-scale simulations. Therefore, these uncertainties must be considered when interpreting
505 global experiments of LULCC sensitivity studies with current LSMs.

506

507 Consistent aggregate performance across many paired sites suggests the problems in these LSMs
508 may not lie primarily with parameter selection at individual sites, but with more fundamental
509 issues of the representation of physical processes in LSMs. The simulation of LULCC may or
510 may not have become more consistent among models since LUCID (de Noblet-Ducoudré et al.
511 2012), but consistency with observed biophysical responses appears to be lacking. LUMIP
512 (Lawrence et al. 2016) will be a step toward better LSM simulation of LULCC responses, and
513 ultimately better simulations of the response of climate to LULCC.

514

684

685

686 **Table 1.** Information about the variables used from FLUXNET2015. The marginal distribution
 687 sampling (MDS) filling method is based on Reichstein et al. (2005); and the ERA-interim filling
 688 method can be found in Vuichard and Papale (2015).

Name	Gap-filling	Description
SW_IN_F	MDS and ERA-interim	downwelling shortwave radiation
LW_IN_F	MDS and ERA-interim	downwelling longwave radiation
PA_F	MDS and ERA-interim	atmospheric pressure
TA_F	MDS and ERA-interim	air temperature
VPD_F	MDS and ERA-interim	vapor pressure deficit
P_F	ERA-interim	precipitation
WS_F	ERA-interim	wind speed
LE_F_MDS	MDS	latent heat flux
H_F_MDS	MDS	sensible heat flux
G_F_MDS	MDS	ground heat flux
NETRAD	n/a	net radiation
LE_CORR	n/a	corrected LE_F_MDS by energy balance closure correction factors. LE_CORR_25, LE_CORR, and LE_CORR_75 are calculated based on 25, 50, and 75th percentiles of the factors, respectively.
H_CORR	n/a	corrected H_F_MDS by energy balance closure correction factors. H_CORR_25, H_CORR, and H_CORR_75 are calculated based on 25, 50, and 75th percentiles of the factors, respectively.

689

690

691 **Table 2.** Information about model simulations. “Nearby” observations indicate that the paired
 692 sites have the identical forcings either from the companion forest or open sites.

Name	Forcings	Description
CLM	observations from individual sites	single-point CLM simulations with its own observations
CLM_forest	observations only from forest sites	single-point CLM simulations with the (nearby) forest observations
CLM_open	observations only from open sites	single-point CLM simulations with the (nearby) open land observations
CLM-PFT	CRUNCEP	global CLM simulations with default soil-column scheme with PFT-level output
CLM-PFTCOL	CRUNCEP	global CLM simulations with default individual-soil-column scheme with PFT-level output
NOAH-MP	observations from individual sites	single-point NOAH-MP simulations with its own observations
NOAH-MP_forest	observations only from forest sites	single-point NOAH-MP simulations with the (nearby) forest observations
NOAH-MP_open	observations only from open sites	single-point NOAH-MP simulations with the (nearby) open land observations

693

694

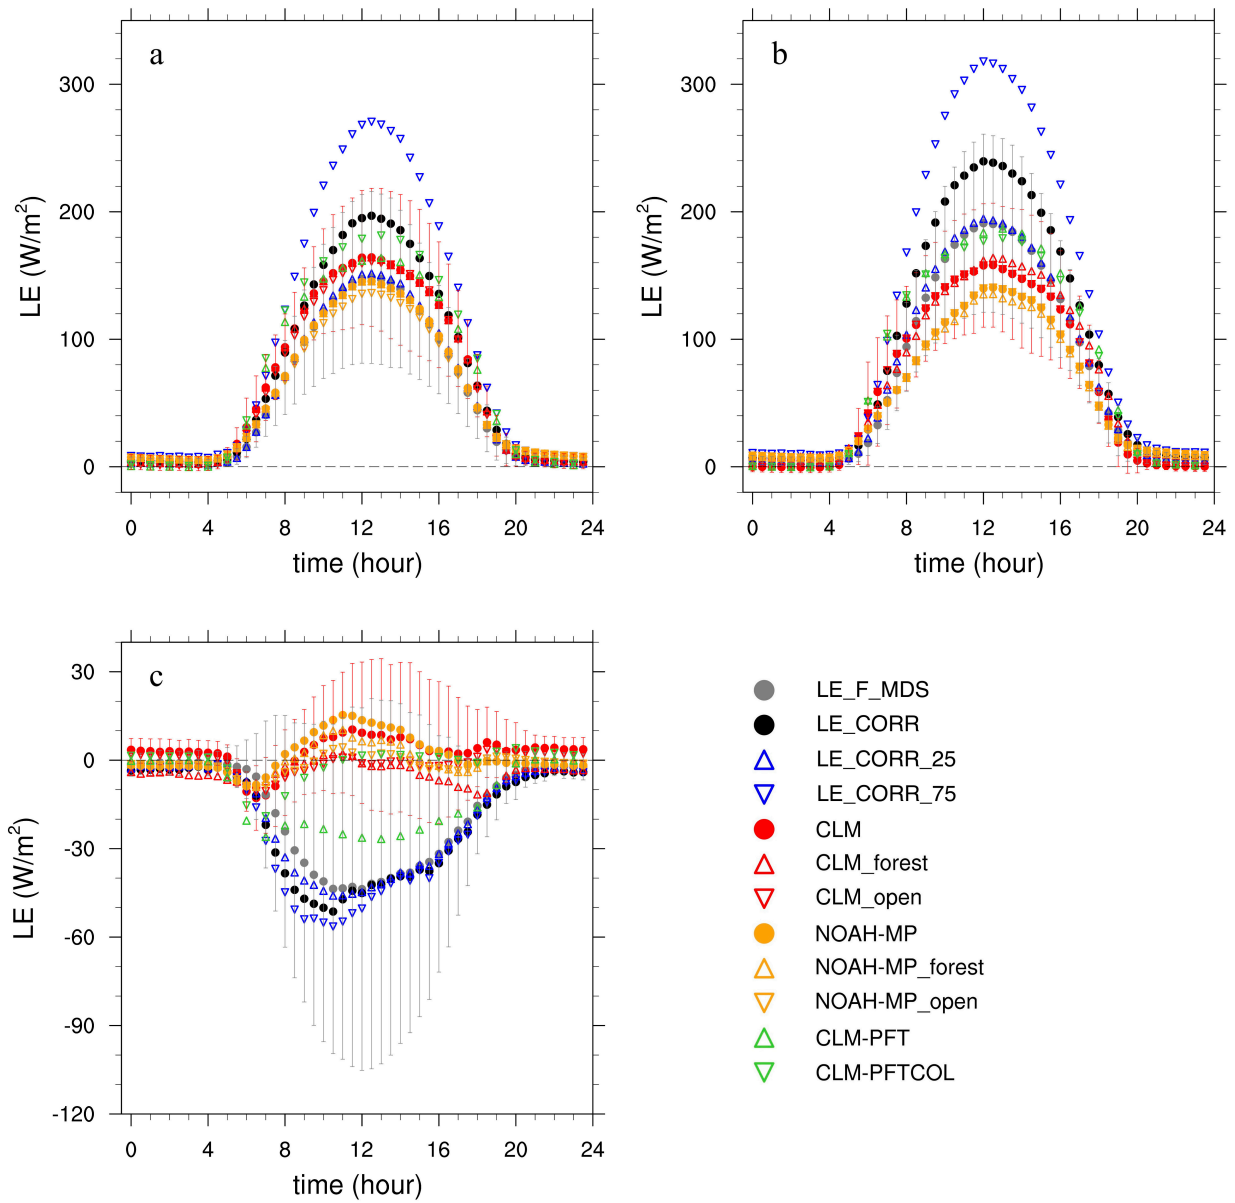

695

696 **Figure 1.** Location and land cover type of the paired sites. The land cover type of each site is

697 based on the reported land cover in FLUXNET database.

698

699

700 **Figure 2.** The diurnal cycle of LE (W/m^2) averaged over all the open sites (a) and forest sites (b)

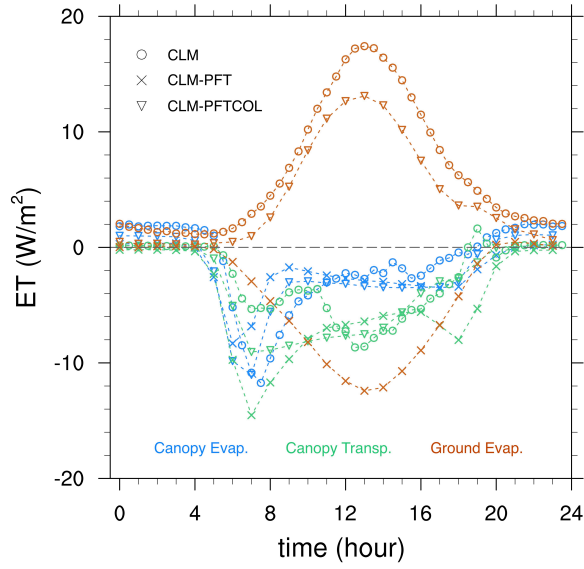

701 and their difference (open – forest, c) during the summer. The gray error bars indicate the

702 standard deviation of the observed LE (MDS) among the sites; the red error bars are for the

703 simulated LE in the CLM case. Details about the four types of FLUXNET observations can be

704 found in Table 1. Information about model simulations in CLM and Noah is described in Table

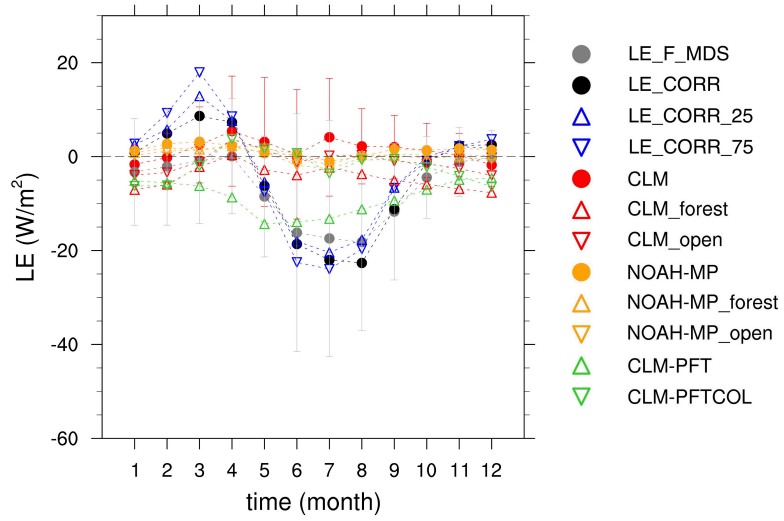

705 2.

706

707 **Figure 3.** Change in the diurnal cycle of components (colors) of evapotranspiration (canopy
 708 evaporation, canopy transpiration, and ground evaporation) due to LULCC from forest to open
 709 land (open – forest).

710

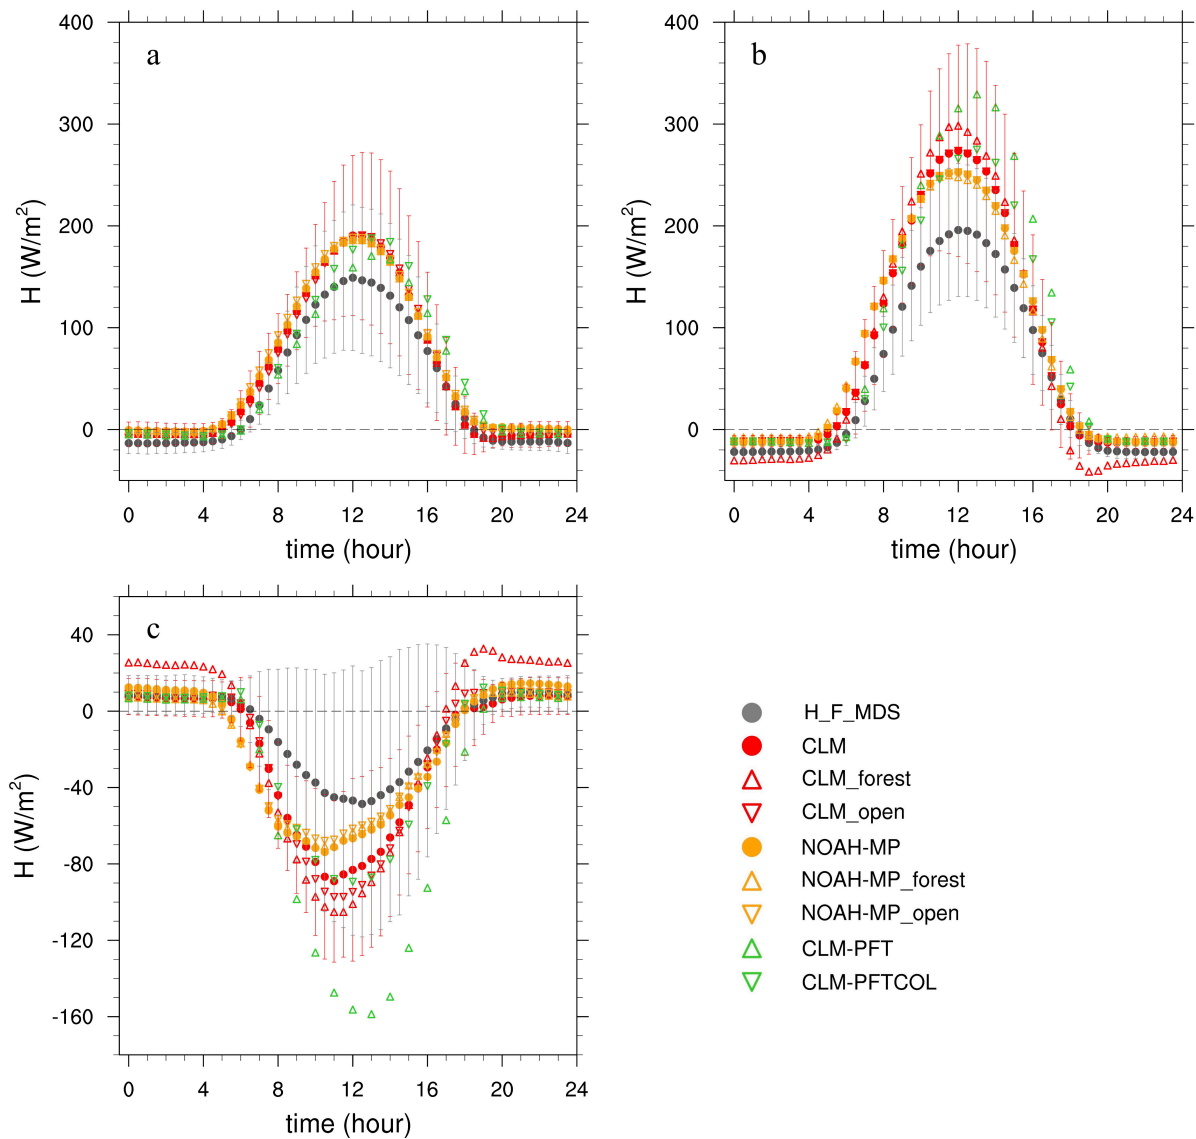

711

712 **Figure 4.** Change in the seasonal cycle of LE (W/m^2) due to LULCC from forest to open land

713 (open – forest).

714

715

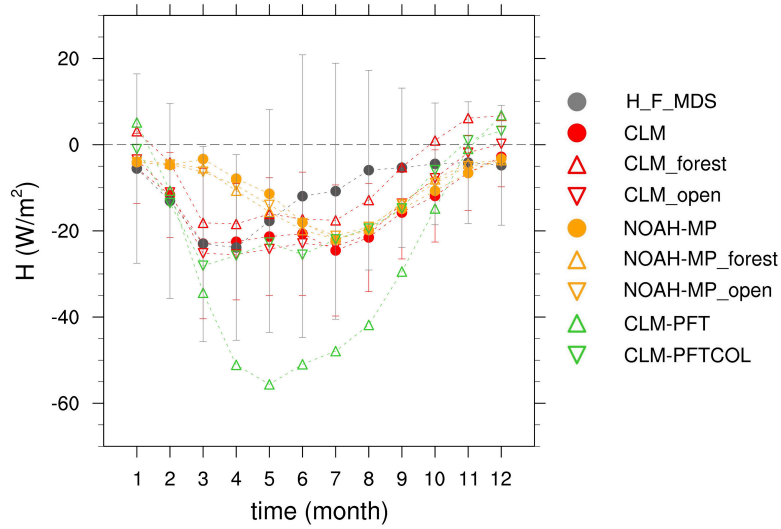

716 **Figure 5.** The diurnal cycle of H (W/m^2) averaged over all the open sites (a) and forest sites (b)

717 and their difference (open – forest, c) during the summer. The gray error bars indicate the

718 standard deviation of the observed H among the sites; the red error bars are for the simulated H

719 in the CLM case.

720

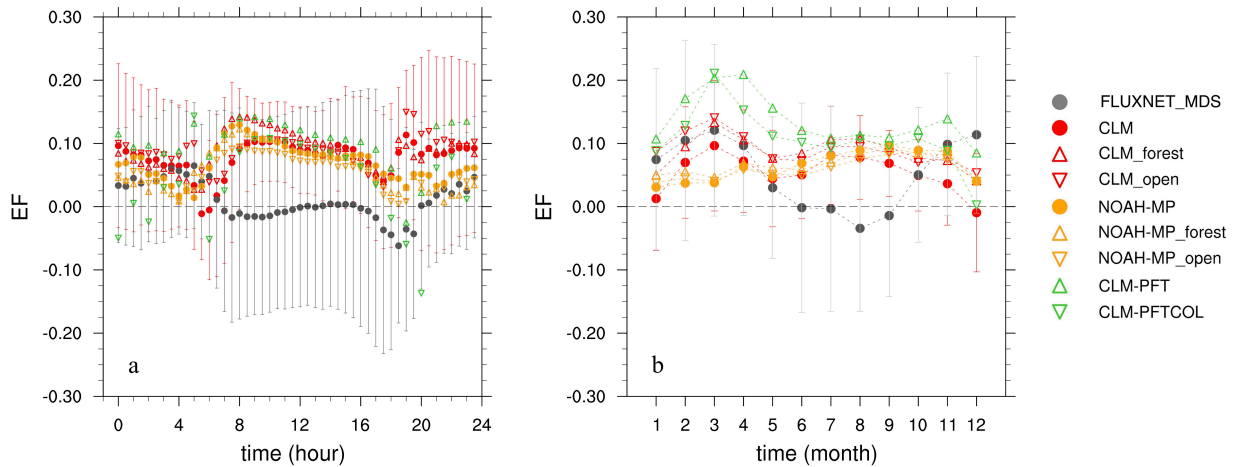

721

722 **Figure 6.** Change in the seasonal cycle of H (W/m^2) due to LULCC from forest to open land
 723 (open – forest).

724

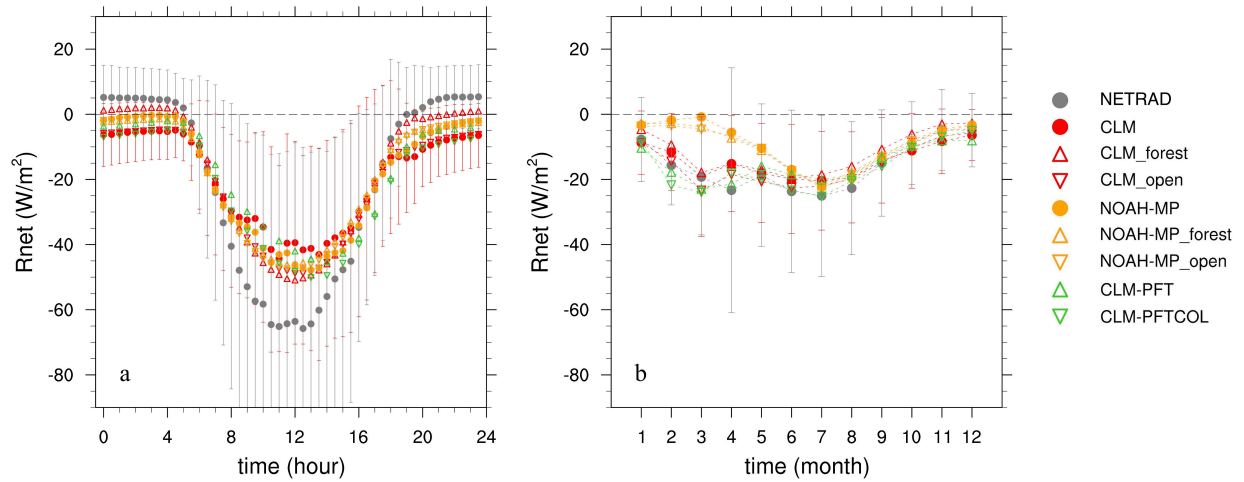

725

726

727 **Figure 7.** Change in the summer diurnal (a) and seasonal (b) cycle of EF (unitless) due to
 728 LULCC from forest to open land (open – forest). The observed EF (FLUXNET_MDS) is
 729 calculated based on the MDS gapfilled LE (LE_F_MDS) and H (H_F_MDS).

730

731

732 **Figure 8.** Change in the summer diurnal (a) and seasonal (b) cycle of G (W/m^2) due to LULCC

733 from forest to open land (open – forest). It should be noted that the changes in the CLM-PFT

734 simulation are much further from the observations than the other simulations. Some of its values

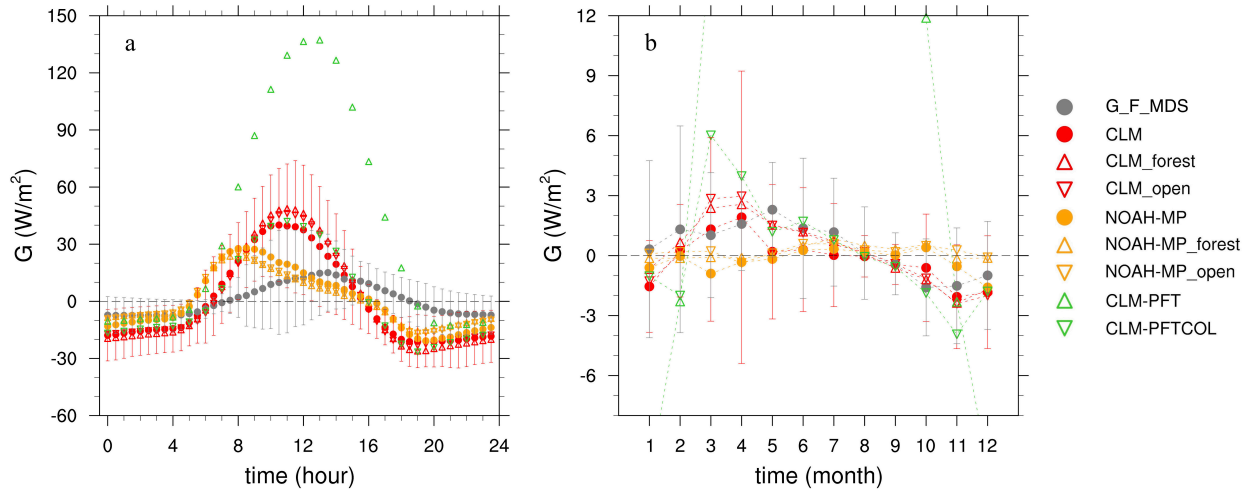

735 are beyond the limit of the figure (b). The smallest value is $-11.2 W/m^2$ in January; while the

736 largest value is $52.9 W/m^2$ in May.

737

738

739

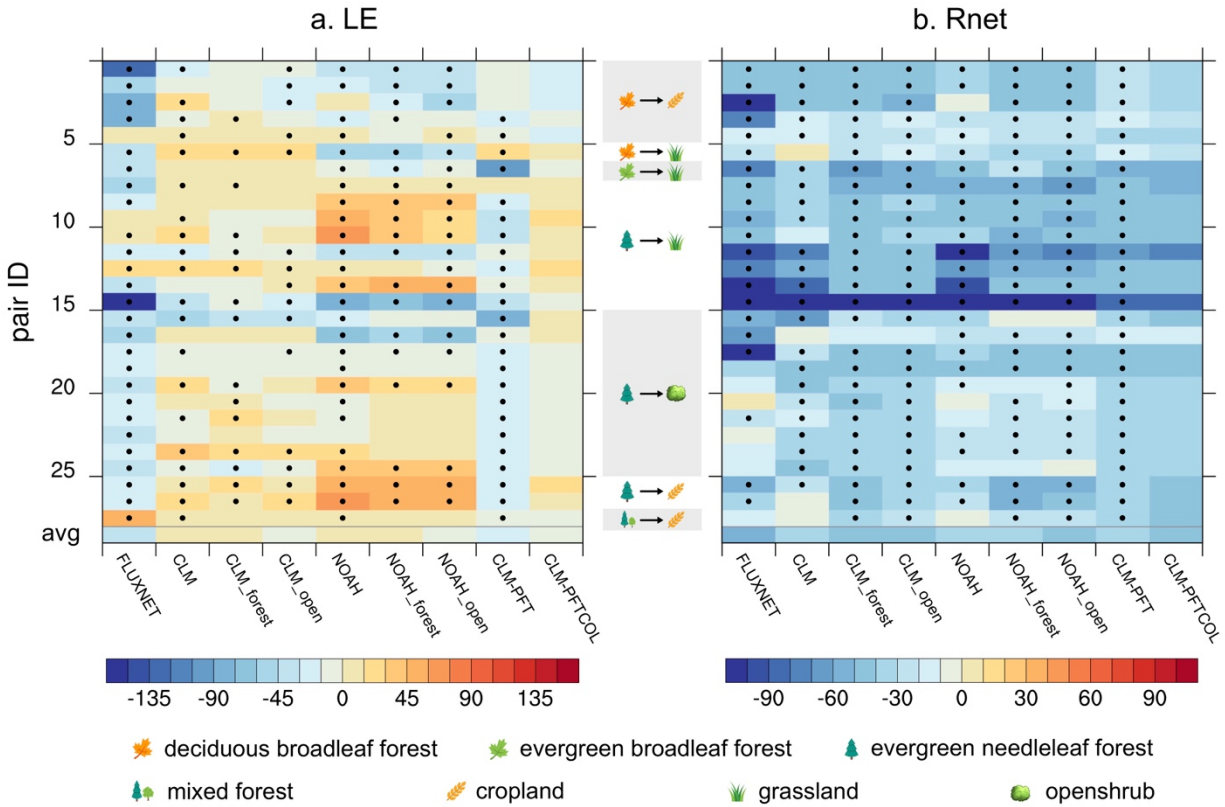

740

741 **Figure 9.** Change in the summer diurnal (a) and seasonal (b) cycle of R_{net} (W/m^2) due to LULCC

742 from forest to open land (open – forest).

743

744

745

746 **Figure 10.** Change (open – forest) in observed and simulated LE (a) and R_{net} (b) during summer
 747 daytime (averaged during the period 08:00 ~ 16:00) over individual pairs and their averages. The
 748 vertical labels show the pair ID from 1 to 28 based on Table S1. The pairs are grouped based on
 749 the type of LULCC (shown as the icons in the middle). The bottom row is the average over all
 750 pairs. The Student's t-test is performed on the daily (daytime average) time series for each pair.
 751 Dots indicate statistically significant changes at the 95% confidence level. No significant test is
 752 carried out for the CLM-PFTCOL simulation (the last column), because we only have long-term
 753 averaged hourly output for each month.

754

755

756

757 **Figure 11.** Sensitivity of differences in simulated surface energy flux changes (left column: *LE*,

758 middle: *H*, and right: *R_{net}*) between “forest forcing” and “open forcing” simulations to site

759 separation (top) and elevation difference (bottom) between the forest and open sites in individual

760 pairs. The pairs No. 3, 7, 12 and 15 are labeled because of the greatest differences in surface

761 fluxes changes.

762

763

764

765

766 **Figure 12.** Change (open – forest) in observed and simulated daytime albedo during late
 767 winter/early spring (FMA, a) and summer (JJA, b). White areas indicate missing observations.

768
