### REVIEW

I think this paper describes a useful product that can be used by the scientific community. However I am a little concerned at the lack of analysis particularly of the bias in the model estimates of potential evaporation (PE). On page 12, lines 9 to 11, you state that there a “small overestimation” of the PE and claim this this is satisfactory. I think you might be brushing it off to casually. The bias is 20% which is not “small”. Firstly, I think you should tell us where this bias is coming from. You mention earlier (Page 12, line 1) that there is a warm bias in the south in the summer. Presumably this is driving this 20% overestimate of PE. Secondly, I think you need to quantify what impact this will have on your drought estimates. Drought isn’t only about rain - it’s about drying as well. With a 20% overestimate of PE in the very dry area of the UK, you might be overestimating the drought. Please add a paragraph or so on the drying bias.

Thank you for this comment, which was also raised by referee #2. We agree with the referee that more discussion is needed on the PE bias. The PE bias can have various sources, including (but not limited to) the positive summer temperature bias. Other possible causes for the PE bias can be through its radiative (e.g., an overestimation of the net radiation through an underestimation of cloud cover) and aerodynamic (wind) components. These two additional possible sources of biases are difficult to correct owing to a lack of observations. Moreover, the uncertainty of the true PE is very large, as highlighted by the discrepancies from observational datasets (i.e. from datasets other than CHES-PE).

To address this point, we have rewritten the discussion around PE biases in the manuscript. We have explained what the pitfalls of bias-correcting PE are in Section 4.1.2, justifying our decision not to correct these biases. We have also clearly stated at several places that the users of this dataset should be aware of this bias and, depending on the application, should account for it in their analysis.

The many plots of results (figs 7, 8, 10, 12, 14 and 15) are hard to read. Firstly they all look much the same. Secondly, there is no map of where these regions are. You should have a map so that we know where catchments such as ‘Dee’ and ‘Tweed’ etc are. Not everyone has a geographical-hydrological map in their heads! In fact what I recommend (although it would take some time) would be to just do the 4 regions that we used in the CHES paper (Robinson et al): Scotland, Wales, England and Lowland England. The advantage is that you have separated the climate zones of the UK and the

plots are easier to digest as there are less of them.

This is a good point and indeed a map of the regions is lacking. We agree that a lower number of regions may be preferable, although we prefer to stick to the UKCP09 water regions as these are river basins. We have selected six representative regions (Western Highlands, North East Scotland, Tweed, North West England, Anglian and Thames) and have added a map of these regions (new Figure 7). The plots for all 19 regions are still included for interested readers, but as part of the supplement rather than in the main part of the paper (see also Supplementary Fig. S3 for a map of all regions).

## Reply to the review by Anonymous Referee #2

We thank anonymous referee #2 for the positive review, which suggests useful additions to the manuscripts. These suggestions are highly appreciated. Answers to the comments are included in blue font right under the unmodified comments from the review.

### REVIEW

Dear Editor,

Comments to authors: Review of “A large set of potential past, present and future hydro-meteorological time series for the UK ’ (Manuscript number: hess-2017-246) submitted by BP. Guillod, RG. Jones, SJ. Dadson, G. Goxon, G. Bussi, J. Freer, AJ. Kay, NR. Massey, SN. Sparrow, DCH. Wallom, MR. Allen, JW Hall to Hydrology and Earth System Sciences (HESS; May 2017). This paper presents a new set of hydro-meteorological projections for the United Kingdom, based on a regional climate model driven by a global atmospheric model, which accounts for uncertainty in the climate system response by sampling a range of changes in the ocean state from CMIP5 models. This is really interesting papers, in particular as it describe a new methodology which could help in accounting better for internal climate variability, which is one of the main source of uncertainty in the global/regional climate models, and which, at the local to regional scales, has been describe to be as important as anthropogenic climate change, even for intervals as long as the next 50 years in the middle and high latitude (Deser et al., 2012, 2013, 2014, 2016; Wallace et al. 2014, 2015), through the development of probabilistic scenarios for hydroclimate variables (including extremes such as drought) which could be used as input in a hydrological, ecological, agricultural models. It is therefore susceptible to interest a lot of researcher, and it is surely appropriated for publication in HESS. However, I have got some concerns regarding the absence of statistical analysis to test the significance of changes, and regarding the choice to only apply bias corrections to precipitation, while there is a clear significant bias in potential evapotranspiration (and probably in temperature). In addition, I feel like some results are a little over-interpreted, e.g. the raw (uncorrected) precipitation output performs better than bias corrected precipitation, as it can only be because the selected bias correction methods is not appropriated.

So my initial rank is to recommend major revisions.

We appreciate the overall positive tone of the reviewer’s comments as well as the relevant points raised, for which we mention our intentions for the revised manuscript.

### Major comments

1. Throughout the paper the authors are describing changes compared to a historical baseline, discrepancies between scenarios and while using different in-

put (e.g. raw precipitation vs. bias-corrected precipitation), but none of these changes/differences are shown to be statistically significant. Although the novelty and the robustness of your approach in developing new hydro-meteorological projections is unquestionable, your interpretation of potential future changes in precipitation (including extreme events), potential evapotranspiration and temperature, or of discrepancies between scenarios, should still be supported by statistical tests (Student's t-test for changes in mean, F-test for changes in variance etc...) to make your results more objective or, at least, less subjective. In addition, as precipitation, temperature and evapotranspiration are likely to be auto-correlated, you might have to consider a test accounting for serial correlations in the time series.

To address this point, we have tested the statistical significance of the changes as follows: for the maps of changes in seasonal mean temperature, precipitation and potential evaporation, a two-sided T-test based on values from individual time series was applied, and grid cells where changes are not significant at the 95% level are hatched (Figs. 10,12,14 and corresponding figures in the supplement). For the comparison of our changes to UKCP09 (Figs. 11 and 13), the same approach cannot be used as UKCP09 only provides changes in the variables, rather than two sets of samples for baseline and future time slices. Thus, for these two figures we decided to consider a change as significant if 0 lies outside of the 5–95% range and to draw the boxes in grey for non-significant changes. For figures 15 and 16, the same procedure as for the maps was used: a two-sided T-test was applied to determine the statistical significance between the mean of future scenarios and the mean of the baseline. Boxes whose mean do not significantly differ from the baseline are drawn in grey. Finally, we have added small edits to the results section where needed to account for the statistical significance information. We believe that these changes allow us to interpret the projected changes in a more objective fashion.

2. In Section 4.1.2 the authors decided not to apply a bias-correction to temperature and evapotranspiration, as they consider their biases “relatively small”. However, I don't think an overestimation of about 20% in evapotranspiration could be considered as small, and it could have a big impact on drought projections, as well as in hydrological and agricultural models which both used evapotranspiration as input. If this is really a small bias, it should be supported by a statistical test showing that bias is not significant, and that the results would have not been statistically different with or without applying bias correction. I agree there would always be large uncertainties when quantifying evapotranspiration, but, at least, this could be quantified (e.g. difference between different formulas, difference between raw and bias-corrected estimates), as it has been proposed in some studies (Sheffield et al., 2012; Zotarelli et al., 2013; Begueria et al. 2014;

Raible et al., 2017). Overall, I would recommend to apply a bias correction to precipitation, temperature and evapotranspiration systematically, and then statically assess their potential differences.

A similar point was raised by referee #1 and we recognise that some discussion is needed around the potential evaporation ( $E_{\text{pot}}$ ) biases (note that the variable is potential evaporation, not actual evapotranspiration). However, we would not like to bias-correct temperature and even less so  $E_{\text{pot}}$  as part of our product, for the following reasons. First, the  $E_{\text{pot}}$  bias may have various origins, including temperature biases but also radiation (e.g. owing to biases in cloud cover) and aerodynamic (wind) components. The latter two are difficult to correct, owing to the lack of long-term gridded observations at the desired resolution. Second, observational estimates of  $E_{\text{pot}}$  from various sources can significantly differ, depending on the assumptions and datasets used as input, implying that a bias-corrected  $E_{\text{pot}}$  would be highly dependent on the chosen source of observed values. Third, the assumption that the same bias correction can be applied to future scenarios would be even more questionable for  $E_{\text{pot}}$  than for precipitation because of the inter-dependence of variables used to compute  $E_{\text{pot}}$ . Fourth, the  $E_{\text{pot}}$  provided in our dataset is one possible formulation and set of parameters, and some data users will compute  $E_{\text{pot}}$  themselves using the other variables provided depending on their need. Therefore, we think that keeping our current approach is appropriate, provided that we clarify these points in the paper and warn potential users about the  $E_{\text{pot}}$  bias and possible implications. We have added a paragraph justifying our approach in Section 4.1.2 as well as the following sentence in the conclusion: “We did not bias-correct potential evaporation but we strongly recommend data users to carefully assess possible impacts of these biases on their results, particularly with respect to drought analysis in the southern part of the UK”.

3. The choice of the bias correction is one of the main source of uncertainties while developing hydro-meteorological scenarios, and it different choices could lead to different results, more or less significant. The authors have chosen to use the simplest possible bias correction method, i.e. a linear bias correction, which is a fair choice knowing the large uncertainties related to the different bias correction procedures. However, at the same time, I would not recommend to conclude that the raw (uncorrected) precipitation output performs better than bias corrected precipitation, as another more sophisticated methods could have perform better (cf. Maraun et al., 2015; Maraun, 2016), and those uncertainties could have major implications, in developing scenarios for droughts or water resources (Clark et al., 2016). For instance, using a simple linear bias-correction, you should perform quite well in fixing the bias in the mean state, and probably the seasonal cycle (as it will captured most of the variance), but it might be totally unlikely to reduce the bias in interannual and/or decadal variability (while it is exactly

where the climate models show the lowest skills; cf. Ault et al., 2012; 2013). This could explain why the bias looks proportionally stronger with a prolonged period of droughts in Figure 6. For instance, in a very recent study, Massei et al. (2017) proposed another approach which could account better for low-frequency variability. However, I'm not sure this could be applied in your study, and you must just be careful when interpreting your results, and should discuss more this issue.

We agree with the referee that our statement that the raw (uncorrected) precipitation output performs better than bias-corrected precipitation was misleading. The reason behind this counter-intuitive finding may indeed lie in the choice of bias-correction methodology and we have corrected our statement in the conclusion from

“For high precipitation extremes, however, we find that the raw (uncorrected) precipitation output performs better than bias-corrected precipitation; this highlights the need of an evaluation of the relevant metrics to choose the suitable set of variables to be used for studies using the climate data set, since the choice of bias correction depends on the intended application”

to

“For high precipitation extremes, the better performance of raw (uncorrected) precipitation output (compared to bias-corrected precipitation) highlights that while the choice of a simple linear bias correction might be appropriate with respect to mean, seasonality, and perhaps accumulated totals over a few months, analysis of short-duration hydrometeorological extremes might require the application of a more sophisticated bias-correction methodology. In addition, the application of a bias-correction technique to climate model output cannot correct for interannual to decadal climate variability, which is known to be poorly captured in current state-of-the-art climate models (e.g., Ault et al., 2012). This issue could potentially lead to an underestimation of the risk of multi-decadal droughts (Ault et al., 2014). As with any model-based dataset, an evaluation of metrics relevant to the processes investigated is recommended in order to choose a suitable set of variables and, where required, to apply a suitable bias-correction technique”.

In addition, we have reformulated and slightly expanded our description of this point in Section 4.2.2, where we now recommend the application of another bias-correction technique for the study of short duration, high precipitation extremes.

### **Minor comments**

- P12-line 3-8: what would have been the bias if you would have used E-OBS for precipitation, and would have been the bias using E-OBS? Why did you not

choose to keep the same data set for precipitation and temperature?

We have chosen to use precipitation data from the CHES-met dataset because it is a widely used product in the UK. However, we had also computed the precipitation bias relative to the E-OBS dataset and the biases look qualitatively similar using that dataset (not shown).

- P13-lines 29-30: It's especially true for the long return period (prolonged periods of droughts), do you have an explanation for that? It could be because your bias correction is only performant for the mean state, and for interannual variability which would expressed most of the variance, while lower-frequency variability might be important for long return period.

We do not have an exact explanation for this. One possibility for the overestimation of low summer precipitation deficit at high return times could be an over-active soil moisture feedback, whereby an initial drying leads to a strong further drying owing to too little evaporation. However one can only speculate on the mechanisms here. Note that it is unclear how the plot (Fig. 6a-d) relates to low-frequency variability, as the variable shown is only a 3-month accumulation (the return time referring to the frequency of the values, not to the length of accumulation). Hence the plots show that the biases are larger for rarer events, not for longer accumulation times (which are shown on panels e-h of the same figure). Nonetheless, we have added the following sentence at the end of the paragraph: "The difficulty for climate models to represent low-frequency variability (Ault et al., 2012), an aspect that is by definition not improved by bias-correction, could also play a role here."

- P-14-lines 3-6: Return time plots of low precipitation amounts in 1–4 consecutive hydrological years primarily showing you that as much you increased the length of the records, as more the model shift from observations, in particular for return period greater than 10 years. However, this should more accurately tested by considering more consecutive days, and then comparing the results.

We agree that the discrepancy between model and observations are smallest for the 1-year accumulation. However, no clear further increase in bias is found for longer accumulation times (2–4 years). It is somewhat surprising that the model overestimate drought at these durations, while the opposite is usually found for long droughts. We add the following sentence there to reflect this feature: "Noteworthy is a small overestimation of dryness at rare frequencies for long accumulation times (two to four years), not present in the one-year accumulated values, which suggests that in this case the climate model overestimates long-term precipitation persistence, unlike what has been shown for longer accumulation times (Ault et al., 2012)".

- P-15-lines 20-22: summer precipitation changes are most sensitive to the North Atlantic SST gradient, but is the North Atlantic SST gradient likely to increase in

summer in the coming 50 to 100 years? It would be great to discuss it in the paper (even briefly). In addition, the North Atlantic SST gradient is closely related to atmospheric zonal circulation patterns, such as the North Atlantic Oscillation (NAO). It would therefore be interesting to discuss the potential implications if the summer NAO was becoming more positively/negatively persistent in the future. It could be an interesting discussion.

We added two sentences as follows, to remind the reader of how the North Atlantic SSTs are projected to change in our ensembles and to mention the NAO: “Note that the median scenario (“FF”, called MMM in this figure for Multi-Model Median) exhibits the CMIP5 median change in this feature, while the four other scenarios depict extreme cases in both direction and should hence be considered as sensitivity scenarios. The mechanisms through which SST influence precipitation may include the North Atlantic Oscillation (NAO), which has been shown to be influenced by SSTs in the Atlantic and to influence European weather (e.g., Woollings et al., 2015).”

We agree with the referee that the link between the North Atlantic SST gradient and NAO is interesting. However, the scope of this paper is foremost to present the climate time series, while a detailed analysis of the sensitivity of atmospheric circulation (including the NAO) to future SST changes would be a separate paper.

- P16 lines 14-15: This suggests a change in the annual cycle, which would be more sensitive to changes in the North Atlantic ocean-atmosphere coupled variability. I should be discuss more in conclusion, for instance.

Thank you for this comment. It is true that, given that summer and winter changes in precipitation are different in the different future scenarios (i.e., SST patterns), the future seasonal cycle will depend on the SST pattern. More generally, since we realised that a short paragraph on the projected changes in climate was lacking in the conclusion, we have added such a paragraph and have included a short mention of this aspect therein.

**Abstract.** Hydro-meteorological extremes such as drought and heavy precipitation can have large impacts on society and the economy. With potentially increasing risks associated with such events due to climate change, properly assessing the associated impacts and uncertainties is critical for adequate adaptation. However, the application of risk-based approaches often requires large sets of extreme events, which are not commonly available. Here, we present such a large set of hydro-meteorological time series for recent past and future conditions for the United Kingdom based on weather@home2, a modelling framework consisting of a global climate model driven by observed or projected sea surface temperature and sea ice which is downscaled to 25km over the European domain by a regional climate model. Sets of 100 time series are generated for each of (i) a historical baseline (1900–2006), (ii) five near future scenarios (2020–2049) and (iii) five far future scenarios (2070–2099). The five scenarios in each future time slice all follow the Representative Concentration Pathway 8.5 (RCP8.5) and sample the range of sea surface temperature and sea ice changes from CMIP5 models. Validation of the historical baseline highlights good performance for temperature and potential evaporation, but substantial seasonal biases in mean precipitation, which are corrected using a linear approach. For extremes in low precipitation over a long accumulation period (>3 months) and shorter duration high precipitation (1–30 days), the time series generally represents past statistics well. Future projections show small precipitation increases in winter but large decreases in summer on average, leading to an overall drying, consistently with the most recent UK climate projections (UKCP09) but larger in magnitude than the latter. Both drought and high precipitation events are projected to increase in frequency and intensity in most regions, highlighting the need for appropriate adaptation measures. Overall, the presented dataset is a useful tool for assessing the risk associated with drought and more generally with hydro-meteorological extremes in the UK.

## 1 Introduction

Extreme weather events such as droughts can have huge socio-economic consequences, so ensuring that society is well prepared to face such events will have multiple benefits. Anthropogenic climate change is expected to have an impact on extreme events: warm temperature extremes and heavy precipitation extremes have been shown to have increased due to human greenhouse gas emissions and these trends are projected to increase in the future (IPCC, 2013). These changes will increase risks in many regions and adequate adaptation will be critical to limit the associated damages.

Despite clear trends and predicted increases in these extremes, understanding the implications for more complex hydrometeorological extremes remains limited. This is the case of drought (e.g., Sheffield et al., 2012), for which the attribution of observed (projected) trends can only be done with low (medium) confidence (IPCC, 2013) due, among other factors, to observational uncertainty and confounding effects from decadal-scale variability combined with relatively small samples due to the comparatively long duration of droughts versus other extreme events. Nonetheless, some highlighted regions may be expected to experience more frequent or more intense droughts due to climate change (the Mediterranean region, Central North America, Central America and Mexico, Northeast Brazil and southern Africa; Seneviratne et al., 2012). Another complication is that drought can be caused by various factors including precipitation deficit, excessive potential evapotranspiration (due to enhanced radiation, wind speed or water pressure deficit), and pre-conditioning (pre-event land water storage including soil moisture, snow, lake and/or groundwater storage) (Seneviratne et al., 2012). Moreover, it can be defined in multiple ways as negative anomalies in precipitation (“meteorological drought”), soil moisture (“agricultural drought”) or streamflow, lake or groundwater levels (“hydrological drought”).

In the United Kingdom (UK), the issue of drought or, more generally, water scarcity, has been highlighted during the 2010–2012 drought. This drought drew attention to the potentially high economic losses that would result from a severe water restriction and prompted recognition that changes in climate and in water demand may increase the risk of such an event in the future highlighted the need to better assess the risk associated with drought in the UK. The MaRIUS project (Managing the Risks, Impacts and Uncertainties of drought and water Scarcity, <http://www.mariusdroughtproject.org>) thus aims at better understanding the physical mechanisms and the inter-sectoral interactions leading to water scarcity, in order to support a risk-based approach for drought management.

Given the long duration, spatial variability and multi-variate nature of droughts, large sets of potential drought events are required, in order to assess the impacts of these on various sectors and to apply a risk-based approach. Available data such as the most recent set of UK Climate Projections (UKCP09, Murphy et al., 2009) provide a large range of possible climate change signals, as well as long time series at any location derived from a weather generator. However, these long time series are not spatially consistent, i.e., one cannot examine interactions between spatially distributed locations, which is critical to the mentioned risk-based assessment, particularly for drought. Other potential sources of data include climate model output from the Fifth coupled Climate Model Intercomparison Projection (CMIP5, Taylor et al., 2012); however, while these provide a wide sampling of modelling uncertainty, they do so with a limited number of transient simulations for each model. The implied low

number of simulated years impedes a proper estimation of the risk associated with rare events and, therefore, the application of risk-based management approaches, for which a large number of spatially-consistent drought events are required.

Therefore, a new set of climate time series is created using weather@home2 (Guillod et al., 2017), an improved atmosphere-only global climate model which is dynamically downscaled over a limited domain by a regional climate model (RCM) and run on volunteers' computers around the globe. Hydro-meteorological variables for hundreds of time series are generated over the UK for the recent past and for future time slices (RCP8.5 with climate response uncertainties), from which drought events can be identified. However, the use of the time series is not restricted to drought studies but can be applied to any type of extreme event. With about 3000 years of data for each 30-year period and scenario, the created dataset allows to examine the very rare (and most severe) events with a high statistical confidence, albeit with limitations associated with the use of model-based data.

This paper presents the new hydro-meteorological climate time series. Section 2 describes the weather@home 2 model as well as observational datasets used for validation of the time series. The model simulations and the generation of the time series are detailed in Sect. 3. The time series covering the recent past are validated in Sect. 4, while the main features of the future projections are shown in Sect. 5.

## 2 Model and Data

### 2.1 Weather@home 2

Weather@home (Massey et al., 2015) consists of an atmospheric global climate model (GCM), HadAM3P, and its regional counterpart, the regional climate model (RCM) HadRM3P, which dynamically downscales the GCM to a higher resolution over a limited domain. As part of the *climateprediction.net* project (Allen, 1999), weather@home takes advantage of computing time donated by volunteers around the world to run very large numbers of climate model simulations, of the order of tens of thousands.

The data analysed in this study is based on version 2 of weather@home (hereafter, w@h2, see Guillod et al., 2017) which uses the more recent land surface scheme MOSES 2. The regional model covers the European CORDEX domain at a horizontal resolution of  $0.22^\circ$  (about  $25 \times 25$ km) on a rotated longitude/latitude grid (e.g., Kotlarski et al., 2014). The model, including its setup for this domain, is described and validated in detail by Guillod et al. (2017).

### 2.2 Observational data

The gridded datasets listed in Table 1 are used for comparison and validation. For temperature, the E-OBS dataset (Haylock et al., 2008) is selected, as it is conveniently available on the same rotated longitude-latitude grid as HadRM3P. For precipitation, we use the CEH-GEAR dataset (Keller et al., 2015), which provides rainfall on a 1 km grid from 1890–2015. Observational estimates of potential evaporation are taken from the CHESSE-PE dataset (Robinson et al., 2015), available from 1961–2012 and derived with two formulations, with and without correction for interception evaporation. For both CEH-GEAR and CHESSE-PE, data are aggregated onto the  $0.22^\circ$  model grid prior to all analyses.

### 3 Methodology

#### 3.1 Model simulations

A total of 11 large ensembles (“batches”) of w@h2 simulations are conducted, producing model output for three distinct time periods and a range of scenarios (see Table 2). The three time periods cover the past century (“historical baseline”; 1900–2006), and two 30-year future time slices (near and far future; 2020–2049 and 2070–2099, respectively) assuming the high greenhouse gas emission scenario RCP 8.5 (Meinshausen et al., 2011). For each future time slice, uncertainty in transient climate response is taken into account by sampling a range of five sea surface temperature (SST) warming patterns derived from the fifth phase of the Coupled Model Intercomparison Project (CMIP5, Taylor et al., 2012), as detailed in Sect. 3.2, while for the historical baseline only one ensemble is generated, using the observed ocean state, leading to the total of 11 batches (1 batch for each time period and SST pattern).

All ensembles are generated using the same overarching design, described in [Guilod et al. \(2017\)](#) for the historical baseline. Essentially, simulations are initialised on the 1st of December before each simulated year (e.g., 1st of December from 2019–2048 for near future), using restart files from earlier 12-month spin-up simulations, and are run for 13 months. The aim is to produce 100 simulations for each year (for each time slice and scenario), but due to the nature of volunteer distributed computing, not all model simulations are completed at the same time. Therefore, in this case, 200–400 simulations per year are sent out and whenever 100 simulations have been returned for each simulated year within a batch, this batch is closed and no additional simulation output is added to it. In cases when the minimum number of simulation per year did not reach 100 after some time, the batch was closed anyway, leading to a minimum number of simulations per year ranging from 85 to 100 depending on the scenario (Table 2).

Months 2-13 of the simulations being returned from each year are analysed, providing around 100 single-year simulations of data for each year (January to December), or a total of 10700 years of data for the historical baseline and 3000 years of data for each future time slice scenario.

For the historical baseline, the simulations are the same as those analysed by [Guilod et al. \(2017\)](#). SSTs and sea ice are prescribed to observed values using version 2 of the HadISST dataset (Rayner et al., 2003; Titchner and Rayner, 2014). Similarly, other input variables such as greenhouse gas concentrations, volcanoes and solar activity, SO<sub>2</sub> concentrations, etc, are prescribed to historical values as described in [Guilod et al. \(2017\)](#).

The future scenarios are 30-year time slices that correspond to years 1975–2004 of the historical baseline but with added climate change. Therefore, natural forcings (volcano and solar activity) are taken from 1975–2004, while greenhouse gases are taken from RCP8.5 for the simulated years (2020–2049 and 2070–2099). For sea surface temperature and sea ice, a similar approach is taken as in attribution studies (e.g., Schaller et al., 2016), but the future (rather than past) SST warming is added to (rather than subtracted from) observations. More specifically, the climate change signal derived from CMIP5 models (i.e., SST warming and corresponding changes in sea ice) is added to the 1975–2004 observed values used in the historical baseline. The details on the creation of future SST and sea ice is given in Sect. 3.2.

A number of daily and monthly variables are saved in the regional model (Table 3). Of particular relevance to hydro-meteorology and extremes, the following variables are available at daily time steps from the regional model output: minimum and maximum temperature (tasmin and tasmax, respectively), precipitation, surface air humidity (mean dewpoint temperature), mean sea level pressure, and additional variables required to compute potential evaporation ( $E_{\text{pot}}$ ) (10m wind speed, and incoming and net longwave and shortwave radiation fluxes at the land surface) as well as offline-computed  $E_{\text{pot}}$  estimates (see Sect. 3.3 for details on the computation). In addition, 5-days averages of soil moisture on the four model levels as well as surface latent and sensible heat fluxes are available. All these variables, plus cloud cover and individual components of precipitation (convective versus large-scale, and snowfall versus rainfall) are available as monthly averages. Finally, weather@home is based on a calendar containing 360 days per year (i.e., 30 days per month), like many GCMs.

### 10 3.2 Sea surface temperature projections

To create the future SSTs and sea ice concentrations (SIC), two datasets are used: every available CMIP5 model simulation (Taylor et al., 2012), including all physics parameter and initial condition perturbations, and the HadISST2 observed SST and SIC (Rayner et al., 2003; Titchner and Rayner, 2014). The CMIP5 model data are used to produce the large scale warming patterns of SST for the two future time slices (2020–2049 and 2070–2099), whereas the HadISST data are used to provide the small scale variability of the SST (whereby “small scale” refers here to anomalies from 30-year averages).

For the AMIP (climate model simulations with prescribed SSTs) component of the CMIP5 project, the projected change in SST and SIC are obtained from a single (per modelling group) coupled ocean / atmosphere model, and the models are integrated for a single decade from 2026–2035. This approach has two disadvantages. Firstly, using a single model does not take into account the variation in the ensemble of CMIP5 models, both in the global mean SST (GMSST) and the pattern of warming produced. Secondly, the small scale variability of the SST patterns do not match those in our observed dataset, which makes comparison between the historical scenario and the two future scenarios difficult. To get around these problems we construct a statistical model of SST warming patterns and impose the small scale variability from the observed dataset, so as to match the historical scenario.

To construct the statistical model we use the SSTs for every model with data available for the RCP8.5 scenario. The below analysis is carried out for each month in the datasets, so as to reflect the greater warming in the December-February season (DJF) in the CMIP5 ensemble. Firstly the SSTs are converted to anomalies by subtracting the 1986–2005 mean obtained from the corresponding historical run with the same model, run, initialisation and perturbation number. This gives a time series of SST anomalies for each CMIP5 ensemble member from 2006–2100. Secondly, to remove the small scale variability and generate the large scale warming patterns, a 30 year running-gradient filter is applied to every gridbox in the SST anomalies.

The statistical model of SST warming patterns is constructed from these smoothed SST anomalies by first performing an empirical orthogonal function (EOF, Wilks, 2011) analysis on the smoothed SST anomalies for the year 2050. This produces a set of patterns (the EOFs) and principal components (PCs) which explain the variation in the smoothed SST anomalies across the CMIP5 ensemble members. The number of EOFs and PCs was truncated at 6 as, during the analysis, it was determined that the first 6 accounted for 98% of the variability. As we are interested in producing transient series of SSTs for two periods,

the 6 EOFs were projected onto the smoothed SST anomalies for each year between 2020–2049 and 2070–2099 to produce timeseries of pseudo–PCs for each model and each year in the two scenarios. Next, a linear regression was performed on each set of pseudo–PCs for each year, to derive a relationship between the pseudo–PCs in that year and the PCs in 2050. These PC–relationships are used in the reconstruction of the SSTs later.

5 The core of the statistical model is a multi–variate distribution (MVD) of the truncated PCs in the year 2050, modelled by a Gaussian copula (Nelsen, 2007) with skew–normal marginals (Azzalini, 2005) using the “copula” and “sn” packages in the R statistical analysis software (R Core Team, 2016). A MVD is used as, although the EOFs are orthogonal to each other, the signs of the PCs within an ensemble member are not independent. Once the copula has been constructed it is sampled 10,000 times, which produces a set of 6 PCs for each sample. The SST warming pattern is then reconstructed from these PCs and  
10 the EOFs for the year 2050, and the GMSST of the warming pattern is calculated and recorded with the PCs. This allows the construction of a probabilistic distribution of the GMSST warming in the CMIP5 ensemble which also contains the information (PCs) of how to construct the GMSST. Note that, for a given percentile, there will be 100 different sets of PCs. This allows the construction of up to 100 different warming patterns for each GMSST value, where the contributions to the mean warming occur in different physical locations. For this experiment we choose the 10th, 50th and 90th percentile values of GMSST so as  
15 to incorporate CMIP5 models with both low and high sensitivity in their GMSST response to elevated GHG concentrations.

Weather in the UK is potentially sensitive to the North Atlantic (NA) SSTs and in particular to gradients thereof (e.g., Rodwell et al., 1999; Rodwell and Folland, 2002). To account for this we use a NA SST gradient index to select the two most different warming patterns, in relation to this metric, from the 100 potential warming patterns for each of the 10th and 90th percentiles. This gradient is defined as the difference between the area weighted means of two areas in the North Atlantic,  
20 following Schaller et al. (2016): A Southern area bounded by the longitude–latitude coordinates 30–50°N, 40–0°W and a Northern area bounded by 50–70°N, 40–0°W.

From the sampling of the output of the copula we form 5 warming patterns for the year 2050, by combining the PCs with the EOFs: p10n corresponds to the pattern with a GMSST warming at the 10th percentile and the minimum NA SST gradient, p10x the 10th percentile GMSST and the maximum NA SST gradient, p90n the 90th percentile and the minimum NA SST  
25 gradient and p90x the 90th percentile and maximum NA SST gradient, and MMM a median scenario with the median GMSST and middle NA SST gradient. Each of these patterns has an associated set of PCs for the year 2050. To generate a time series of SST anomalies the linear relationship between the original PCs in the year 2050 and the pseudo–PCs is used to construct time series of PCs for each of the 5 warming patterns above. These PCs (derived from the linear relationship) are then combined with the EOFs for the year 2050 to generate a time series of SST anomalies between the years 2020–2049 and 2070–2099 for  
30 each of the 5 warming patterns.

To generate absolute climatological SST values, the time series of SST anomalies are added to the 1986–2005 mean of the HadISST 2 dataset (since the above procedure was applied to anomalies from those same years). Since the future time slices are to be compared to the reference time period 1975–2004 (baseline), the small scale variability from these years is then also added onto the sum of the SST anomalies and HadISST mean. This small scale variability is also derived from the  
35 HadISST 2 data by applying the 30 year smoother and then subtracting the smoothed data from the original HadISST 2 data.

This calculates the residuals of the smoother for 1975–2004 when compared to the original datasource and removes the large scale variability from HadISST, which was already added by the warming patterns.

To construct the sea-ice we use the 10 best CMIP5 models at representing historical sea-ice between 1979–2005, as ranked by Shu et al. (2015). For each future period (2020–2049 and 2070–2099), for every grid box we pool the SST anomalies for the RCP8.5 scenario and the corresponding SIC anomalies. We then derive a linear relationship, for each grid box, between the SST anomaly and the SIC anomaly by using a linear regression. Timeseries of SIC absolute values are then constructed for each grid box by calculating the SIC anomaly from the timeseries of SST anomalies computed above and the linear relationship between SST anomaly and SIC anomaly. The 1986 to 2005 mean of the HadISST2 SIC is then added to the timeseries of SIC anomalies and then some post-processing is performed. Firstly, ice holes, which occur where a grid box with no ice is surrounded by 8 grid boxes with ice, are filled with the mean value of the 8 surrounding grid boxes. Secondly isolated ice, where a grid box with ice is surrounded by grid boxes with no ice, are removed by setting the SIC in the grid box to 0. Thirdly, a longitudinal smoother is applied to the resulting data field.

As a result of this procedure, five SST time series are obtained for each future time slice (near and far future), which have the same small scale variability as the 1975–2004 HadISST SSTs and sample the inter-model variability in SST warming from CMIP5 both in terms of GMSST and NA SST gradient. These 5 patterns are hereafter referred to as “scenarios” and are summarized in Table 2. Supplementary Figs. S1 and S2 display the resulting warming imposed on observed SSTs for near and far future scenarios, by season and scenario.

### 3.3 Potential evaporation estimates

Potential evaporation ( $E_{\text{pot}}$ ) is defined as the amount of water that would evaporate from the land surface (soil, vegetation) into the atmosphere if soil moisture supply was not limiting. Although a form of  $E_{\text{pot}}$  is computed in the code of the land surface model MOSES 2, it cannot be directly saved as an output and must therefore be computed “offline” from the meteorological model output. Since  $E_{\text{pot}}$  is an important variable that is used as an input to some impact models (e.g., hydrological models), this computation is done and the estimated  $E_{\text{pot}}$  time series are included in the dataset along with the other variables. To do so, we estimate daily  $E_{\text{pot}}$  (in  $\text{mm day}^{-1}$ ) from the atmospheric model output based on the Penman-Monteith equation (Monteith, 1965) as follows (modified from Rudd and Kay, 2015):

$$E_{\text{pot}} = \frac{1}{\lambda} \frac{\Delta R_n + \rho_a c_a (e_s - e_d) / r_a}{\Delta + \gamma (1 + r_s / r_a)}, \quad (1)$$

where the following variables depend on the atmospheric variables:  $\Delta$  is the rate of change of saturated vapour pressure with temperature ( $\text{kPa } ^\circ\text{C}^{-1}$ ),  $R_n$  is net radiation at the surface ( $\text{W m}^{-2}$ ),  $e_s$  is the saturation vapour pressure at near surface air temperature ( $\text{kPa}$ ),  $e_d$  is the near surface vapour pressure ( $\text{kPa}$ ),  $r_a$  is the aerodynamic resistance to vapour transfer in the atmosphere ( $\text{s m}^{-1}$ ) and  $r_s$  is the bulk surface (canopy or bare soil) resistance ( $\text{s m}^{-1}$ ). The following are constants in Eq. (1):  $\lambda$  is the latent heat of evaporation ( $2.45 \cdot 10^6 \text{ J kg}^{-1}$ ),  $\rho_a$  is the near surface air density ( $1 \text{ kg m}^{-3}$ ),  $c_a$  is the specific heat of air ( $1013 \text{ J kg}^{-1} \text{ } ^\circ\text{C}^{-1}$ ),  $\gamma$  is the psychrometric constant ( $0.066 \text{ kPa } ^\circ\text{C}^{-1}$ ).

The saturation vapour pressure  $e_s$  can generally be computed from temperature  $T$  (in °C) as

$$e_s(T) = 0.611 \exp\left(\frac{17.27T}{T + 237.3}\right). \quad (2)$$

Therefore, we can derive

$$\Delta = \frac{de_s}{dT} = 17.27 \cdot 237.3 \frac{e_s(T)}{(T + 237.3)^2} \quad (3)$$

- 5 where  $T$  is approximated by the average of daily minimum and daily maximum temperature ( $T = (\text{tasmin} + \text{tasmax})/2$ ). For the computation of  $e_s$  itself from daily data, however, we use a more accurate approach consisting of averaging  $e_s$  values estimated from daily minimum and maximum temperature (tasmin and tasmax), i.e.,

$$e_s = \frac{es(\text{tasmin}) + es(\text{tasmax})}{2}. \quad (4)$$

- The near surface vapour pressure can be directly estimated from daily averaged dewpoint temperature (tdps, in °C) based on  
10 Eq. (2),

$$e_d = 0.611 \exp\left(\frac{17.27\text{tdps}}{\text{tdps} + 237.3}\right), \quad (5)$$

and the aerodynamic resistance is computed from the daily mean 10m wind speed (wss, in  $\text{m s}^{-1}$ ) using

$$r_a = \frac{243.489}{\text{wss}}, \quad (6)$$

hence including a logarithmic correction for wind height.

- 15 Finally, surface resistance  $r_s$  is computed as in Rudd and Kay (2015), consistently with MORECS  $E_{\text{pot}}$  estimates (Hough and Jones, 1997) and leading to the monthly surface resistance values shown in Table 4.  $E_{\text{pot}}$  is not only affected by meteorological conditions, but also by vegetation. In particular, for future projections an important driver for vegetation is the ambient  $\text{CO}_2$  concentration: plant stomata may need to open less widely with higher  $\text{CO}_2$  concentrations, thereby conserving water (e.g., Keenan et al., 2013). Not accounting for this effect in offline  $E_{\text{pot}}$  estimations has been shown to lead to an overestimation of  
20 continental drying (Milly and Dunne, 2016), which is particularly relevant for drought analyses. Therefore, along with  $E_{\text{pot}}$  estimates for future time slices using the same  $r_s$  value as in the baseline (variable pepm), an additional variable (pepm\_adjrs) is introduced which accounts for the impact of  $\text{CO}_2$  on stomatal resistance and, therefore, on  $E_{\text{pot}}$ . To do so, we follow Rudd and Kay (2015) and use the estimate of change in crop and grass conductance per 1 ppm  $\text{CO}_2$  concentration increase of Kruijt et al. (2008) ( $-9.3 \cdot 10^{-2}\%$ ), and apply these to change in the 30-year averaged  $\text{CO}_2$  concentration between each future time  
25 period (469.5 ppm in the near future and 798.6 ppm in the far future) and 1975–2004 values (352.7 ppm). The resulting monthly  $r_s$  values are displayed in Table 4 for pepm, and pepm\_adjrs for near and far future.

Both variables (pepm and pepm\_adjrs) are computed for each day using the  $r_s$  value of the corresponding month, and monthly values are subsequently computed by averaging the daily values.

### 3.4 Generation of continuous time series from single years

Unlike other extreme events such as heat waves, heavy precipitation or cold spells, droughts often extend over months to years. While for short events (i.e., from a day to, say, one month), the direct use of single-year simulations can be suitable, longer, continuous time series are required to study droughts. However, a limitation of weather@home is that it can generate  
5 simulations of only relatively short durations owing to the relatively slow computation on volunteers' personal computers. Here, we develop a methodology to derive plausible long continuous time series from a large ensemble of single-year simulations, whereby simulations in a given year are "stitched" to those of the next year using an appropriate criterion.

The criterion based on which simulations are "stitched" ideally ensures that the weather history of a simulation  $S_y$  on year  $y$ , which is stitched to a simulation  $S_{y+1}$  on year  $y+1$ , is consistent with the conditions found at the beginning of simulation  $S_{y+1}$ .  
10 Given the slow nature of the temporal evolution of droughts, emphasis is put on obtaining continuous time series not necessarily from one day to the next, but rather at a temporal scale of the order of a week. Additionally, given the use of a large ensemble of simulations to construct multiple time series, the objective is not to derive time series that are really continuous (a task that may be considered impossible given the chaotic nature of the atmosphere), but rather to derive a set of time series that can be considered as continuous in the sense that their statistics can hardly be distinguished from those of continuous simulations.  
15 Therefore, we focus on those components of the climate system that exhibit significant temporal memory (or auto-correlation) and that may impact the atmosphere. The ocean (i.e., sea surface temperature and sea ice) is a major component with these characteristics; however, being prescribed to observations in our simulations, it is continuous by definition and hence it does not need additional consideration for stitching purposes. Another such component is the land surface, in particular soil moisture. Soil moisture exhibits a few relevant characteristics: First, it exhibits memory of typically a few weeks to months (e.g., Koster  
20 and Suarez, 2001) and, therefore, one may want to ensure that this memory is not lost in the stitching process – this may be particularly critical in the case of droughts. Second, the temporal evolution of soil moisture is mainly driven by precipitation minus evapotranspiration ( $P - E$ ), i.e., by the weather in previous weeks to months. In other words, soil moisture can be seen as an approximate integrator of  $P - E$  over time. Ensuring that soil moisture is continuous therefore also likely constrains the history of the weather, which in turn increases the temporal consistency in atmospheric conditions in the stitched time series  
25 (for example, simulations with wet soils at the end of a year are likely to have exhibited wet conditions in December, while simulations with dry soils at the end of the year likely display less rainfall and higher temperature in December). Finally, soil moisture has been shown to be involved in key feedbacks relevant to droughts and heat waves (Seneviratne et al., 2010), such as soil moisture–temperature (Hirschi et al., 2011; Miralles et al., 2014) and soil moisture–precipitation (Roundy et al., 2013; Guillod et al., 2015) feedbacks. Therefore, ensuring continuous soil moisture avoids biases in the statistics of the weather in  
30 the following few weeks. Note that this last characteristic is most relevant in transitional regions between wet and dry climate and is probably not critical in the UK in the winter season, when our simulations are stitched. Other variables that could have been considered include snow; however given that snow is not very frequent at the end of December over the UK, it may be difficult to distinguish between the large number of simulations which don't exhibit any snow at all.

Based on these considerations, we use soil moisture as a basis for stitching. Figure 1 displays an example of time series that are obtained with our simulation setup for two consecutive years, with the first month of the simulations (grey lines, implicitly part of a 13-months spin-up) leading to 12-months simulations (coloured). Stitching the 1990 simulations to the 1991 simulations is based on identifying the best match between the 1990 end-of-simulation values (last value for each simulation) and the value at the same time step in the 1991 simulations, i.e., the last value in the spin-up (in grey) leading to the 1991 simulations. Five-days averages (i.e., pentads) of soil moisture in the upper 1m of the soil (3 out of 4 model levels in this case) over the British Isles are used for this purpose.

While Fig. 1 is useful to understand the principle of the stitching methodology, the problem is more complex for gridded data as there are multiple locations (or grid cells), and, thus, multiple time series to consider for each set of simulations. An appropriate simplification of this problem is to ensure continuity of the main spatial patterns of soil moisture. To do this, we concentrate on the main modes of variability by computing the EOFs for the last pentad of December at the end of our simulations (Fig. 2). The leading EOF pattern is homogeneous in sign and thus characterises the overall soil moisture conditions within the analysed domain, while the second EOF characterises a Southeast–Northwest contrast. Together, these two leading EOFs explain 60% of the total variance, while further EOFs account for a much lower fraction of the variability (6% and lower). Hence we retain these two EOFs and use the reduced two-dimensional space of the principal components (PCs) corresponding to these EOFs (hereafter, PC1-2 space) to compare soil moisture fields and find similar conditions, defined by the lowest possible distance in this two-dimensional space.

The procedure used for stitching is the following:

1. Wait until a minimum of  $n$  simulations is available for each year, which will allow the creation of  $n$  time series (e.g.,  $n = 100$  for historical baseline).
2. Compute the PCs of soil moisture at the last pentad of December in months 1 ("start-of-run") and 13 ("end-of-run") of each simulation, i.e., obtaining the starting and ending soil moisture conditions.
3. Starting with the year  $Y$  with the lowest number of simulations available ( $= n$ ), all simulations are stitched forward as follows: the distance in the soil moisture PC1-2 space between each "end-of-run" value from simulations on year  $Y$  and each "start-of-run" value from simulations on year  $Y + 1$  is computed. The Hungarian algorithm (R function 'solve\_LSAP' in package 'clue', Kuhn, 1955, 1956; Papadimitriou and Steiglitz, 1982; Hornik, 2005, 2016) is then applied to find the combination that minimises the sum of the squared distances.
4. The year  $Y + 1$  simulations that have been selected are used and the previous step is repeated until the last year of the time series is reached.
5. The same procedure is applied backward, i.e., matching "start-of-run" values on year  $Y$  to "end-of-run" values on year  $Y - 1$ . This is done repeatedly until the first year of the time series is reached.

The output of this procedure is a table which lists, for each time series, the simulation identifier for each year. The performance of the stitching methodology is evaluated from the historical baseline (1900-2006) by considering the soil moisture “error” obtained through stitching, using comparison of stitched and continuous simulations.

Fig. 3(a) shows the distribution of simulations in the PC1-2 space, for the last pentad in December. As detailed above, to create continuous time series, soil moisture at the end of the simulations on year  $Y$  (month 13 of the simulation; last December pentad) is compared to soil moisture at the same time step in month 1 of simulations leading to year  $Y + 1$ . The distribution of the obtained distances in the PC1-2 space at the time of stitching is shown in black on Fig. 3(b). To evaluate this in the context of a continuous simulation, we analyse changes between consecutive soil moisture pentads in continuous simulation (continuous lines on Fig. 3b-d), taken from the last pentad in December to any of the first three pentads in January (i.e., transition at the beginning of our simulations). We find that the difference at the time of stitching (dashed black line) is substantially smaller than typical changes with a lag of one pentad in continuous simulations (continuous green line), both in terms of distance in PC1-2 space (Fig. 3b) and changes in these PCs considered individually (Fig. 3c,d), i.e., the soil moisture error is smaller than a temporal lag of one pentad. Furthermore, changes between the last December and first January pentads (i.e., with a lag of one) are only slightly larger in the stitched ensemble (dashed lines) than in continuous simulations (continuous lines). For a lag of three pentad (purple), the changes in soil moisture PCs are very similar in stitched and continuous simulations. In these panels, these changes can also be compared to what would happen in a randomly stitched ensemble (dotted lines). The changes in such an ensemble are, as expected, independent of the lag (since no temporal correlation is retained), and are substantially larger than those found in both the soil-moisture-stitched and continuous ensembles (dotted lines, lying on top of each other for all lags). These results show that the presented methodology allows to successfully stitch single-year simulations to each other, thereby ensuring consistency in weather statistics on time scales of weeks.

## 4 Validation of the historical baseline

The global and regional models in weather@home 2 have been validated thoroughly in [Guillod et al. \(2017\)](#) with respect to the simulated mean climate, trends and extremes, including the British Isles domain averages. Here, we further validate the 100 baseline time series at a more local scale over the UK. Section 4.1 investigates the biases in mean climate and describes the bias correction taken to alleviate major biases, while Sect. 4.2 focuses on hydro-meteorological extremes, i.e., low and high precipitation events. [In addition to maps, some of the analyses are conducted for 19 river basin regions within Great Britain used in the UKCP09 climate projections \(Murphy et al., 2009\) and shown in Supplementary Fig. S3.](#)

### 4.1 Mean climate and bias correction

#### 4.1.1 Mean biases

Figure 4a–d shows the seasonal biases in surface air temperature with respect to the E-OBS dataset (Haylock et al., 2008). Biases are remarkably small for raw climate model output (within  $1^{\circ}\text{C}$  and often below  $0.5^{\circ}$ ), with two main exceptions: a cold

bias present in all seasons in the Northwest (Argyll region), and a warm bias in summer (June to August, JJA) in the South and Southeast.

Biases in precipitation with respect to the CEH-GEAR dataset (Fig. 4e–l), on the other hand, are more significant. In particular, precipitation is strongly underestimated in summer (20–50% or up to 1 mm day<sup>-1</sup>) and, to a lower extent, in autumn.

5 Conversely, winter precipitation tends to be overestimated in the Southeast. Possible mechanisms for these biases are discussed in [Guilod et al. \(2017\)](#). These biases have implications, particularly for the investigation of droughts and future drought risk, and the application of a bias-correction technique is therefore necessary. The next section (4.1.2) describes the approach chosen to correct precipitation data.

Another important variable for hydro-meteorological extremes is  $E_{\text{pot}}$ , whose biases are shown in Fig. 4m–p with respect to CHES-PE (without interception correction) and highlight ~~a small an~~ overestimation in summer (in the order of 20%) ~~-This bias is satisfactory, given large uncertainties in relative to this dataset. A possible reason for this overestimation is the warm temperature bias in this season, although possible biases in the radiative (net radiation) or aerodynamic (wind) components could also play a role. This bias should be kept in mind by users of the data, in particular when analysing droughts since these may thereby be overestimated. However, we note that large uncertainties are associated with the estimation of  $E_{\text{pot}}$  quantification, including the formula used in both models and observations, stemming among others from the formula and parameters used and, for observations, from the input data sources (Milly and Dunne, 2017).~~

#### 4.1.2 Bias correction

~~Since biases in temperature and~~ Biases in temperature being relatively small, they are not explicitly corrected. Although correcting the biases in  $E_{\text{pot}}$  ~~are relatively small, these two variables are not corrected. However,~~ might seem appealing

20 owing to their significant amplitude, such a procedure is not attractive since it comes with strong assumptions that might not hold. First, the origin of  $E_{\text{pot}}$  biases may be multiple, from temperature biases to bias in the radiation (e.g., overestimated net radiation owing to underestimated cloud cover) and aerodynamic (wind) components of the  $E_{\text{pot}}$  computation. Hence, to properly bias-correct  $E_{\text{pot}}$ , variables used to compute it should be corrected individually before computing  $E_{\text{pot}}$ . However, the lack of long-term gridded observations at a suitable resolution for some of these variables hampers such a procedure.

25 Second,  $E_{\text{pot}}$  is not observed directly but estimated from meteorological variables, leading to large discrepancies between observed estimates owing to various assumptions (formulation, parameters) and data used to compute them. This implies that a bias-corrected  $E_{\text{pot}}$  would be highly dependent on the chosen source of observed  $E_{\text{pot}}$ . Third, the assumption that the same bias correction can be applied to future scenarios would be even more questionable for  $E_{\text{pot}}$  than for precipitation because of the inter-dependence of the variables used to compute it. Based on these considerations,  $E_{\text{pot}}$  is not bias-corrected in our

30 dataset. However, users are recommended to investigate whether these biases have an impact on their results and to take these into account, especially when investigating summer drought. This recommendation also applies to users that compute  $E_{\text{pot}}$  themselves using an alternative formulation.

By contrast, the substantial precipitation biases may be particularly problematic for drought analysis and correcting for these is therefore necessary. To do so, a simple linear approach was chosen, using monthly bias correction factors (e.g., Lafon

et al., 2013). The choice of bias-correction algorithm depends on the nature of the biases present and the uncertainty with which properties of the observed and modelled precipitation distributions can be estimated (e.g., Teutschbein and Seibert, 2012; Lafon et al., 2013). For example, if biases are present in higher order moments of the simulated precipitation distribution then more sophisticated bias correction techniques are warranted than if only the mean is biased. Nonetheless, the higher order moments of the precipitation record can only be corrected if they can be estimated with confidence, which is not always possible for short-duration datasets. There is therefore a trade-off between reducing biases and introducing additional (often unconstrained) uncertainty. As recommended by Lafon et al. (2013), we use the simplest possible method which is able to correct significant biases in the data. In the present analysis we use a linear bias correction, which we calculate offers adequate correction of seasonal biases in the mean and which does not adversely affect higher order moments of the rainfall distribution. It is also noted that for drought studies using climate model outputs the distribution of dry days (i.e., days with precipitation < 1 mm) can be important to preserve. In the present case we find that this distribution is maintained without further specific corrections (Supplementary Fig. S3S4). These were defined based on the overlapping time period between all observational datasets (CEH-GEAR, CHES-PE, E-OBS) and our baseline, i.e., years 1961–2006. The mean precipitation for each calendar month was computed from the 100 baseline time series, and their ratio to the corresponding values in CEH-GEAR were computed (Supplementary Fig. S4S5). However, in order to avoid sudden discontinuities between grid cells, a spatial smoothing was applied to the ratio using a 3-by-3 grid cells moving box and taking weights of 1/2 for the center box and 1/16 for the surrounding 8 boxes, leading to the precipitation bias correction factors shown in Fig. 5. Note that only the Great Britain coverage of CEH-GEAR data are used for bias correction, since CEH-GEAR data over Northern Ireland are available as a separate product and have not been processed.

Subsequently, daily and monthly precipitation values were multiplied by the factor for the corresponding month. The bias-corrected precipitation is also made available as part of the dataset as an additional variable (prbc, see Table 3). Unless explicitly mentioned, analyses in the rest of this study are based on bias-corrected precipitation data.

#### 4.1.3 Inter-member variability

While the previous two subsections only consider the model climatology averaged from all 100 time series, part of the difference with observation may arise from natural variability, as expressed from the climatology of the individual time series. Indeed, although we often consider the observed climatology as the true climatology (albeit with some measuring errors), it is in fact one possible climatology among many and is determined by the one trajectory through the “weather phase space” that occurred by chance. This is due to the highly non-linear, chaotic behaviour of the atmosphere (e.g., Lorenz, 1965).

To assess the variability in climatologies in the 100 time series, Supplementary Figs. S5–S8 S6–S9 display the full range, interquartile range and median of climatologies (out of the 100 modelled climatologies) as well as observations for the 19 river basin regions used in UKCP09 (Murphy et al., 2009) within Great Britain. For temperature (Supplementary Fig. S5S6), all climatologies are relatively similar, but a larger spread is found for precipitation (Supplementary Figs. S6 and S7 and S8 for raw and bias-corrected values, respectively). Nonetheless, the observed climatology generally lies outside of all 100 climatologies for the main biases. It should be noted that some biases persist after bias-correction (e.g., in the Western Highland and Tay

regions on Fig. [S7S8](#)) due to the spatial smoothing applied to the bias correction factors. For  $E_{\text{pot}}$  (Supplementary Fig. [S8S9](#)), both variants from the CHES-PE dataset are shown (with and without interception correction) and the main [feature-features](#) are captured relatively well, apart from an overestimation in the Southern regions in summer (see also Fig. 4).

## 4.2 Hydrometeorological extremes

5 In this section, the ability of the time series to represent the distribution of dry and wet extreme precipitation events is assessed, first at the scale of Great-Britain averages for prolonged dry periods (Sect. 4.2.1) and then at the regional scale for prolonged dry period and for shorter, high precipitation events (Sect. 4.2.2). Comparison to CEH-GEAR is done based on the overlapping years, i.e., 1900–2006, and using only data over Great Britain(~~CEH-GEAR data over Northern Ireland have not been processed~~).

### 10 4.2.1 Great Britain-averaged dry events

Fig. 6a–d show, for averaged values over Great Britain, return time plots of low precipitation (bias-corrected) cumulated over a whole season. For w@h, return values are displayed for each time series (grey) as well as when pooling all time series together (black). Overall, observed values lie within the range of the simulated values. However, w@h tends to overestimate winter low precipitation values (i.e., not dry enough) but underestimate summer low precipitation values (i.e., overestimated summer droughts). Nonetheless, even in those cases there are individual time series which look similar to the CEH-GEAR dataset, suggesting that natural variability could explain some of those apparent biases. [The difficulty for climate models to represent low-frequency variability \(Ault et al., 2012\), an aspect that is by definition not improved by bias-correction, could also play a role in this feature.](#)

While short droughts do not usually pose a serious threat to Great Britain, prolonged periods of drought (e.g., multi-annual) are more problematic. Therefore, we also show return time plots for multiple (one to four) consecutive hydrological years (October to September) on panels e–h of Fig. 6. At these longer time scales, the climate time series perform very well compared to the observed return values, which lie well within the ensemble. These results are encouraging for the MaRIUS project, as they suggest that the dataset may well represent precipitation accumulation over long time period, which is the most critical aspect to British droughts. [Noteworthy is a small overestimation of dryness at rare frequencies for long accumulation times \(two to four years\), not present in the one-year accumulated values, which suggests that in this case the climate model overestimates long-term precipitation persistence, unlike what has been shown for longer accumulation times \(Ault et al., 2012\).](#) The next section goes into further details through validation at the regional scale.

### 4.2.2 Regional extremes

The analysis presented in the previous section was applied to regional averages of bias-corrected precipitation. To summarize the main findings, we focus on [six selected UKCP09 river basin regions \(Fig. 7; results for all 19 regions are shown in the Supplement\) which are representative of various climate conditions within the country and include two regions particularly](#)

prone to droughts (Thames and Anglian). We focus on precipitation totals over multiple hydrological years and display, for each region, the distribution of 100 return values estimated from the individual time series as boxplots, with the value estimated from the CEH-GEAR dataset overlaid as a white dot, for a number of return times (Fig. 8; see Supplementary Fig. S10 for all regions). Overall, the observed values lie well within the range of modelled values, with a few exceptions: in some regions (e.g.,

5 ~~Northern Highland, North East Scotland, Northumbria, South East England and South West England~~) the time series slightly underestimate the values (i.e., overestimate drought intensity), while values are overestimated (i.e., dryness is underestimated) in the Western Highland region, probably due to the remaining bias after correction (see Sect. 4.1.3). For shorter durations, a similar plot for low seasonal precipitation is shown in Supplementary Fig. ~~S9-S11~~ and allows dataset users to assess the performance of the dataset depending on their region and purpose.

10 Although the dataset was created within a project focusing on droughts, it could be used for other hydro-meteorological extremes such as floods. Therefore, we provide validation of high precipitation events at the regional level by focusing on total precipitation over a defined number  $N$  of consecutive days,  $rxNday$  for  $N = 1, 5$  and 30 days. Figure 9 show the return values for these 3 indices in a similar way as Fig. 8, but showing the results for both raw (uncorrected) and bias-corrected precipitation –(see also Supplementary Fig. S12 for all regions). The observed estimates are found to mostly lie within the

15 spread of values obtained from the climate time series for raw precipitation, but less so for bias-corrected precipitation. This suggests that the simple linear monthly bias-correction that has been applied may not be appropriate for such events. An alternative hypothesis is that the model represents the processes related to high precipitation formation relatively well (e.g., representation of UK-scale dynamical systems and thermodynamic processes, Schaller et al., 2016), but has more difficulties to represent longer-term persistence – a common feature of climate models (e.g., Ault et al., 2012). Therefore, we recommend

20 the ~~use of uncorrected precipitation values from the time series for studies that focus~~ application of another bias-correction technique (e.g., quantile-quantile mapping) for studies on high precipitation events.

It should be noted that the analysis of short-term events should be done on individual years separately rather than on the whole time series, e.g.,  $rx5day$  should not lie at the transition from one year to the next since the weather is not strictly continuous (Sect. 3.4). For example, for  $rx5day$ , for each year, the first value is from January 1–5 and the last values from

25 December 25–30 (the 360 days in a year are split into 12 months of 30 days), but it may not be appropriate to use the five pentads that range from December 26–January 1 to December 30–January 4, in order to exclude undesirable concatenation of inconsistent weather systems.

## 5 Future projections

In this section, we display changes in the five far future scenarios with respect to the 1975–2004 baseline, while corresponding

30 changes for the near future time slice are shown in the Supplement. First, changes in seasonal averages are displayed for the main variables, with a comparison to the UKCP09 projections (Murphy et al., 2009) at the regional level (Sect. 5.1). Indeed, UKCP09 data provide, among others, projected changes for a number of climate variables, time periods and climate scenarios.

Second, changes in extremes are investigated at the regional level for prolonged low precipitation period and for short, high precipitation extremes (Sect. 5.2).

## 5.1 Changes in mean climate

5 Fig. 10 shows the changes in mean temperature in all far future scenarios with respect to the baseline (1975–2004) and for each season. All changes are statistically significant at the 95% level according to a two-sided T-test based on climatological values from individual time series for both time periods. Generally, temperature increases are highest in the scenarios with higher global mean SST increases (FF-p90x and FF-p90n) and lowest in the scenarios with low global mean SST increases (FF-p10n and FF-p10x). Consistently with UKCP09, temperature increases is largest in the Southeast and in summer in all scenario. Similar but lower increases in temperature are found in the near future time slice (Supplementary Fig. ~~S10~~S13).

10 Fig. 11 shows the distribution of all possible changes in temperature (i.e., from all combinations of the future time series with the baseline time series) and in UKCP09 (high emission scenario A1FI), relative to the years 1961–1990 for consistency with the UKCP09 data. The spread of UKCP09 values account for a wider range of uncertainty than in our time series, as it includes various climate models and parameter uncertainty. However, our various future scenarios generally cover the range of mean changes projected by the latest UK climate change scenarios ~~-(see also Supplementary Fig. S14 for all regions).~~

15 The patterns of changes in seasonal mean precipitation (Figs. 12) highlight that, while in winter precipitation changes seem mostly related to global mean SST increases (as for temperature), summer precipitation changes are most sensitive to the North Atlantic SST gradient: time series FF-p10n and FF-p90n induce the smallest precipitation decreases, while FF-p10x and FF-p90x lead to the largest precipitation decrease. Thus, large SST gradients in the North Atlantic (as defined by the metric described in Sect. 3.2) lead to drier summer conditions. Note that the median scenario (“FF”, called MMM in this figure for Multi-Model Median) exhibits the CMIP5 median change in this feature, while the four other scenarios depict extreme cases in both direction and should hence be considered as sensitivity scenarios. The mechanisms through which SST influence precipitation may include the North Atlantic Oscillation (NAO), which has been shown to be influenced by SSTs in the Atlantic and to influence European weather (e.g., Woollings et al., 2015). It should be noted that changes in raw (without bias correction) precipitation are smaller in JJA, leading to an overall weaker drying in absolute terms. Most of the changes  
20 are statistically significant, apart from substantial areas in MAM and SON in individual cases and small areas in DJF. Similar patterns of change, but smaller in amplitude and thereby less robustly significant (especially in DJF), are identified in the near future time slices (Supplementary Fig. ~~S11~~S15). By definition, relative changes are similar in both raw and bias-corrected precipitation as the same multiplicative factors are applied to both time periods.

30 Comparison of precipitation changes to UKCP09 (Fig. 13; see also Supplementary Fig. S16 for all regions) reveals that the simulated time series lies on the dry end of the standard UK climate projections. The changes may thus be more similar to UKCP02, the previous UK climate scenarios, which were based on the same models that are used in w@h. This feature is important to keep in mind, especially when analysing changes in drought. The dataset can thus be seen as an ideal test bed for dry conditions, but the actual future may potentially not be as dry as suggested by the climate time series presented in this

paper. Note that in some cases such as DJF in North East Scotland, changes are mostly not statistically significant in the sense that no change is included in the 5–95% range.

Finally, projected changes in seasonal mean  $E_{\text{pot}}$  are displayed in Fig. 14, using the  $E_{\text{pot}}$  formulation where stomatal resistance is adjusted to CO<sub>2</sub> future concentrations.  $E_{\text{pot}}$  substantially increase in summer, and to a lower extent in autumn and spring. The changes are mostly driven by the global mean SST increase, similar to temperature and as one may expect due to the strong controls exerted by temperature on this variable. We note that not adjusting stomatal resistance to increased CO<sub>2</sub> concentrations in the future (Supplementary Fig. S12S17) would result in a significantly stronger increase in  $E_{\text{pot}}$ , and therefore recommend to use `pepm_adjrs` for future analyses to prevent overestimating increases in drought. As for temperature and precipitation, the near future time slice displays changes that are qualitatively similar to those of the far future but smaller in amplitude (Supplementary Figs. S13 and S14S18 and S19).

## 5.2 Changes in hydrometeorological extremes

As for the validation of extremes done in Sect. 4.2.2, we concentrate on extremes of low precipitation cumulated over a number of consecutive hydrological years, and on high precipitation extremes cumulated over a small number of consecutive years.

Fig. 15 displays the 10-year return value (i.e., 3rd highest value in each 30-year time series) of low precipitation accumulated over two hydrological years –(see Supplementary Fig. S20 for all regions). The distribution of the values estimated from each time series is shown for the baseline and for each far future scenario, whereby boxes for future scenarios whose mean value does not significantly differ from the baseline according to a two-sided T-test at the 95% level are displayed in grey. Generally, a strong drying is found, i.e., 10-year dry events are getting more intense. In most regions, most of the difference between the individual future scenarios (i.e., SST warming patterns) appears to be related to the North Atlantic SST pattern, rather than to global mean SSTs. This suggests, given the findings of Fig. 12, that the summer response may drive the changes in longer droughts (2 hydrological years in this case).

Similarly, Fig. 16 displays the change in 10-year return value of `rx5day`, using uncorrected precipitation data since these perform better than bias-corrected for high precipitation events as highlighted in Sect. 4.2.2. High precipitation extremes are expected to increase in intensity in most scenarios, (except in those with low global mean sea surface temperature increase (FF-p10n and FF-p10x) in some regions), despite a smaller signal-to-noise ratio induced by the sampling of 10-year return values from 30-year time series. Unlike for drought, global mean SST increases appear to be the main factor leading to the response in extreme high precipitation, consistently with the Clausius-Clapeyron relationship (higher SST leading to higher evaporation and higher moisture content) and with the current understanding of atmospheric thermodynamics (e.g., Schaller et al., 2016). Results for all regions are shown in Supplementary Fig. S21.

In the near future time slice, similar but smaller changes are found for low precipitation (Supplementary Figs. S15S22), i.e., a increase in drought severity may already be expected in this time period. However, for high precipitation events (`rx5day`, Supplementary Fig. S16S23), the increase is very small in this time period and cannot be distinguished from natural variability is in most cases not statistically significant.

## 6 Conclusions

This paper presents a new set of climate projections for the United Kingdom, based on a regional climate model driven by a global atmospheric model which accounts for uncertainty in the climate system response by sampling a range of changes in the ocean state from CMIP5 models. The dataset includes a large number of spatio-temporally consistent time series for the recent  
5 past (1900–2006) and for the near and far future (30-yr time slices ending in the middle and at the end of the 21st century, respectively). Future projections follow the assumption of a high greenhouse gas emission scenario (RCP 8.5), allowing to test the sensitivity of the system to relatively large changes in climate forcing. The analysis could be repeated for alternative RCP scenarios.

An advantage of this data set compared to previous UK climate projections is the availability of a large number of spatially  
10 consistent time series, which is important for risk analysis of hydrological phenomena that are sensitive to spatial and temporal variability. Moreover, the availability of a large number of time series allows to better account for internal variability (albeit only the atmospheric part of it), which has been shown to be a main source of uncertainty in climate projections (e.g., Deser et al., 2014). This comes at the expense of essentially using only one climate model (global and regional). However, in an effort to sample as wide a range of conditions as possible, part of the uncertainty in the climate system response is  
15 incorporated by using a range of projected changes in ocean states from CMIP5 models.

One of the challenges associated with the chosen approach is the generation of continuous time series from a large set of single-year simulations. A novel methodology has been developed and validated, which is based on identifying simulations with the best matching soil moisture patterns to ensure continuity in slowly-evolving hydro-meteorological variables, the ocean state being continuous by definition as it is prescribed. This methodology is shown to be a promising tool for the application  
20 of weather@home to long-lasting extreme events such as drought.

The created time series are shown to represent mean climate and extreme hydro-meteorological events relatively well, after correcting for a substantial precipitation bias. We did not bias-correct potential evaporation but we strongly recommend data users to carefully assess possible impacts of these biases on their results, particularly with respect to drought analysis in the southern part of the UK. For high precipitation extremes, ~~however, we find that the the better performance of raw (uncorrected)~~  
25 precipitation output ~~performs better than (compared to bias-corrected precipitation; this highlights)~~ highlights that while the choice of a simple linear bias correction might be appropriate with respect to mean, seasonality, and perhaps accumulated totals over a few months, analysis of short-duration hydrometeorological extremes might require the application of a more sophisticated bias-correction methodology. In addition, the application of a bias-correction technique to climate model output cannot correct for interannual to decadal climate variability, which is known to be poorly captured in current state-of-the-art  
30 climate models (e.g., Ault et al., 2012). This issue could potentially lead to an underestimation of the risk of multi-decadal droughts (Ault et al., 2014). As with any model-based dataset, an evaluation of metrics relevant to the need-of-an-evaluation of the relevant metrics to chose the processes investigated is recommended in order to chose a suitable set of variables to be used for studies using the climate data set, since the choice of bias correction depends on the intended application and, where required, to apply a suitable bias-correction technique.

The projected changes in climate, using 5 SST warming patterns, mostly cover the temperature range of UKCP09, but tend to lie on the dry end of the precipitation changes obtained in UKCP09. Prolonged periods of low precipitation are projected to become more frequent and intense, as are short-duration high precipitation events. The analysis of the projected changes also provides some useful insights into the oceanic drivers. Some variables are most sensitive to the overall (global) SST warming amplitude (e.g., temperature, winter precipitation) while others are most sensitive to the SST gradient in the North Atlantic (e.g., summer precipitation). These results also suggest that the future seasonal cycle may depend on the oceanic response to climate change, in particular with respect to the North Atlantic, and ocean-atmosphere interactions.

In the context of the MaRIUS project, these time series are being used as input to hydrological, ecological and agricultural models, among others. Combining these output with, for example, water resource models, will allow for an in-depth investigation of the drivers of water scarcity in the UK and for the identification of suitable adaptation measures. Additionally, the availability of a large number of time series, driven by different SST patterns, will allow to identify the oceanic, meteorological, and hydrological drivers of drought in the UK in subsequent analyses. The spatio-temporal structure of drought in the UK, and how it may change in the future, will also be investigated as part of MaRIUS.

*Data availability.* The dataset will be made available on the Centre for Environmental Data Analysis (CEDA) platform after publication of the paper in HESS discussion. Data, in NetCDF format, will be provided as yearly files for each simulation and with a table indicating the simulations corresponding to each time series and year, and will include the variables listed in Table 3 for all the time series for each scenario (Table 2).

*Author contributions.* B.P. Guillod designed the modelling experiments with input from R.G. Jones, N.R. Massey, J.W. Hall and M.R. Allen. N.R. Massey created the future SSTs and sea ice boundary conditions. A.L. Kay assisted with the  $E_{pot}$  computation. B.P. Guillod, G. Coxon, S.J. Dadson, R.G. Jones, G. Bussi and J. Freer designed and evaluated the bias correction methodology. S.N. Sparrow and D.C.H. Wallom managed the climateprediction.net infrastructure and model simulations thereon. B.P. Guillod ran the model simulations, designed the stitching methodology, analysed the data and wrote the paper. All co-authors provided comments on the text.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* This work was undertaken within the MaRIUS project: Managing the Risks, Impacts and Uncertainties of droughts and water Scarcity, funded by the Natural Environment Research Council (NERC), and undertaken by a project team spanning the University of Oxford [NE/L010364/1], University of Bristol [NE/L010399/1], Cranfield University [NE/L010186/1], the Met Office, and the Centre for Ecology and Hydrology [NE/L010208/1]. **Figure 1.** Illustration of the simulation design and stitching, using soil moisture model data averaged over the Thames catchment. Each panel shows, for a given year (top: 1990; bottom: 1991), 5-days averages of soil moisture in the upper 1 m of the soil for 20 model simulations. The first month of the simulations (December of the previous year, part of the spin-up) is indicated by grey lines, followed by the 12 months (January to December) in colours. End-of-year values of 1990 simulations and the same time steps in the spin-up leading to 1991 values, highlighted by dark grey boxes, have to be compared to find the combination allowing the best match between simulations. Light grey boxes indicates the same time steps that will be used to stitch to 1989 (top) and 1992 (bottom).

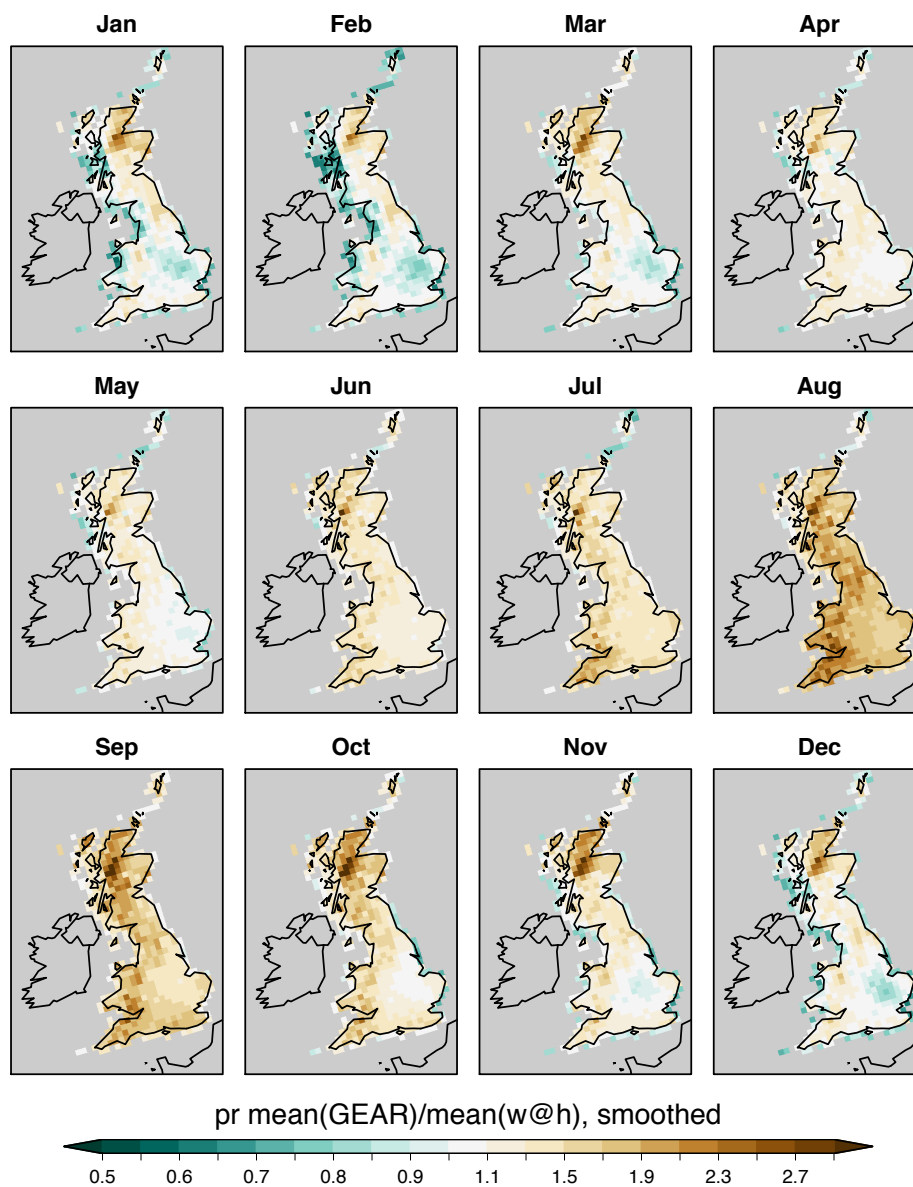

**Figure 2.** Leading EOFs of upper 1m soil moisture over the British Isles in the last pentad in December. The fraction of explained variance is indicated on each panel.

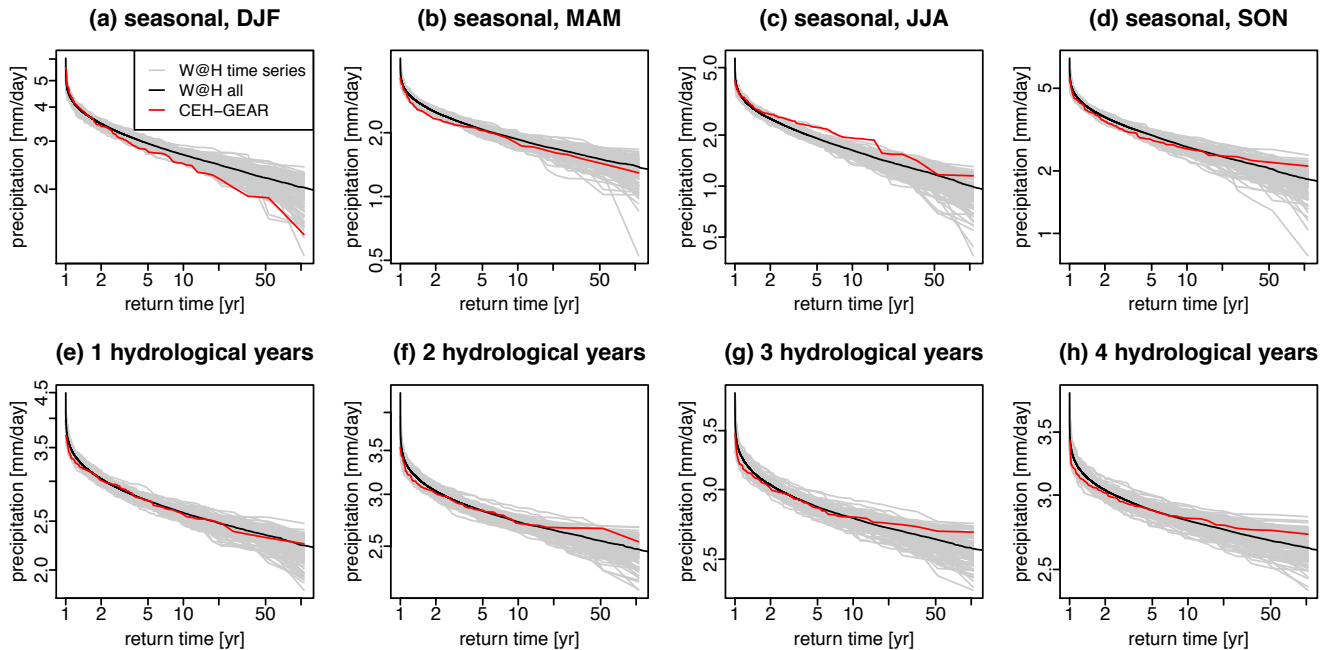

**Figure 3.** Temporal continuity of soil moisture in the stitched ensemble compared to continuous simulations in the historical baseline (1900–2006). (a) Bivariate distribution of soil moisture PCs 1 and 2 at the last December pentad. (b-d) Empirical cumulative distribution function of the changes in the PC1-2 space between the last pentad in December and the three subsequent pentads (colors) in continuous simulations (continuous lines), the stitched ensemble (thick lines) and a randomly stitched ensemble (points). The dashed black line shows the ECDF of the same distance at the time of stitching, i.e., between the same pentad in stitched simulations. (b) Absolute distance in the PC1-2 space, (c) Change in PC1 and (d) change in PC2.

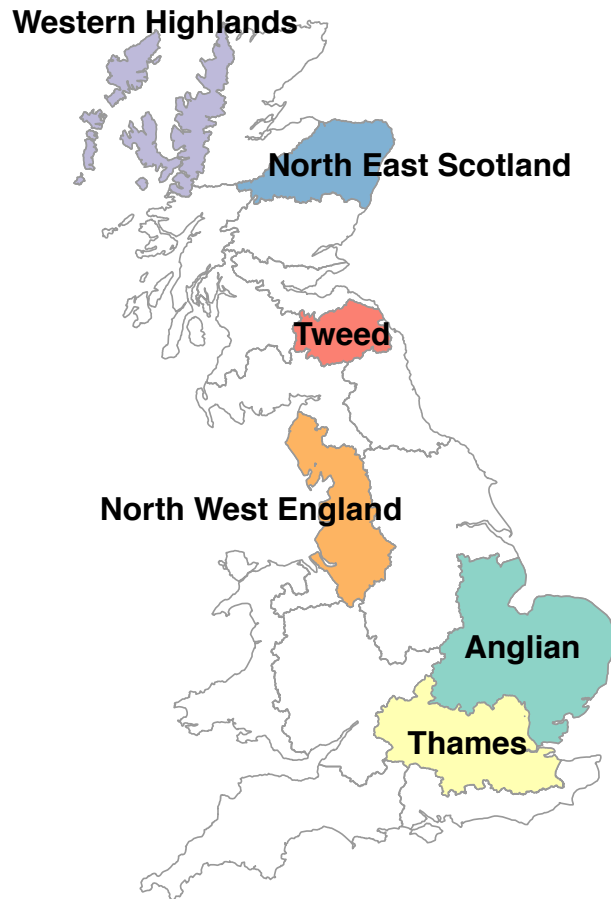

**Figure 4.** Seasonal biases in (a–d) mean surface air temperature, (e–h) precipitation in  $\text{mm day}^{-1}$ , (i–l) precipitation in %, and (m–p)  $E_{\text{pot}}$ , for years 1961–2006. Each column is for a season as indicated in the labels.

**Figure 5.** Bias-correction multiplicative factor applied to precipitation. A spatial smoothing was applied to the monthly ratios between observed (GEAR) and modelled (W@H) 1961–2006 precipitation (see Supplementary Fig. [S4-S5](#) for the unsmoothed ratio).

**Figure 6.** Return time plots of (a–d) low seasonal precipitation and (e–h) low precipitation accumulated in 1–4 consecutive hydrological years, for Great Britain averages from 1900–2006. (red) CEH-GEAR, (grey) individual w@h time series, (black) all w@h time series pooled together. For each time series, seasonal or (multi-)year averages of precipitation were computed and spatially aggregated over Great Britain prior to the computation of return values.

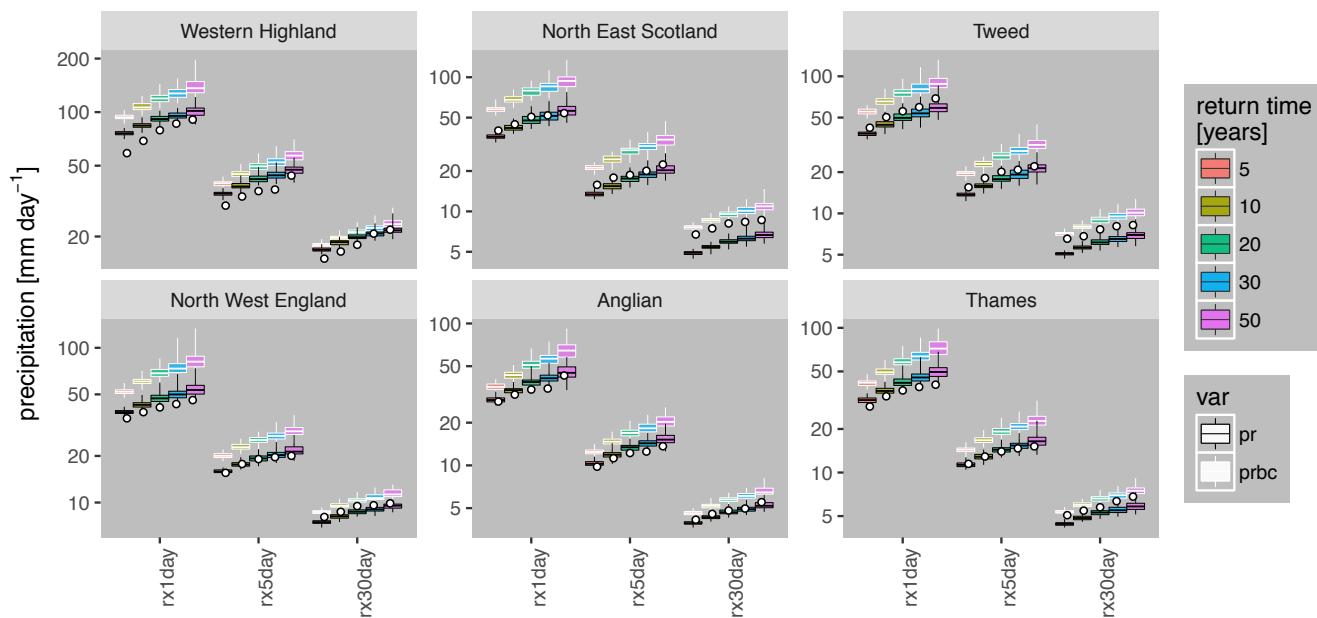

**Figure 7.** Return values Subset of low precipitation accumulated over 1–4 hydrological years (x-axis) six river basin regions in the 100 baseline time series (boxplot) and Great Britain used in CEH-GEAR (white dot) for each region (panel), for return times of 5–50 years the analysis. See All 19 UKCP09 river basin regions are shown in Supplementary Fig. S9 for the same analysis on seasonal precipitation rather than hydrological years S3. Whiskers display the range from individual time series.

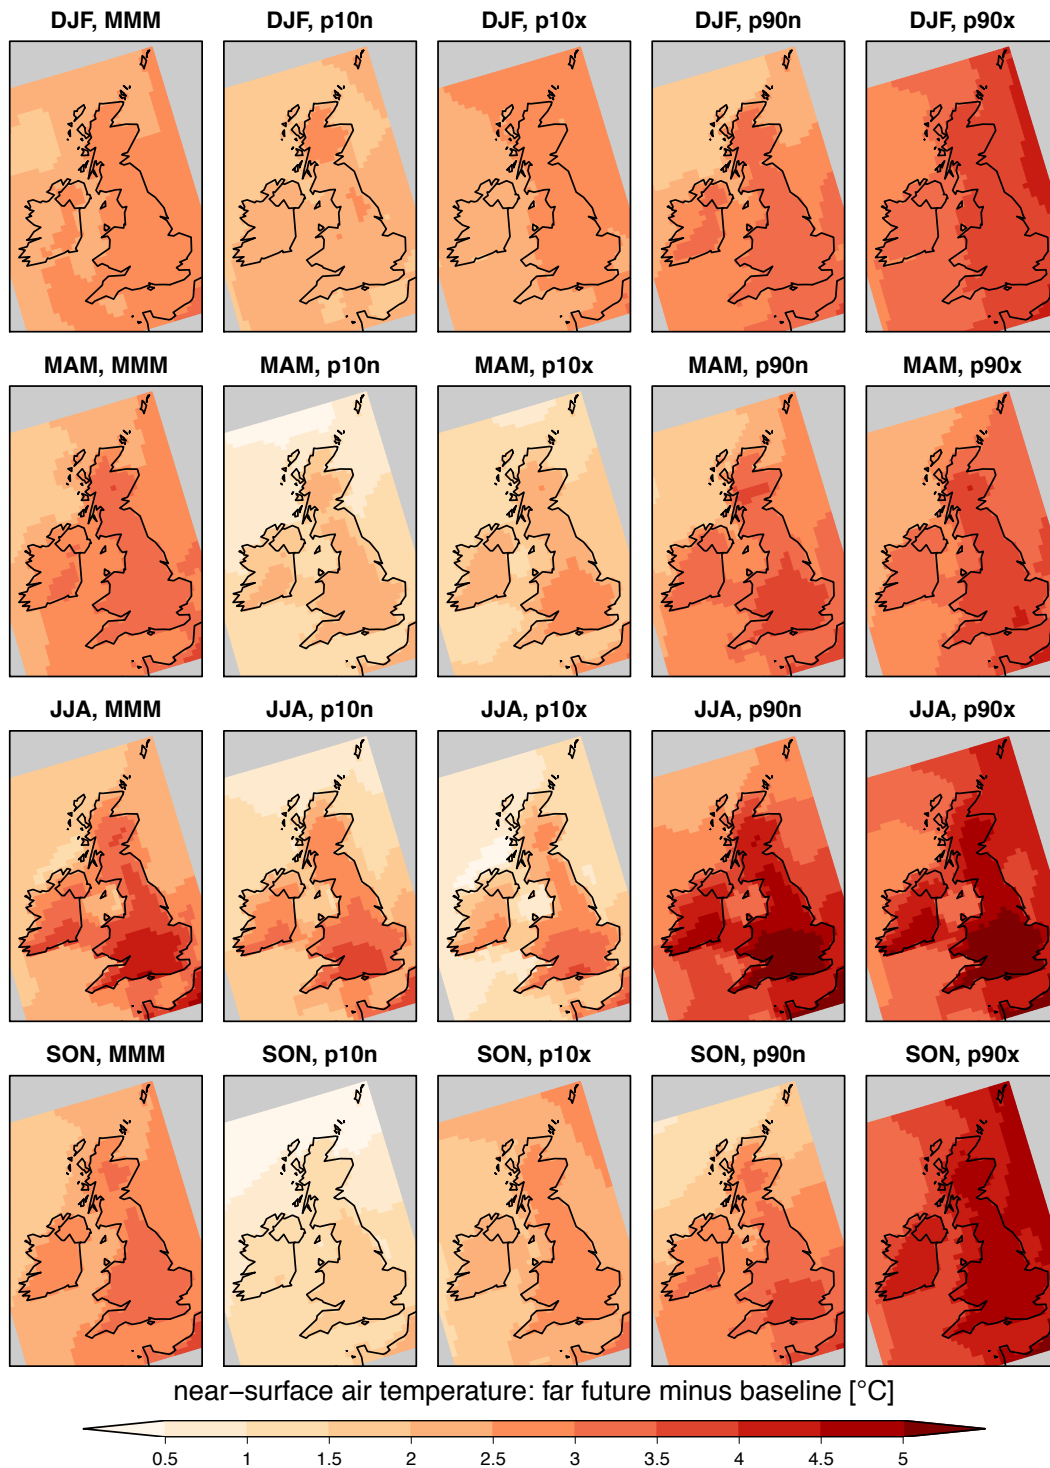

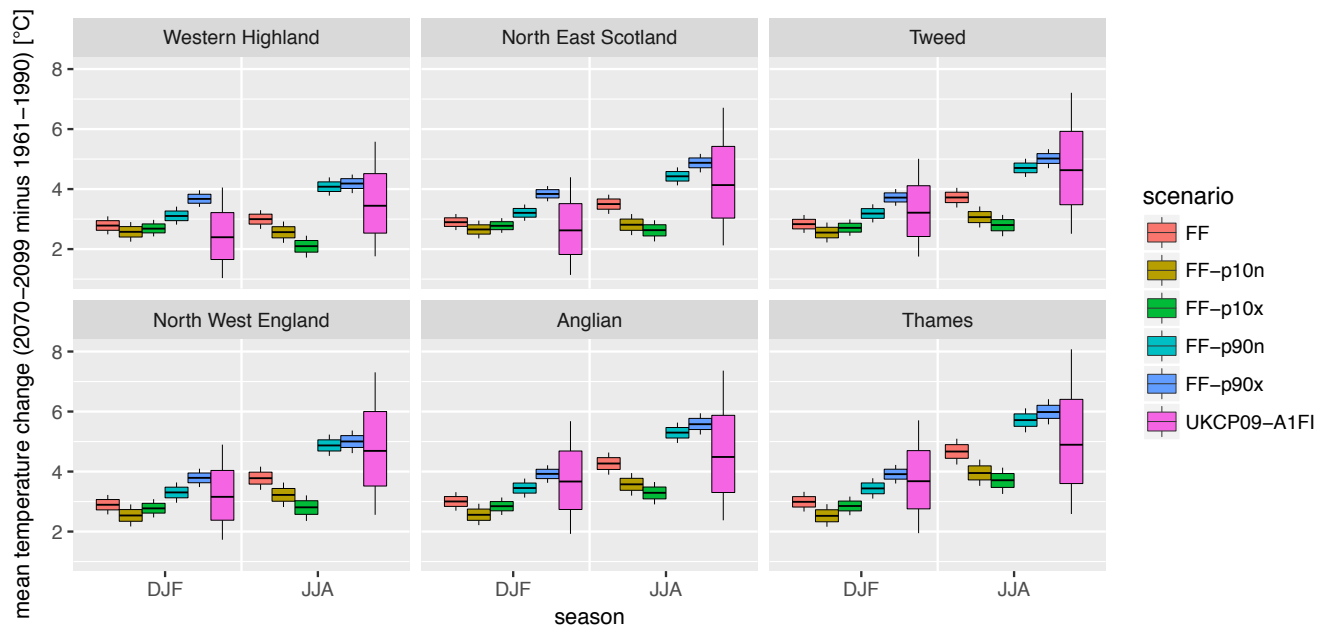

**Figure 8.** [Return values of low precipitation accumulated over 1–4 hydrological years \(x-axis\) in the 100 baseline time series \(boxplot\) and in CEH-GEAR \(white dot\) for each region \(panel\), for return times of 5–50 years. See Supplementary Fig. S10 for the plots for all regions, and Supplementary Fig. S11 for the same analysis on seasonal precipitation rather than hydrological years. Whiskers display the range from individual time series.](#)

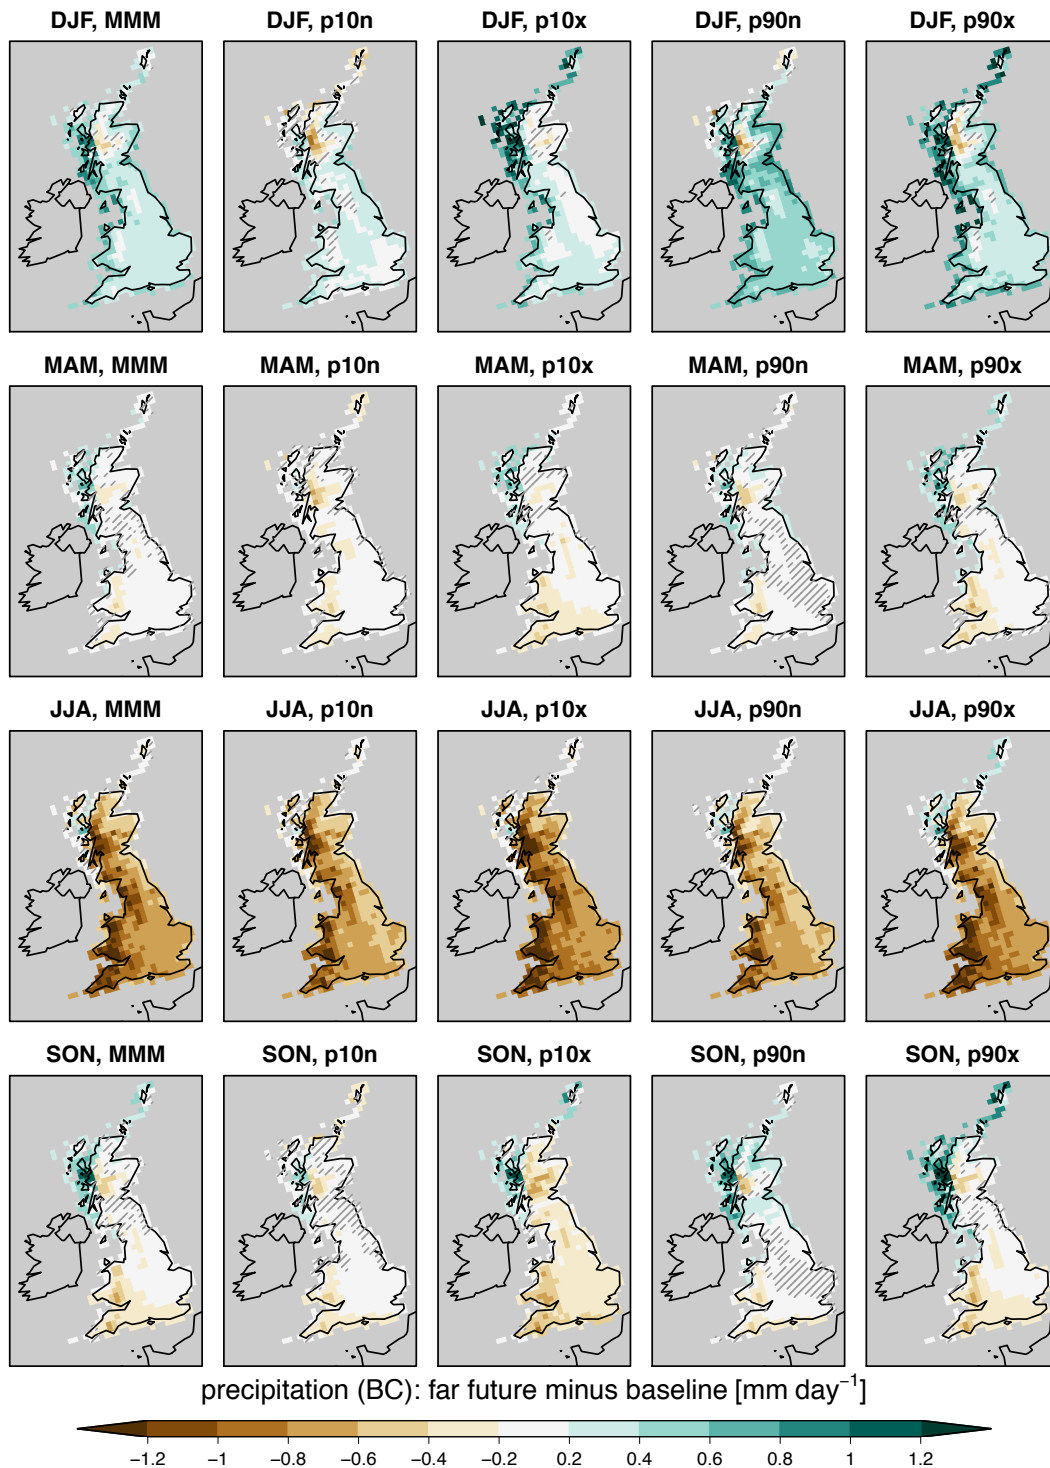

**Figure 9.** Return values of high precipitation indices rx1day, rx5day and rx30day (x-axis) in the 100 baseline time series (boxplot) and in CEH-GEAR (white dot) for each region (panel), for return times of 5–50 years (colour). Bias-corrected precipitation data is boxed in white (raw precipitation data in black). Whiskers display the range from individual time series. Note that for these metrics, the raw precipitation data compares better to observations than bias-corrected values. [See Supplementary Fig. S12 for the plots for all regions.](#)

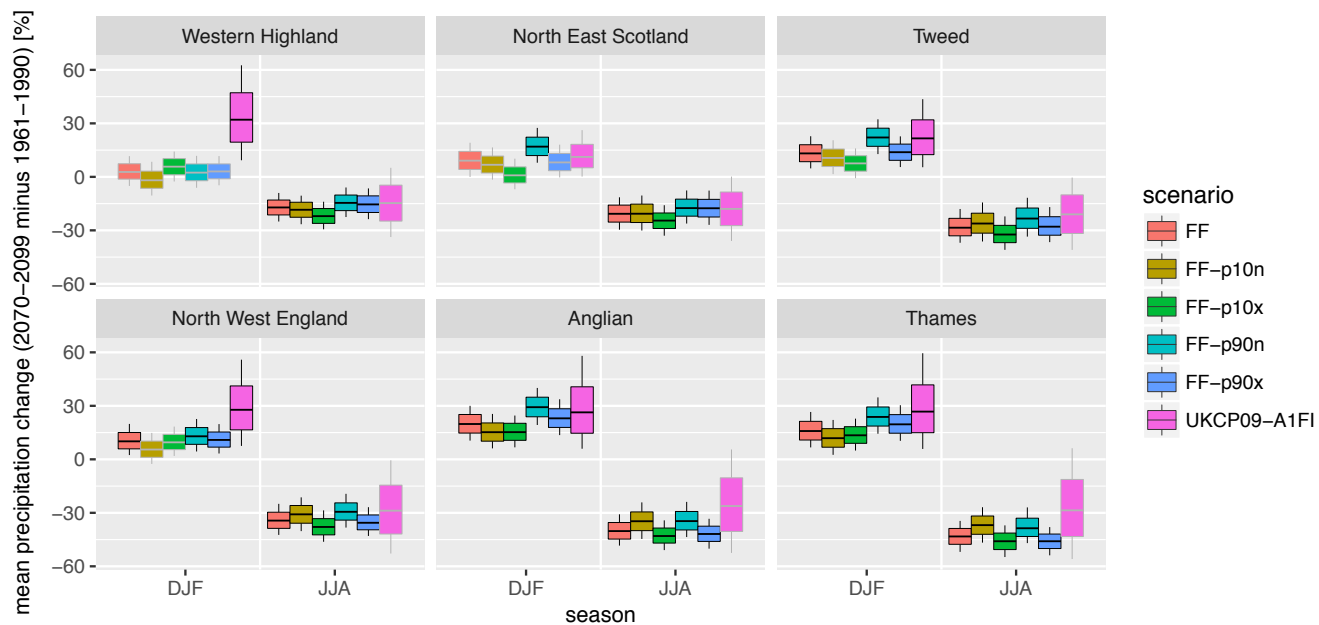

**Figure 10.** Difference in near-surface air temperature between far future and baseline (years 1975–2004 therein) for each season (row) and scenario (column). [Hatching indicates grid-cells with statistically non-significant changes at the 95% level according to a two-sided T-test \(almost all grid cells are significant here\).](#) The corresponding figure [34](#) the near future time slices is shown in Supplementary Fig. [S13](#).

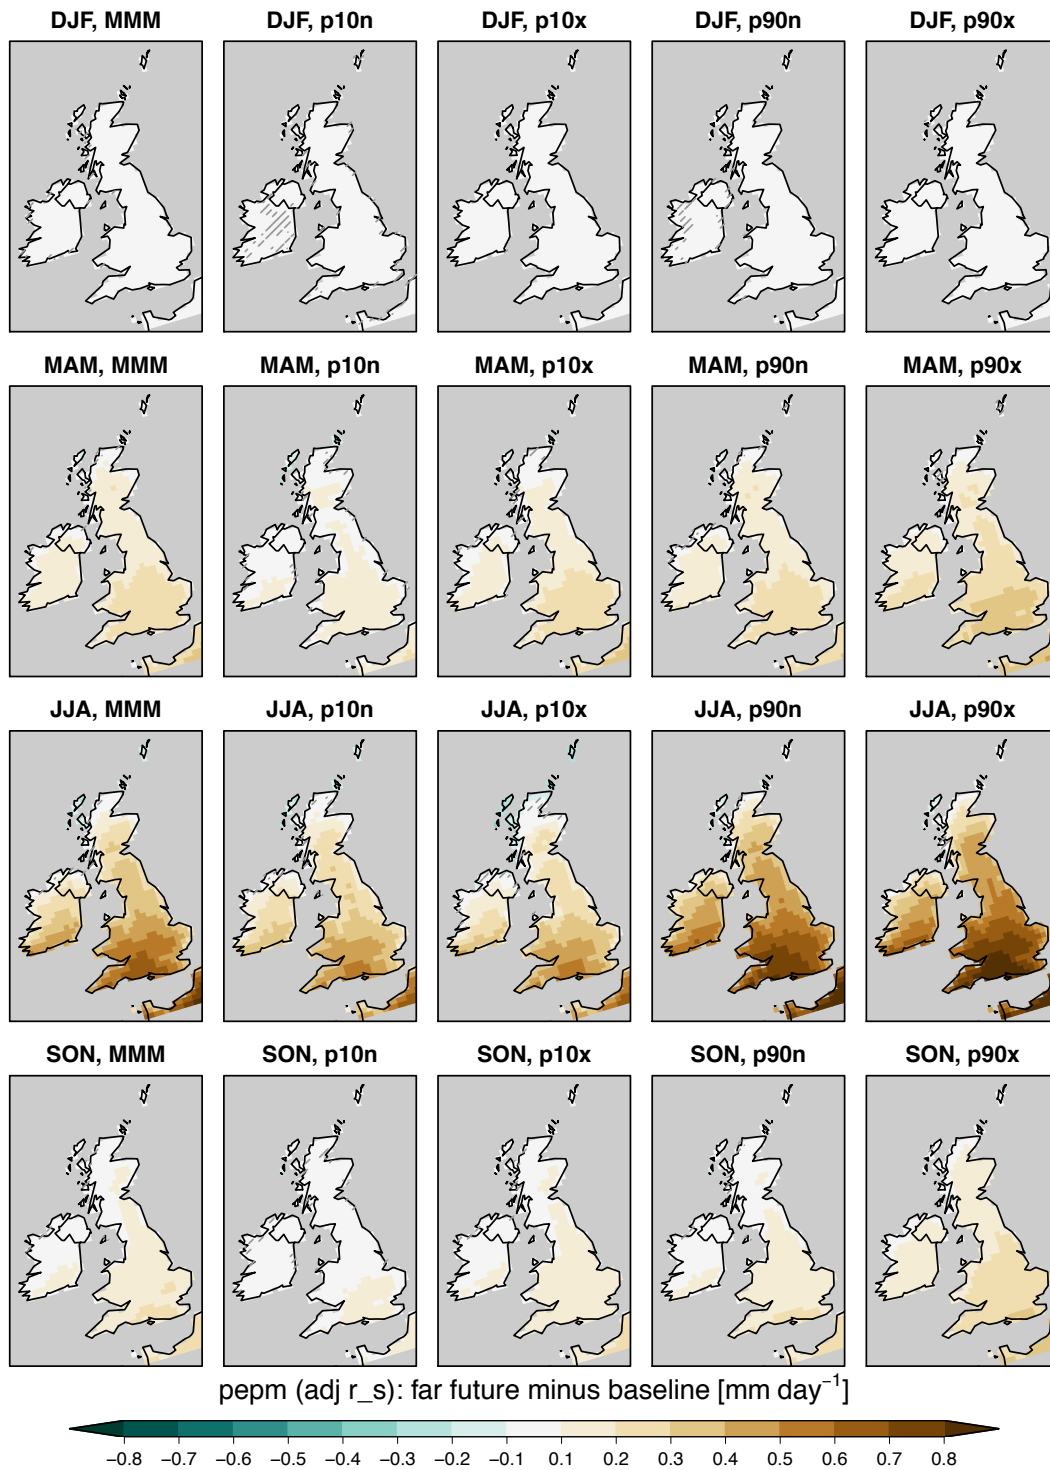

**Figure 11.** Comparison of temperature projections with UKCP09: For each region, boxes show changes (2070–2099 minus 1961–1990) in JJA (left boxes) and DJF (right boxes) in the 5 sets of MaRIUS time series and in UKCP09 (high emission scenario: SRES A1FI; 10000 values available). Whiskers display the 10–90% range from each group. [See Supplementary Fig. S14 for the plots for all regions.](#)

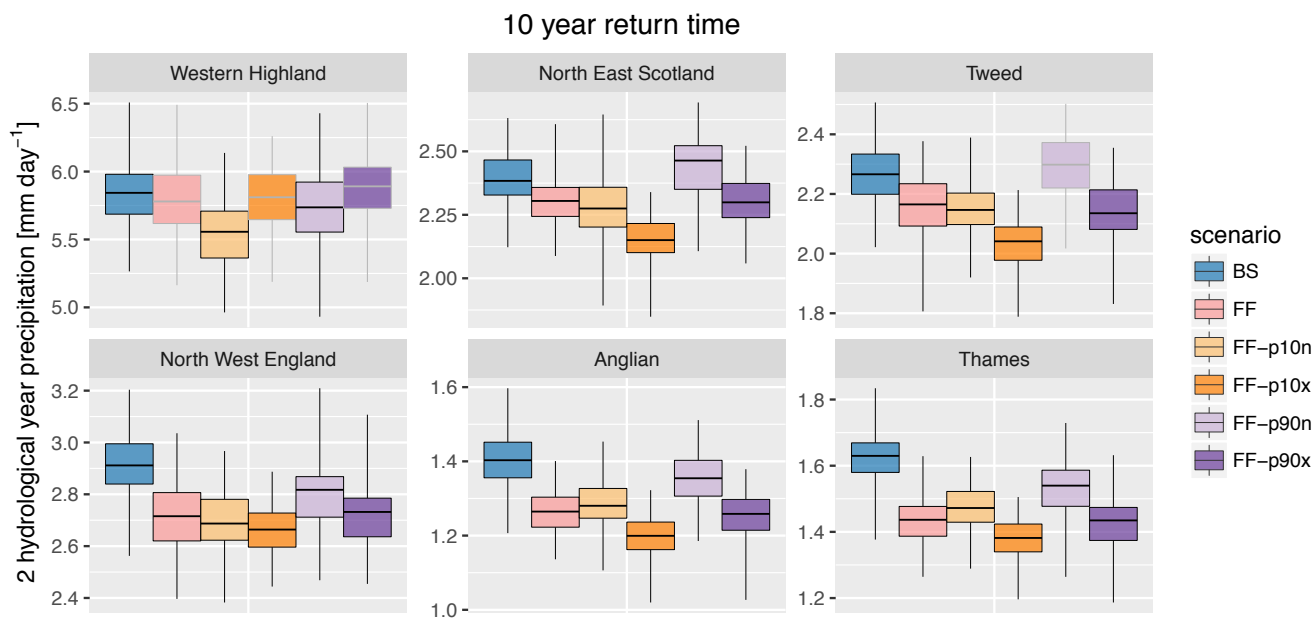

**Figure 12.** Same as Fig. 10 but for precipitation (bias-corrected, prbc). [Hatching indicates grid-cells with statistically non-significant changes at the 95% level according to a two-sided T-test.](#) The corresponding figure for the near future time slices is shown in Supplementary Fig. [SHS15](#).

**Figure 13.** Same as Fig. 11 but for precipitation, in %. [Grey boxes indicate cases where 0 lies within the 5–95% range. See Supplementary Fig. S16 for the plots for all regions.](#)

**Figure 14.** Same as Fig. 10 but for  $E_{\text{pot}}$  (with stomatal resistance adjusted to  $\text{CO}_2$  concentration; see Supplementary Fig. [S12-S17](#) for the changes when stomatal resistance is kept constant). [Hatching indicates grid-cells with statistically non-significant changes at the 95% level according to a two-sided T-test.](#) The corresponding figures for the **38** far future time slices are shown in Supplementary Fig. [S13-S18](#) and [S14S19](#).

**Figure 15.** Distribution of return values of 10-year event for low precipitation on two consecutive hydrological years (boxplot) for each region (panel) and scenario (colour). Whiskers display the range from individual time series. The Grey boxes for future scenarios indicates statistically non-significant change in mean return value with respect to the baseline at the 95% level according to a two-sided T-test. See Supplementary Fig. S20 for the plots for all regions, and the corresponding figure for the near future time slices is shown in Supplementary Fig. S15S21.

**Figure 16.** Distribution of return values of 10-year event for rx5day (boxplot) for each region (panel) and scenario (colour), using raw precipitation data (i.e., not bias-corrected). Whiskers display the range from individual time series. The Grey boxes for future scenarios indicates statistically non-significant change in mean return value with respect to the baseline at the 95% level according to a two-sided T-test. See Supplementary Fig. S22 for the plots for all regions, and the corresponding figure for the near future time slices is shown in Supplementary Fig. S16S23.

**Table 1.** Observational datasets. For the mean climate validation the common overlapping period 1961–2006 is used, while for precipitation extremes validation the overlap period between the historical baseline and CEH-GEAR (1900–2006) is used.

Variable	Dataset	Time period	Native resolution	Reference
Temperature	E-OBS (version 12.0)	1950–2014	0.22°	Haylock et al. (2008)
Precipitation	CEH-GEAR	1961–2014	1 km	Keller et al. (2015); Tanguy et al. (2015)
Potential evapotranspiration	CHESS-PE	1961–2012	1 km	Robinson et al. (2015)

**Table 2.** List of the climate time series for various scenarios. GM SST stand for Global Mean SST.

Name	Short name	Years	GM SST percentile	SST North Atlantic index	# time series	Remark
Historical Baseline	bs	1900–2006	Observed (HadISST 2)		100	“Baseline” refers to years 1975–2004 of the historical baseline
Near Future	nf	2020–2049	50	50	100	
Near Future p10n	nf-p10n	2020–2049	10	min	91	
Near Future p10x	nf-p10x	2020–2049	10	max	91	
Near Future p90n	nf-p90n	2020–2049	90	min	89	
Near Future p90x	nf-p90x	2020–2049	90	max	85	
Far Future	ff	2070–2099	50	50	100	
Far Future p10n	ff-p10n	2070–2099	10	min	89	
Far Future p10x	ff-p10x	2070–2099	10	max	86	
Far Future p90n	ff-p90n	2070–2099	90	min	90	
Far Future p90x	ff-p90x	2070–2099	90	max	86	

**Table 3.** Output variables available in the dataset at various temporal frequencies.

Temporal resolution	Variable name	Description	unit
daily only	tasmax	Maximum air temperature at 1.5 m above ground	K
	tasmin	Minimum air temperature at 1.5 m above ground	K
daily & monthly	pr	Mean precipitation flux	mm s <sup>-1</sup>
	prbc	Bias-corrected pr (Sect. 4.1.2)	mm s <sup>-1</sup>
	pepm	Penman-Monteith potential evaporation (Sect. 3.3)	mm day <sup>-1</sup>
	pepm_adjrs (future only)	Future Penman-Monteith potential evaporation with stomatal resistance adjusted to atmospheric CO <sub>2</sub> concentration (Sect. 3.3)	mm day <sup>-1</sup>
	tdps	Mean dew point temperature at 1.5 m above ground	K
	wss	Mean wind speed at 10 m above ground	m s <sup>-1</sup>
	rsds	Mean incoming shortwave radiation at the surface	W m <sup>-2</sup>
	rlds	Mean incoming longwave radiation at the surface	W m <sup>-2</sup>
	rss	Mean net shortwave radiation at the surface	W m <sup>-2</sup>
	rls	Mean net longwave radiation at the surface	W m <sup>-2</sup>
	hfls	Mean latent heat flux at the surface	W m <sup>-2</sup>
5 days averages & monthly	psl	Mean sea level pressure	Pa
	hfss	Mean sensible heat flux at the surface	W m <sup>-2</sup>
monthly only	moisture_content_of_soil_layer	Mean soil moisture content in each layer	m
	tas	Mean air temperature at 1.5 m above ground	K
	prsn	Total snowfall flux	mm s <sup>-1</sup>
	prrc	Convective rainfall flux	mm s <sup>-1</sup>
	prsnrc	Convective snowfall flux	mm s <sup>-1</sup>
	clt	Fractional cloud cover	–

**Table 4.** Monthly surface resistance values ( $r_s$ , in  $\text{s m}^{-1}$ ) used in the computation of  $E_{\text{pot}}$ . The baseline values are shown under pepm, and are kept constant in future time slices for variable pepm. pepm\_adjrs are future values accounting the changes in  $\text{CO}_2$  concentration (see Sect. 3.3 for details).

Months	pepm	pepm_adjrs (near future)	pepm_adjrs (far future)
January	88.7	94.5	115.9
February	88.7	94.5	115.9
March	69.5	75.8	101.6
April	56.8	62.7	88.5
May	44.5	49.5	72.2
June	64.3	71.2	102.1
July	64.3	71.2	102.1
August	73.7	81.5	115.8
September	75.4	82.8	114.2
October	78.0	84.8	112.1
November	87.1	93.7	118.8
December	88.7	94.5	115.9
