We appreciate the editor and both referees for their valuable and insightful comments, which have greatly improved our manuscript. Below we describe the modifications made according to their comments. For clarity, comments are given in italics and blue, and our responses are given in plain text. The line numbers within brackets indicate the location of the modifications in the revised manuscript. The revised manuscript with all revisions tracked is appended at the end of this document.

-Referee#1-

> *There are many researches focusing on reasons, causes and modelling of nonstationarity of hydrological extremes such as: Xihui Gu, Qiang Zhang, Vijay P. Singh, Peijun Shi, 2017. Nonstationarities in the occurrence rate of heavy precipitation across China and its relationship to climate teleconnection patterns. International Journal of Climatology, DOI: 10.1002/joc.5058. Xihui Gu, Qiang Zhang, Vijay P. Singh, Peijun Shi, 2017. Changes in magnitude, frequency and timing of heavy precipitation across China and its potential links to summer temperature. Journal of Hydrology, 547, 718-731. Xihui Gu, Qiang Zhang, Vijay P. Singh, Peijun Shi, 2017. Nonstationarity in timing of extreme precipitation across China and impact of tropical cyclones. Global and Planetary Change, 149, 153-165. Xihui Gu, Qiang Zhang, Vijay P. Singh, Lin Liu, 2016. Nonstationarity in the occurrence rate of floods in the Tarim River basin, China, and related impacts of climate indices. Global and Planetary Change, 142, 1-13. Qiang Zhang, Xihui Gu, Vijay P. Singh, Mingzhong Xiao, Xiaohong Chen, 2015. Evaluation of flood frequency under non-stationarity resulting from climate change and human activities in the East River basin, China. Journal of Hydrology, 527, 565-575. Qiang Zhang, Xihui Gu, Vijay P. Singh, Mingzhong Xiao, Chong-Yu Xu, 2014. Stationarity of annual flood peaks during 1951-2010 in the Pearl River basin, China. Journal of Hydrology, 519, 3263-3274. What are the motivations, research objectives and novel points of this current study when compared to standing researches? My strong suggestion is that thorough literature review is pretty necessary. New findings, new ideas, new methods, if any, should be pointed out with enough citations to justify authors' statements.*

AUTHORS' REPONSE: Thank you for introducing the overlooked references and for the good suggestion of enhancing the literature review. Following the advice of the reviewer, we have made a more comprehensive literature survey by citing and discussing important recent publications in the field, including those introduced by the reviewer. We have also improved the description of motivations, research objectives and novel points of this current study. The related paragraphs have been changed into the following:

"In hydrological analysis and design, conventional frequency analysis estimates the statistics of a hydrological time series based on recorded data with the stationary hypothesis which means that this series is 'free of trends, shifts, or periodicity (cyclicity)' (Salas, 1993). However, global warming and human forces have changed climate and catchment conditions in some regions. Time-varying climate and catchment conditions can affect all aspects of the flow regime, i.e. changing the frequency and magnitude of floods, altering flow seasonality, and modifying the characteristics of low flows, etc. The hypothesis of stationarity has been suspected (Milly et al., 2008). If this problematic method is still used, the frequency analysis may lead to high estimation error in hydrological design. Therefore, considerable literatures have introduced the concept of hydrologic nonstationarity into analysis of various hydrological variables, such as annual runoff (Arora, 2002; Jiang et al., 2017; Jiang et al., 2015; Liu et al., 2017; Xiong et al., 2014; Yang and Yang, 2013), flood (Chen et al., 2013; Gilroy and Mccuen, 2012; Gu et al., 2016; Kwon et al., 2008; López and Francés, 2013; Tang et al., 2015; Xiong et al., 2015b; Yan et al., 2016; Zhang et al., 2014; Zhang et al., 2015), low flow (Du et al., 2015; Jiang et al., 2014; Liu et al., 2015), precipitation (Cheng and AghaKouchak, 2014; Gu et al., 2017a, b, c; Mondal and Mujumdar, 2015; Shahabul Alam et al., 2014; Villarini et al., 2010) and so on. Compared with the literatures on annual runoff, floods and precipitation, the literatures on the nonstationary analysis of low flow are relatively limited." [Lines 62-78]

"To our knowledge, compared with the nonstationary flood frequency analysis, the studies on the nonstationary frequency analysis of low-flow series is not very extensive because of incomplete knowledge of low flow generation (Smakhtin, 2001). Most of these studies explain nonstationarity of low-flow series only by using climatic indicators or a single indicator of human activity. However, the indicators of catchment conditions (e.g. recession rate) related to physical hydrological processes have seldom been attached in nonstationary modeling of low flow series.This lack of linking with hydrological process makes it impossible to accurately quantify the contributions of influencing factors for the nonstationarity of low flow series, and such a scientific demand for tracing the sources of nonstationarity of low-flow series and qualifying their contributions motivated the present study…" [Lines 100-109]

"The goal of this study is to trace origins of nonstationarity in low flows through developing a nonstationary low-flow frequency analysis framework with the consideration of the time-varying climate and catchment conditions (TCCCs) and human activity (HA). In this framework, the climate and catchment conditions are quantified using the eight indices, i.e., meteorological variables (total precipitation P, mean frequency of precipitation events λ, temperature T and potential evapotranspiration ET), basin storage characteristics (base-flow index BFI, recession constant K) and aridity indexes (climate aridity index AI_{ET}, the recession-related aridity index AI_K). The specific objectives of this study are: (1) to find the most important index to explain the nonstationarity of low-flow series; (2) to determine the best subset of TCCCs indices and/or human activity indices (i.e., population *POP*, irrigation area *IAR*, and gross domestic product *GDP*) for final model through stepwise selection method to identify nonstationary mode of low-flow series; and (3) to quantify the contribution of selected explanatory variables to the nonstationarity." [Lines 131-142]

There are no exact and/or results included in the Abstract section. Or only limited words describing results. More details and particularly in a quantitative way should be provided for description of results and conclusions

AUTHORS' REPONSE: The reviewer is correct. In the modified abstract, we have provided more quantitative results and conclusions. In the revision of the second part of the Abstract, the description of results and findings has been modified as following:

"The results from stepwise regression for the optimal explanatory variables show that the variables related to irrigation, recession, temperature and precipitation play an important role in modeling. Specifically, analysis of annual minimum 30-day flow in Huaxian shows that AI_K is of the highest relative importance among the optimal variables, followed by *IAR (note to reviewer: Irrigated area – a newly added index in the revised version), BFI* and AI_{ET}; and nonstationary GA distribution model with these optimal variables has an AIC value of 207.0, while the AIC values of other models just with AI_K or time as explanatory variables or without any variable are 217.4, 225.5, 232.3, respectively. We conclude that the incorporation of multiple indices related to low-flow generation permits tracing various driving forces." [Lines 29-36]

In Introduction section, it was noticed that there are numerous researches focused on nonstationary low flow frequency analysis. However, no novel points were listed and hence research motivations were not well justified. Besides, as a tributary of the Yellow River, evaporation or evapotranspiration, irrigation, population, GDP and so on should be included as factors influcing low flow changes. Related works have been done using Budyko framework by Prof. Dawen Yang from Tsinghua University and Prof. Qiang Zhang from Beijing Normal University and other colleagues from China. Besides, I still have no idea about how the authors developed the framework to evaluate low flow frequency from a nonstationary perspective.

AUTHORS' REPONSE: Thanks to the reviewer for pointing out this. Firstly, in the introduction section, the related part has been reorganized and modified in order to clarify our research motivations more clearly. Related part for study motivation, refer to the response of the first comment above.

Secondly, following the reviewer's advice, besides the following indices (K, AI_K and *BFI*) that are related to human activities and the indices (K, AI_K and *BFI*) that are linked to physical hydrological processes, in the revised version, we have included the irrigation area (*IAR*), the Gross Domestic Product (*GDP*), and population (*POP*) indices. The process of their change with time has been presented (see Fig. 5 in the revised manuscript). The Pearson correlation coefficients between low-flow series and these indices have been presented (see Fig. 6 in the revised manuscript). The models (M2b, M5, and M6, as described in Table 2 in the revised manuscript) are added. The summary of their results have been presented in Table 5 in the revised manuscript. Analysis of all new results has been shown in Figs. 7, 8, 9, 10 and 11 in the revised manuscript. Besides, we have added the following statements in the discussion section in the revised manuscript.

“The related researches (Jiang et al., 2015; Yang and Yang, 2011; Yang and Yang, 2013; Zhang et al., 2015) have applied the Budyko framework to analyze the impacts of climate change and/or human activity on annual runoff. Indeed, for annual runoff, the Budyko framework is a good method because it used the mean annual water-energy balance equation to consider generation process of total runoff. Unfortunately, to our knowledge, there is a lack of equation derived from basic physics laws for generation process of low flows. Therefore, we emphasize the importance of TCCCs variables to modeling of low-flow nonstationarity.” [Lines 507-513]

Thirdly, the framework is composed of the time varying and GLM methods, and the method of stepwise selection for TCCCs indices and human activity indices. And to address this comment, we have added a flow chat of methodology (Fig. 1 in the revised manuscript) to explain how the framework is organized.

> *In Method section, a working framework should be formulated besides some descriptions.*

AUTHORS’ REPONSE: Thank you for your good suggestion. Following the reviewer’s suggestion we have added a flow chart of methodology, as show in Fig. 1 in the revised manuscript.

> *Why the authors choose Weihe River basin as a case study? Are there any unique features of the study region when compared to other alternative rivers?*

AUTHORS’ REPONSE: The nonstationarity of annual runoff in Weihe River basin has been shown to be very significant (Lin et al., 2012; Xiong et al., 2014). The previous studies have demonstrated that the climate change and human activities play an important role in annual runoff changes. When compared to other alternative rivers, the nonstationarity mode of low flows in the study region is so complex that it is difficult to be identified due to the influence of various factors. This feature aroused our interest in choosing the study area. We try to demonstrate that the nonstationarity of low flows in this basin is caused by multiple factors and more effective analysis model should incorporate not only a single climate index or human activity indices but also the other climate indices and catchment condition indices. We have clarified this point.

-Referee#2-

> ***General Comment*** *This work covered an interesting topic. It is qualified for HESS after a minor revision. Authors incorporated multiple variables into time-varying model by GLM, and called this a nonstationary mode considering TCCCs. They calculated and compared AIC of this mode with that of the stationary mode and the nonstationary mode with a single covariate in two stations in Weihe. Then they concluded this TCCCs nonstationary mode was the optimal one for nonstationary low flow frequency analysis in Weihe.*

AUTHORS' REPONSE: Thank you for your positive evaluation and a good summary of the paper.

> *It's a pity that they did a lot of work without clearly stating their motivation. Authors first raised an issue in review that the previous studies in low flow failed to provide a link between hydrological process and frequency analysis, and this made it difficult for tracing the origins of low flow change. While readers might think they intend to trace these origins (which was also hinted by the title), they defended that "the goal of this study is to develop a nonstationary low-flow frequency analysis framework". It is better for them to keep consistent in the whole introduction section.*

AUTHORS' REPONSE: Thank you for your comments and the good suggestion. This is also pointed out by reviewer 1. Following the reviewer's advice, we have also better stated our study motivation as following.

"To our knowledge, compared with the nonstationary flood frequency analysis, the studies on the nonstationary frequency analysis of low-flow series are not very extensive because of incomplete knowledge of low flow generation (Smakhtin, 2001). Most of these studies explain nonstationarity of low-flow series only by using climatic indicators or a single indicator of human activity. However, the indicators of catchment conditions (e.g. recession rate) related to physical hydrological processes have seldom been attached in nonstationary modeling of low flow series.This lack of linking with hydrological processes makes it impossible to accurately quantify the contributions of influencing factors for the nonstationarity of low flow series, and such a scientific demand for tracing the sources of nonstationarity of low-flow series and qualifying their contributions motivated the present study…" [Lines 100-109]

We have also explicitly defined and stated the study objectives in the 5th paragraph of the Introduction Section, as follows:

"The goal of this study is to trace origins of nonstationarity in low flows through developing a nonstationary low-flow frequency analysis framework with the consideration of the time-varying climate and catchment conditions (TCCCs) and human activity (HA). In this framework, the climate and catchment conditions are quantified using the eight indices, i.e., meteorological variables (total precipitation P, mean frequency of precipitation events λ, temperature T and potential evapotranspiration ET), basin storage characteristics (base-flow index BFI, recession constant K) and aridity indexes (climate aridity index AI_{ET}, the recession-related aridity index AI_K).The specific objectives of this study are: (1) to find the most important index to explain the nonstationarity of low-flow series; (2) to determine the best subset of TCCCs indices and/or human activity indices (i.e., population *POP*, irrigation area *IAR*, and gross domestic product *GDP*) for final model through stepwise selection method to identify nonstationary mode of low-flow series; and (3) to quantify the contribution of selected explanatory variables to the nonstationarity." [Lines 131-142]

Besides, to better show the advantage of this framework, which was composed of the time-varying and GLM method, they should compare it with other models using only climatic indicators or a single indicator of human activity, just as they mentioned in the review, not just the mode with either AIK or BFI as the explanatory variable.

AUTHORS' REPONSE: Thank you for the comment. Our study had included the model with climate indicators. But, indeed, the model with a single indicator of human activity (e.g. irrigation, population, GDP as mentioned by the first reviewer) was not involved in the original submission. Thus to address this comment, the main and supplementary texts have been revised to compare the nonstationary mode considering TCCCs with the nonstationary mode considering human activity (irrigation, population, GDP), as also stated in the reply to reviewer 1. The process of their change with time has been presented (see Fig. 5 in the revised manuscript). The Pearson correlation coefficients between low-flow series and these indices have been presented (see Fig. 6 in the revised manuscript). The models (M2b, M5, and M6, as described in Table 2 in the revised manuscript) are added. The summary of their results has been presented in Table 5 in the revised manuscript. All new results have been shown in Figs. 7, 8, 9, 10 and 11 in the revised manuscript. Statements in the Results Section have been added and revised, as shown in the revised manuscript with tracked changes.

In addition, there are some mistakes and improper statements in this paper; outlines of methods and results are unclear, and the discussion is weak. It is better for authors to put together contents of results and discussion, and further discuss their results and compared with other related works.

AUTHORS' REPONSE: Thank you for your comment. The mistakes and improper statements have been carefully checked and corrected in the revised version; to clarify methods, a flow chart of methodology and a table which summarizes the explanatory variables have been added; and we have revised the contents of results and discussion, following the reviewer's good suggestion. The revised manuscript has included further discussion of results and comparison with other related works as following:

“Overall, the causes of nonstationarity in category for two gauging stations have no clear difference, but have some differences in the relative importance. As shown in Table 5, when modeling the low-flow series of Huaxian using TCCCs variables, the optimal model (M4) preferred the variables are related to recession process; however, for Xianyang, the preferred variables are related to temperature. The reason for this may be that as a downstream station, Huaxian station suffers more intensive human activity, so that the importance of temperature change to the low-flow change is reduced, and meanwhile the importance of streamflow recession (related to the capability of water storage) change is enhanced.” [Lines 493-501]

“The related researches (Jiang et al., 2015; Yang and Yang, 2011; Yang and Yang, 2013; Zhang et al., 2015) have applied the Budyko framework to analyze the impacts of climate change and/or human activity on annual runoff. Indeed, for annual runoff, the Budyko framework is a good method because it used the mean annual water-energy balance equation to consider generation process of total runoff. Unfortunately, to our knowledge, there is a lack of equation derived from basic physics laws for generation process of low flows. Therefore, we emphasize the importance of TCCCs variables to modeling of low-flow nonstationarity.” [Lines 507-513]

> ***Specific Comment*** *The logic of review in the introduction is not smooth. Some references mentioned in the paragraph starting from Line 52, such as Lars Gottschalk's work, were badly concluded and they'd better be put in the next paragraph.*

AUTHORS’ REPONSE: Thank you for pointing out this and for your good suggestion. To address your comment, we have revised the introduction as mentioned above.

> *A flow chart of methodology is needed.*

AUTHORS’ REPONSE: This is a good point. To address your comment, we have added it (Fig. 1 in the revised manuscript).

> *Line 127 Meaning of this sentence is obscure.*

AUTHORS’ REPONSE: The sentence has been revised as following: “The distribution type used to build the nonstationary model is outlined”

> *Further explanation for the selection of 8 candidate variables is needed.*

AUTHORS’ REPONSE: Thank you for the comment. To address this comment, the 1st paragraph of ‘Section 2.3 Candidate explanatory variables’ has been revised. And the reason for the selection of 8 candiadte variables has been listed in Table 3 in the revised manuscript.

> *Indices more related to irrigation, like irrigation area, need to be considered, since (Line278) In the Weihe basin, the impacts of agricultural irrigation on runoff have been found to be significant.*

AUTHORS' REPONSE: Thank you for the comment. Following reviewer's suggestions, we have included this index (irrigation area) as mentioned above.

Both those 8 explanatory variables and data resources can be summarized in two tables.

AUTHORS' REPONSE: This is a good point. To address this comment, we have revised the text and added Table 3 in the revised manuscript.

I don't see much use in Figure 2.

AUTHORS' REPONSE: Thank you for the comment. Following your suggestion, the Figure has been deleted in the revised manuscript.

Why do you need to study all the series from AM1, 7, 15 to 30?

AUTHORS' REPONSE: The main reason for including four series is to investigate whether the time scale of the series affects the nonstationary mode. As shown in Figure 7 (the revised manuscript), the effect of time scale is existed but limited. In response to this good comment, we have revised the part of the Multiple Covariate Analysis Section to focus on the AM_{30} series.

In some subplans in Figure 8, AIC of either M2 or M3 is worse than M1. What is the probable cause? The conclusion in Line 391 cannot be directly generated from Figure8.

AUTHORS' REPONSE: We have explained that this phenomenon mainly appears in the AM_1 and AM_7 series. AM_1 and AM_7 series are more vulnerable, which means that multiple causes can affect them. The nonstationary mode with one or two physical explanatory variables (M2 or M3) cannot work well for AM_1 and AM_7. However, the overall decreased trend caused by multiple factors is consistent with the nonstationary mode with time (M1).

What is the impact of location difference on the different AIC results in two stations? Needs to add discussion.

AUTHORS' REPONSE: This is a good point. Following the reviewer's suggestion, we have added a supplemental part to the discussion section (see lines 482-489 in the revised manuscript).

The standard of selecting M4 variables with stepwise selection method needs to be further clarified.

AUTHORS' REPONSE: Following the reviewer's suggestion, we have clarified the standard of the models' variables using Fig. 1 in the revised manuscript.

Table5 and 6 can be merged into one table.

AUTHORS' REPONSE: Agree, corrected.

Formula 2, no need to put "i=" on the top

AUTHORS' REPONSE: Corrected.

Table2, add explanation for parameters down below the table

AUTHORS' REPONSE: Corrected.

The definition, reason of selection, and formula of 8 indices should be listed in a table.

AUTHORS' REPONSE: Corrected.

Line228, 234, 242 add blank space before the paragraph (need to check in the whole paper)

AUTHORS' REPONSE: Corrected.

Line298 slash tag between "n" and "day" is missing (check the whole paper)

AUTHORS' REPONSE: Corrected.

Line304 mistake in time tense

AUTHORS' REPONSE: Corrected.

Line388 incomplete sentence

AUTHORS' REPONSE: Corrected.

Figure1 mark the location of Weihe in the map of China with a rectangular frame

AUTHORS' REPONSE: Corrected.

Figure3 adding R

AUTHORS' REPONSE: Corrected.

Figure 3 &4 lines are too thick

AUTHORS' REPONSE: Corrected.

Figure5&6 differences among colors are too delicate to be seen

AUTHORS' REPONSE: Corrected.

Table 3 &4 add division lines among rows of different stations

AUTHORS' REPONSE: Corrected.

Mistake in references, year of "Bivariate frequency analysis of nonstationary low-flow series based on the time-varying copula" was 2015

AUTHORS' REPONSE: Thank you for pointing out this. We have corrected this.

Abstract:

Under the background of global climate change and local anthropogenic activities, multiple driving forces have introduced ~~a variety of~~ various non-stationary components into low-flow series. This has led to a high demand on low-flow frequency analysis that considers nonstationary conditions for modeling. In this study, through a nonstationary frequency analysis framework ~~of low-flow frequency analysis has been developed on basis of~~ with the Generalized Linear Model (GLM) to consider time-varying distribution parameters, ~~. In GLMs,~~ the ~~candidate~~ multiple explanatory variables were~~as~~ incorporated to explain ~~the time-varying~~ the variation in low-flow distribution parameters. These variables are comprised of the three indices of human activities (i.e., population *POP*, irrigation area *IAR*, and gross domestic product *GDP*) and the eight measuring indices of the climate and catchment conditions ~~in low flow generation,~~ (i.e., total precipitation P, mean frequency of precipitation events λ, temperature T, potential evapotranspiration ET, climate aridity index AI_{ET}, base-flow index BFI, recession constant K and the recession-related aridity index AI_K). This framework was applied to model the annual minimum flow series of both Huaxian and Xianyang gauging stations in the Weihe River, China. ~~Stepwise regression analysis was performed to obtain the best subset of those candidate explanatory variables for the final optimum model.~~ The results from stepwise regression for the optimal explanatory variables show that ~~the inter-annual variability in the variables of those selected best subsets~~ the variables related to irrigation, recession, temperature and precipitation play~~s~~ an important role in modeling ~~annual low flow series~~. Specifically, analysis of annual minimum 30-day flow in Huaxian shows that AI_K is of the highest relative importance among the optimal variables, followed by *IAR*, *BFI* and AI_{ET}~~;~~, and nonstationary GA distribution model with these optimal variables has~~ve~~ an AIC value of 207.0, while the AIC values of other models just with AI_K or time as explanatory variable~~s~~ or without any variable are 217.4, 225.5, 232.3, respectively. ~~AI_K is of the highest relative importance among the best subset of eight candidates, followed by *BFI* and AI_{ET}.~~ We conclude that ~~The~~ the incorporation of multiple indices related to low-flow generation permits tracing various driving forces. The established link in nonstationary analysis will be beneficial to ~~predict~~ analyze future occurrences of low-flow extremes in similar areas.

1. Introduction

Low flow is defined as the 'flow of water in a stream during prolonged dry weather' (WMO, 1974). Yu et al. (2014) quantitatively described a low flow event as a segment of hydrograph during a period of dry weather with discharge values below a preset (relatively small) threshold. According to WMO (2009), annual minimum flows averaged over several days can be used to measure low flows. During low-flow periods, the magnitude of river flow will greatly restrict its various functions (e.g. providing water supply for production and living, diluting waste water, ensuring navigation, meeting ecological water requirement). Therefore, ~~T~~the investigation of the magnitude and frequency of low flows is of primary importance for engineering design and water resources management (Smakhtin, 2001). ~~For~~ In recent years, low flows, as an important part of river flow regime, have been attracting ~~the~~ an increasing attention~~s~~ of hydrologists and ecologists~~,~~ ~~due to~~ in the context of the significant impacts of climate change and human activities ~~on most functions (e.g. providing water supply for production and living, diluting waste water, ensuring navigation, meeting ecological water requirement) of river flow during low-flow periods.~~ (Bradford and Heinonen, 2008; Du et al., 2015; Kam and Sheffield, 2015; Kormos et al., 2016; Liu et al., 2015; Sadri et al., 2015; Smakhtin, 2001; WMO, 2009). In general, under the impact of a changing environment, combinations of multiple factors, such as precipitation change, temperature change, irrigation area change and construction of reservoirs, can drive various patterns of streamflow changes (Liu et al., 2017; Tang et al., 2015). Unfortunately, when subjected to a variety of influencing forces, low flow is more vulnerable than high flow or mean flow. Therefore, it is a pretty important issue in hydrology to identify low-flow changes, track multiple driving factors and quantify their contributions from the perspective of hydrological frequency analysis.

In hydrological analysis and design, conventional frequency analysis estimates the statistics of a hydrological time series based on recorded data with the stationary hypothesis which means that this series is “free of trends, shifts, or periodicity (cyclicity)” (Salas, 1993). However, global warming and human forces have changed climate and catchment conditions in some regions. Time-varying climate and catchment conditions can affect all aspects of the flow regime, i.e. changing the frequency and magnitude of floods, altering flow seasonality, and modifying the characteristics of low flows, etc. The hypothesis of stationarity has been suspected (Milly et al., 2008). If this problematic method is still used, the frequency analysis may lead to high estimation error ~~and costly~~in hydrological design. Therefore, considerable literatures have introduced the concept of hydrologic nonstationarity into analysis of various hydrological variables, such as annual runoff (Arora, 2002; Jiang et al., 2017; Jiang et al., 2015; Liu et al., 2017; Xiong et al., 2014; Yang and Yang, 2013), flood (Chen et al., 2013; Gilroy and Mccuen, 2012; Gu et al., 2016; Kwon et al., 2008; López and Francés, 2013; Tang et al., 2015; Xiong et al., 2015b; Yan et al., 2016; Zhang et al., 2014; Zhang et al., 2015), low flow (Du et al., 2015; Jiang et al., 2014; Liu et al., 2015), precipitation (Cheng and AghaKouchak, 2014; Gu et al., 2017a, b, c; Mondal and Mujumdar, 2015; Villarini et al., 2010) and so on. Compared with the literatures on annual runoff, floods and precipitation, the literatures on the nonstationary analysis of low flow are ~~very~~relatively limited.

Previous hydrological literatures on frequency analysis of nonstationary ~~low flow~~ hydrological series mainly focus on two aspects: development of nonstationary method and exploration of covariates reflecting changing environments. Strupczewski et al. (2001) presented the method of time-varying moment which assumes that the hydrological variable of interest obeys a certain distribution type, but its moments change over time. The method of time-varying moment was modified to be the method of time-varying parameter values for the distribution representative of hydrologic data (Richard et al., 2002). Villarini et al. (2009) presented this method using the Generalized Additive Models for Location, Scale, and Shape Parameters (GAMLSS) (Rigby and Stasinopoulos, 2005), a flexible framework to assess nonstationary time series. The time-varying parameter method can be extended to the physical covariate analysis by replacing time with any other~~s~~ physical covariates (Du et al., 2015; Jiang et al., 2014; Kwon et al., 2008; López and Francés, 2013; Liu et al., 2015; Villarini et al., 2010; Villarini and Strong, 2014). For example, Jiang et al. (2014) used reservoir index as an explanatory variable~~s~~ based on the time-varying copula method for bivariate frequency analysis of nonstationary low-flow series in Hanjiang River, China. Du et al. (2015) took precipitation and air temperature as the explanatory variables to explain the inter-annual variability in low flows of Weihe River, China. Liu et al. (2015) took Sea Surface Temperature in Nino3 region, the Pacific Decadal Oscillation, the sunspot number (3 years ahead), the winter areal temperature and precipitation as the candidate explanatory variables to explain the inter-annual variability in low flows of Yichang station, China. Kam and Sheffield (2015) ascribed the increasing inter-annual variability of low flows over the eastern United~~s~~ States to North Atlantic Oscillation and Pacific North America.

~~Low flows are more vulnerable to influences of climate change and human activities than high flows. However,~~ To our knowledge, compared with the nonstationary flood frequency analysis, the studies on the nonstationary frequency analysis of low-flow series is not very extensive because of incomplete knowledge of low flow generation (Smakhtin, 2001). Most of these studies explain nonstationarity of low-flow series only by using climatic indicators or a single indicator of human activity. However, the indicators of catchment conditions (e.g. recession rate) related to physical hydrological processes have seldom been attached in nonstationary modeling of low flow series. ~~This leads to lack of linking with hydrological process, which in turn would exclude further analysis, such as accurately tracing origins of change in low flow series~~This lack of linking with hydrological processes makes it impossible to accurately quantify the contributions of influencing factors for the nonstationarity of low flow series, and such a scientific demand for tracing the sources of nonstationarity of low-flow series and qualifying their contributions motivated the present study. The knowledge of low-flow generation has been increased by efforts of hydrologists, which can help develop physical covariates to address nonstationarity. Low flows generally originate from groundwater or other delayed outflows

(Smakhtin, 2001; Tallaksen, 1995). Their generation relates to both an extended dry weather period (leading to a climatic water deficit) and complex hydrological processes which determine how these deficits propagate through the vegetation, soil and groundwater system to streamflow (WMO, 2009). Thus, not only climate condition~~s~~ drivers (e.g. potential evaporation exceeds precipitation), but also catchment condition~~s~~ drivers (e.g. the faster hydrologic response rate to precipitation) can cause low flows.

The significant factors such as precipitation, temperature, evapotranspiration, streamflow recession, large-scale teleconnections and human forces may play important roles in influencing low-flow generation (Botter et al., 2013; Giuntoli et al., 2013; Gottschalk et al., 2013; Jones et al., 2006; Kormos et al., 2016; Roderick et al., 2013; Sadri et al., 2015). Gottschalk et al. (2013) presented a derived low flow probability distribution function with climate and catchment characteristics parameters (i.e., the mean length of dry spells λ^{-1} and recession constant of streamflow K) as its distribution parameters. Botter et al. (2013) derived "a measurable index" (λ^{-1}/K) which can be used for discriminating erratic river flow regimes from persistent river flow regimes. Recently, ~~in~~ Van Loon and Laaha (2015) used climate and catchment characteristics (e.g. the duration of dry spells in precipitation and the base flow index) to explain the duration and deficit of hydrological drought event and offered a further understanding of low-flow generation. Th~~o~~ese studies indicated that climate and catchment conditions play an important role in producing low flows.

The goal of this study is to trace origins of nonstationarity in low flows through developing a nonstationary low-flow frequency analysis framework with the consideration of the time-varying climate and catchment conditions (TCCCs) and human activity (HA). ~~The goal of this study is to develop a nonstationary low-flow frequency analysis framework with the consideration of the time-varying climate and catchment conditions (TCCCs).~~ In this framework, the climate and catchment conditions are quantified using the eight indices, i.e., meteorological variables (total precipitation P, mean frequency of precipitation events λ, temperature T and potential evapotranspiration ET), basin storage characteristics (base-flow index BFI, recession constant K) and aridity indexes (climate aridity index AI_{ET}, the recession-related aridity index AI_K). The specific objectives of this study are: (1) to find the most important index to explain the nonstationarity of low-flow series; (2) to determine the best subset of TCCCs indices and/or human activity indices (i.e., population *POP*, irrigation area *IAR*, and gross domestic product *GDP*) for final model through stepwise selection method to identify nonstationary mode of low-flow series; and (3) to quantify the contribution of selected explanatory variables to the nonstationarity. ~~The non-stationary frequency analysis with TCCCs developed in this study is able to give the trace of nonstationary low-flow drivers and to estimate the contribution of each driver to the change in low-flow series.~~

This paper is organized as follows. Section 2 describes the methods. ~~We describe t~~The Weihe River basin and available data sets used in this study are described in Section 3, followed by a presentation of the results and discussion in Section 4. Section 5 summarizes the main conclusions.

2 Methodology

The flowchart of how to organize the nonstationary low-flow frequency analysis framework is shown in Fig. 1. The whole process is divided into three steps. The first step is preliminary analysis, including the graphical presentation of both explanatory variables and low-flow series, the statistical test for nonstationarity and the correlations between each explanatory variable and each low-flow series. The second step is single covariate analysis for the most important explanatory variable. The third step is multiple covariate analysis for the optimal combination. We use a low-flow frequency analysis model and stepwise regression method to accomplish the last two steps. In ~~this~~ the following sub-sections, first, the low-flow frequency analysis model is constructed based on the nonstationary probability distributions method, in which distribution parameters serving as response variables can vary as functions of explanatory variables. Second, ~~the candidate distributions are described to determine the different types of nonstationary frequency curves.~~ the distribution types used to build the nonstationary model are outlined. Then, the ~~eight~~ candidate explanatory variables related to the time-varying climate and catchment conditions (TCCCs) and human activity (HA) are clarified~~presented to incorporate time-varying climate and catchment conditions (TCCCs) into distribution models for the nonstationary frequency analysis~~. Finally, estimation of model parameters and selection of models are illustrated.

<Figure 1>

2.1 Construction of the low-flow nonstationary frequency analysis model

Generally, a nonstationary frequency analysis model can be established based on the time-varying distribution parameters method (Du et al., 2015; López and Francés, 2013; Liu et al., 2015; Richard et al., 2002; Villarini and Strong, 2014). For the nonstationary probability distribution $f_Y\left(Y_t\middle|\boldsymbol{\theta}^t\right)$, let Y_t be a random variable at time t $(t=1,2,...,N)$ and vector $\boldsymbol{\theta}^t=[\theta_1^t,\theta_2^t,...,\theta_m^t]$ be the time-varying parameters. The number of parameters m in hydrological frequency analysis is generally limited to three or less. The function relationship between the k^{th} parameter θ_k^t and the multiple explanatory variables is expressed as follows:

$$g_k\left(\theta_k^t\right)=h_k\left(x_1^t,x_2^t,...,x_n^t\right) \tag{1}$$

where $x_1^t,x_2^t,...,x_n^t$ are explanatory variables; n is the number of explanatory variables; $g_k(\cdot)$ is the link function which ensures the compliance with restrictions on the sample space and is usually set to natural logarithm for the given negative predictions; $h_k(\cdot)$ is the function for nonstationary modeling. The theory of Generalized Linear Model (Dobson and Barnett, 2012) is used to build function relationships between distribution parameters and their explanatory variables. In GLMs, the response relationship can be generally expressed as

$$g_k\left(\theta_k^t\right)=\alpha_{0k}+\sum_{i=1}\alpha_{ik}x_i^t \tag{2}$$

where α_{ik} $(i=0,1,2,...,n,k=1,...,m)$ are the GLM parameters.

In order to ~~give a further nonstationary analysis~~compare the nonstationary models constructed by various combinations of explanatory variables, Eq. (2) is modified in this study using dimensionless method for the standard GLM parameters. The value of θ_k^t could be assumed to be equal to its mean ($\bar{\theta}_k$) when all explanatory variables are equal to their mean ($\bar{x}_i$), i.e.,

$$\theta_k^t\left(x_1^t=\bar{x}_1,x_2^t=\bar{x}_2,...,x_n^t=\bar{x}_n\right)=\bar{\theta}_k \tag{3}$$

Eq. (2) is then modified as

$$\begin{gathered}g_k\left(\frac{\theta_k^t}{\bar{\theta}_k}\right)=\beta_{0k}+\sum_{i=1}^{i=n}\beta_{ik}z_i^t\\ z_i^t=\frac{x_i^t-\bar{x}_i}{s_i},\qquad i=1,2,\ldots,n\\ \beta_{0k}=g_k\left(\frac{\theta_k^t}{\bar{\theta}_k}\middle|\theta_k^t=\bar{\theta}_k\right)=g_k\left(1\right)\end{gathered} \tag{4}$$

where z_i^t is normalized explanatory variable~~s~~; s_i is the standard deviation of x_i^t; β_{ik} $(i=1,2,...,n,k=1,...,m)$ are the standard GLM parameters. Let the link function $g_k(\cdot)$ be the natural logarithmic function $\ln(\cdot)$ and θ_l^t be the distribution parameter in $[\theta_1^t,\theta_2^t,...,\theta_m^t]$ with most significant change, the degree of nonstationarity in low flow series can be defined as $\ln(\theta_l^t)-\ln(\bar{\theta}_l)$. Then, the contribution c_i^t of each explanatory variable x_i^t to $\ln(\theta_l^t)-\ln(\bar{\theta}_l)$

could be defined as

$$c_i^t = \beta_{il} \frac{x_i^t - \overline{x}_i}{s_i} \tag{5}$$

2.2 Candidate distribution functions

We need to select the form of probability distribution $f_Y(\cdot)$ to determine what type of nonstationary frequency curves will be produced. Various probability distributions have been compared or suggested in modeling of low-flow series (Du et al., 2015; Hewa et al., 2007; Liu et al., 2015; Matalas, 1963; Smakhtin, 2001). An extensive overview of distribution functions for low flow is given in Tallaksen et al. (2004). Following these recommendations, we consider five distributions, i.e. Pearson-III (PIII), Gamma (GA), Weibull (WEI), Lognormal (LOGNO) and Generalized Extremes Value (GEV) as candidates in this study (Table 1). In the case of Pearson-III distribution, considering that the parameter θ_3 of Pearson-III as lower bound should approach zero and the parameter θ_3 of GEV is quite sensitive and difficult to be estimated, we assume them to be constant in this study.

2.3 Candidate explanatory variables

We look for variables $x_1^t, x_2^t, ..., x_n^t$ that can explain parts of the variations in distribution parameters $\boldsymbol{\theta}^t$. From the perspective of low-flow generation, the dependency between low-flow regime and both climate and catchment conditions has been presented by previous studies (Botter et al., 2013; Gottschalk et al., 2013; Van Loon and Laaha, 2015). We focus on eight measuring indices: total precipitation, mean frequency of precipitation events, temperature, potential evapotranspiration, climate aridity index, base-flow index, recession constant and recession-related aridity index. These indices were chosen to incorporate time-varying climate and catchment conditions (TCCCs) in nonstationary modeling~~,~~ of low-flow frequency and serving as candidate explanatory variables. The values of them at each year could be estimated from hydro-meteorological data. Annual precipitation (P) and temperature (T) are calculated directly by meteorological data. The remaining TCCCs indices need to be estimated indirectly. Detailed estimation procedures are shown ~~as follows~~ in following subsections. In addition to TCCCs indices, the three indices of human activity (irrigation area, population and gross domestic product) are included, and the reasons for selecting all indices are summarized in Table 2.

2.3.1. Annual mean frequency of precipitation events (λ)

Annual mean frequency of precipitation events is defined as an index to represent the intensity of precipitation recharge to the streamflow:

$$\lambda = \frac{1}{W}\sum_{w=1}^{w=W}\frac{N_w(A)}{t_r} \tag{6}$$

where $N_w(A)$ is the number of daily rainfall events A (with values more than the threshold 0.5 mm) in w^{th} windows with a length t_r; W is the number of windows.

2.3.2. Annual climate aridity index (*AI_{ET}*)

The ratio of annual potential evaporation to precipitation, commonly known as the climate aridity index, has been used to assess the impacts of climate change on annual runoff (Arora, 2002; Jiang et al., 2015). The climate aridity index largely reflects the climatic regimes in a region and determines runoff rates (Arora, 2002). Therefore, we choose the annual climate aridity index as a measure of time-varying climate and catchment conditions and estimate its value in a whole region using

$$AI_{ET} = \frac{ET}{P} \tag{7}$$

where P is annual areal precipitation (mm); ET is annual areal potential evapotranspiration. The Hargreaves equation (Hargreaves and Samani, 1985) is applied to calculate ET using the R-package ‘Evapotranspiration’ (Guo, 2014).

2.3.3. Annual base-flow index (*BFI*)

The base flow index (*BFI*) is defined as the ratio of base flow to total flow. This index has been applied to quantify catchment conditions (e.g. soil, geology and storage-related descriptors) to explain hydrological drought severity (Van Loon and Laaha, 2015). We also choose annual base flow index (BFI) as a measure of TCCCs. BFI is estimated using a hydrograph separation procedure in R-package ‘lfstat’ (Koffler and Laaha, 2013).

2.3.4. Annual streamflow recession constant (*K*)

Recession constant is an important catchment characteristic index measuring the time scale of the hydrological response and reflecting water retention ability in the upstream catchment (Botter et al., 2013). Various estimation methods have been developed to extract recession segments and to parameterize characteristic recession behavior of a catchment (Hall, 1968; Sawaske and Freyberg, 2014; Tallaksen, 1995).

In this study, annual recession analysis (ARA) is performed to obtain annual streamflow recession constant (*K*). In ARA, the linearized Depuit-Boussinesq equation is used to parameterize characteristic recession behavior of a catchment and is written as

$$-\frac{dQ_t}{dt} = \frac{1}{K} Q_t \qquad (8)$$

where Q_t is the value at time t. Eq. (8) is investigated by plotting data points $\frac{dQ_t}{dt}$ against Q_t of all extracted recession segments from hydrographs at each year. The criteria of recession segments extraction ~~is~~ are based on the Manual on Low-flow Estimation and Prediction (WMO, 2009). Then, the annual recession rate (K^{-1}) is estimated as the slope of fitted straight line of these data points with least square method. We calculated K using R-package 'lfstat' (Koffler and Laaha, 2013).

2.3.5. Annual recession-related aridity index (AI_K)

In this study, recession-related aridity index is defined as the ratio of recession rate (K^{-1}) to mean precipitation frequency (λ), denoted as

$$AI_K = \frac{K^{-1}}{\lambda} \tag{9}$$

This ratio plays an important role in controlling ~~on~~ river flow regime (Botter et al., 2013; Gottschalk et al., 2013) and serves as an indicator measuring the recession-related aridity degree of the streamflow in river channel. For example, faster recession process or lower precipitation frequency may lead to increased runoff loss or decreased precipitation supply. Consequently, the higher the value AI_K is, the more likely low flow events occur, and vice versa.

2.4 Parameter estimation

The model parameters including $\overline{\theta}_k (k=1,2,...,m)$ and β_{ik} $(i=1,2,...,n,k=1,...,m)$ are estimated. $\overline{\theta}_k (k=1,2,...,m)$ are estimated from outputs of stationary frequency analysis through maximum likelihood method. We have

$$L\left(\overline{\theta}_1, \overline{\theta}_2, ..., \overline{\theta}_m\right) = \sum_{t=1}^{t=N} \ln\left[f_Y\left(y_t \middle| \overline{\theta}_1, \overline{\theta}_2, ..., \overline{\theta}_m \right) \right] \tag{10}$$

where y_t is observed low flow at time t; N is the number of samples. The parameters β_{ik} $(i=1,2,...,n,k=1,...,m)$ are estimated through maximum likelihood method to produce nonstationary low-flow frequency curves:

$$L\begin{pmatrix}\beta_{11},\ldots,\beta_{n1}\\ \ldots\\ \beta_{1m},\ldots,\beta_{nm}\end{pmatrix}=\sum_{t=1}^{t=N}\ln\left\{f_Y\left(y_t\left|\theta_1^t\left(z_1^t,\ldots,z_n^t\left|\beta_{11},\ldots,\beta_{n1}\right.\right),\ldots,\theta_m^t\left(z_1^t,\ldots,z_n^t\left|\beta_{1m},\ldots,\beta_{nm}\right.\right)\right.\right)\right\} \tag{11}$$

The residuals (normalized randomized quintile residuals) are used to test the goodness-of-fit of fitted model objects (Dunn and Symth, 1996):

$$\hat{r}_t=\Phi^{-1}\left(F_Y\left(y_t\left|\hat{\boldsymbol{\theta}}^t\right.\right)\right) \tag{12}$$

where $F_Y(\cdot)$ is the cumulative distribution of y_t; $\Phi^{-1}(\cdot)$ is the inverse function of the standard normal distribution. The distribution of the true residuals $\hat{r}_t$ converges to standard normal if the fitted model is correct. Worm plot (Buuren and Fredriks, 2001) is used to check whether $\hat{r}_t$ have a standard normal distribution.

2.5 Model selection

Model selection contains the selection of the type of probability distribution and the selection of the explanatory variables to explain the response variables (i.e., distribution parameters θ_1 and θ_2). In order to obtain the final optimal model, the selection of the explanatory variables for θ_1 and θ_2 is conducted by a stepwise selection strategies (Stasinopoulos and Rigby, 2007; Venables, 2002): i.e. select a best subset of candidate explanatory variables for θ_1 using a forward approach (which starts with no explanatory variable in the model and tests the addition of each explanatory variable using a chosen model fit criterion); given this subset for θ_1 select another subset for θ_2 (forward). The stepwise selection strategies can get a series of stepwise models with different numbers of explanatory variables, as shown in Fig1. In order to detect how the number of explanatory variables influences the performance of the model for describing non-stationarity, we investigate the ~~five~~ eight types of stepwise models as shown in Table 3: the zero-covariate model or stationary model (M0), the time covariate model (M1), single physical covariate model M2 (single TCCCs covariate model M2a or single HA covariate model M2b), ~~the double physical~~two TCCCs covariates model (M3)~~ and~~ , the optimal ~~number physical~~TCCCs covariates model (M4), ~~as shown in Table 2~~ the optimal HA covariates model (M5) and the final model (M6). The model fit criterion is based on the Akaike's information criterion (Akaike, 1974) as shown by the following

$$AIC = -2ML + 2df \tag{13}$$

where ML is the log-likelihood in Eq. (11) and df is the number of degrees of freedom. The model with the lower AIC value was considered better.

3. Study Area and Data

3.1. The study area

The Weihe River, located in the southeast of the Northwest Loess Plateau, is the largest tributary of the Yellow River, China. The Weihe River has a drainage area of 134 766 km^2, covering the coordinates of 33°42′-37°20′N 104°18′-110°37′E (Fig. ~~1~~2). This catchment generally has a semi-arid climate, with extensive ~~sub-humid~~ continental monsoonal influence.

Average annual precipitation of the whole area over the period 1954-2009 is about 540 mm, and has a wide range (400-1000 mm) in various regions. Under the significant impacts of climate change and human activities in the Weihe River basin in recent decades, the hydrological regime of the river has changed over time (Du et al., 2015; Jiang et al., 2015; Xiong et al., 2015a).

<Figure ~~1~~2>

In the Weihe basin, the impacts of agricultural irrigation on runoff have been found to be significant (Jiang et al., 2015; Lin et al., 2012). Lin et al. (2012) mentioned that the annual runoff of the Weihe River was significantly affected by irrigation diversion of the Baoji Gorge irrigation area. The irrigated area of Baoji Gorge Irrigation Area increased over time since the founding of P.R. China in 1949, and due to one influential irrigation system project in that area, it became more than twice of the original ~~one~~ irrigation area since 1971. Jiang et al. (2015) demonstrated that in the Weihe basin, irrigated area, as compared with the other indices e.g. population, gross domestic product and cultivated land area, was a more suitable human explanatory variable for explaining the time-varying behavior of annual runoff. With~~in~~ the above background, it is important to considering the effects of human activities that mainly originate from irrigation diversion, and especially for studying low flow series in this basin. In this study, we use the available data (1980-2005) of the irrigation diversion system on plateau in Baoji Gorge Irrigation Area in Zhang (2008) to provide some information for the knowledge of low flow generation. The estimations of annual recession rate (K^{-1}) by the daily streamflow data are expected to incorporate the information of impacts of water diversions on the low flows in the river channel.

3.2. ~~Streamflow d~~Data

We used daily streamflow records (1954-2009) provided by the Hydrology Bureau of the Yellow River Conservancy Commission from both Huaxian station (with a drainage area of 106 500 km^2) and Xianyang station (with a drainage area of 46 480 km^2). Low-flow extreme events were selected from the daily streamflow series using the widely-used annual minimum series method (WMO, 2009). AM_n is the annual minimum ~~*n*-~~*n*-day flow during hydrological year ~~defined to star~~beginning~~t~~ on 1 March. Consequently, AM_1, AM_7, AM_{15} and AM_{30} are selected as low-flow extreme events in this study. The original measure unit of streamflow data ($\mathrm{m^3 \cdot s^{-1}}$) is converted to $10^{-4}\ \mathrm{m^3 \cdot s^{-1} \cdot km^{-2}}$ ~~by dividing by the corresponding drainage area (km^2)~~ for convenience of comparison of results between the Huaxian and Xianyang gauging stations

~~3.3. Precipitation and temperature data~~

We downloaded daily total precipitation and daily mean air temperature records for 19 meteorological stations over the basin from the National Climate Center of the China Meteorological Administration (source: http://cdc.cma.gov.cn). The areal average daily series of both variables above Huaxian and Xianyang stations are calculated using the Thiessen polygon method (Szolgayova et al., 2014; Thiessen, 1911). The annual average temperature (T) and annual total precipitation (P) over the period 1954-2009 are calculated for each catchment.

Human activity data (i.e. gross domestic product, population and irrigation area) were taken from annals of statistics provided by the Shaanxi Provincial Bureau of Statistics (http://www.shaanxitj.gov.cn/) and Gansu Provincial Bureau of Statistics (source: http://www.gstj.gov.cn/).

4. Results and discussion

4.1. Identification of nonstationarity

~~Figure 2 shows that the Weihe River basin is characterized by a warm and humid summer (June, July, and August) with low ratio of irrigated diversion, and by a cold and dry winter (December, January, and February) with high ratio of irrigated diversion. The majority of the low flow events in this basin occur in these two seasons and show a bimodal frequency distributions of occurrence with two peaks in February and June, respectively (Fig. 2a). This result implies that the generation of low flows may be influenced by more than one factor such as high ratio of irrigated diversion, high air temperature or lack of precipitation.~~

~~<Figure 2>~~

Graphical representation and statistical test provide a preliminary analysis for low-flow nonstationarity. The graphical representations of time-series data help visualize the trends of related variables (i.e. low-flow, TCCCs and HA variables), the density distributions of TCCCs variables and the correlations between low-flow variables and these explanatory variables. In Fig. 3, ~~Overall~~overall, four annual minimum streamflow series (AM_1, AM_7, AM_{15} and AM_{30}) in both Huaxian and Xianyang gauging stations show overall decreasing trends, as indicated by the fitted (dashed) trend lines~~ in Fig. 3~~. Compared with Huaxian, Xianyang has a larger runoff modulus (the flow per square kilometer) and a larger decrease in annual minimum streamflow series. For example, the decline slope of AM_{30} is -0.0725 $(10^{-4}\,\mathrm{m}^3\cdot\mathrm{s}^{-1}\cdot\mathrm{km}^{-2}/\mathrm{yr})$ in Huaxian station ~~which~~ while Xianyang station it is ~~larger than~~ -0.1338 $(10^{-4}\,\mathrm{m}^3\cdot\mathrm{s}^{-1}\cdot\mathrm{km}^{-2}/\mathrm{yr})$~~ in Xianyang station~~.

<Figure 3>

Figure 4 shows the kernel density estimations and time processes of ~~the eight candidate explanatory~~TCCCs variables~~ (Sect. 2.3) reflecting the TCCCs~~ for both Huaxian (H) and Xianyang (X) stations. The results show that these variables have different variation patterns. For example, the mean frequency of precipitation events (λ) has a decreasing trend, while temperature (T) has an increasing trend. As presented by Fig. 5, three HA variables have a significant upward trend, especially the irrigation area IAR which is increased greatly after about 1970, suggesting that the impact of human activities in this basin has increased over time.

<Figure 4>

<Figure 5>

The significance of trends in the four annual minimum streamflow series and ~~eight explanatory~~TCCCs variables is tested by the Mann-Kendall trend test (Kendall, 1975; Mann, 1945; Yue et al., 2002), and the change ~~-~~points in these series are detected by the Pettitt's test (Pettitt, 1979). The results in Table ~~3~~ 4 show that in both Huaxian and Xianyang stations, the decreasing trends in all the four low-flow series (AM_1, AM_7, AM_{15} and AM_{30}) and two explanatory variables (λ and P), and the increasing trends in T, ET, and AI_{ET} are significant at the 0.05 level (Table ~~3~~4), but BFI shows no significant trends. However, K and AI_K had significantly decreasing trends only in Huaxian station ($p\text{-}value < 0.05$). The results of change-point detection show that all low-flow series are located at 1968-1971 ($p\text{-}value < 0.05$) except AM_{30} at Xianyang station whose change point is located at 1993 ($p\text{-}value < 0.05$); for the eight candidate explanatory variables, the change points of the variables related to temperature (T, ET, AI_{ET}) in both stations are located at 1990-1993 ($p\text{-}value < 0.05$), the change points of the variables related to precipitation (λ, P) in both stations are close at 1984-1990 ($p\text{-}value \le 0.186$) and the change points of the variables related to streamflow recession (K, AI_K) in Huaxian station are located at 1968-1971 ($p\text{-}value < 0.05$). However, BFI in both stations and K and~~,~~ AI_K in Xianyang station show no significant change points.

A preliminary attribution analysis is performed using the Pearson correlation matrix to investigate the relations between the annual minimum series and eight candidate explanatory variables. Figure 6~~5~~ indicates that there are significant linear correlations between the four minimum low-flow series (AM_1, AM_7, AM_{15} and AM_{30}) and all the explanatory variables except GDP, ~~with~~ have the absolute values of Pearson correlation coefficients larger than 0.27 ($p\text{-}value < 0.05$). These potential physical causes of nonstationarity in low flows are further considered by establishing low-flow nonstationary model with TCCCs and HA variables in the following section.

<Figure ~~5~~6>

4.2. Nonstationary frequency analysis models

4.2.1 Single covariate models

Figure 7~~6~~ presents the AIC values of the ~~three~~ four types of models (M0, M1, M2a and M2b~~M2, M1 and M0~~) fitted for the low flow series (AM_1, AM_7, AM_{15} and AM_{30}). Some interesting results are shown as follows. First, nonstationary models (M1, M2a and M2b~~M2 and M1~~) have lower AIC values than stationary model (M0), which suggests that nonstationary models are worth considering. Second, for Huaxian station, irrespective of the chosen explanatory variables, the distribution type plays an important role in modeling nonstationary low flow series. For example, PIII, GA and WEI distributions in AM_{15} and AM_{30} ~~most~~ cases have lower AIC values than LOGNO and GEV distributions. However, for Xianyang, choosing a suitable explanatory variable may be more important than choosing a distribution type. For example, variables t, P, T, ~~and~~ AI_{ET}, POP and IAR in most cases have lower AIC values than the other explanatory variables. Finally, in Huaxian, the lowest AIC values ~~the best M2 models~~ for modeling AM_1, AM_7, AM_{15} and AM_{30} are found in GEV_M2b_*IAR*, LOGNO_M2b_*IAR*, PIII_M2a_AI_K and GA_M2a_ AI_K, respectively ~~are all found in the M2_~~$\cancel{AI_K}$ ~~model (using~~ $\cancel{AI_K}$ ~~as an explanatory variable)~~; while in Xianyang, the lowest AIC values~~the best M2 models~~ for modeling AM_1, AM_7, AM_{15} and AM_{30} are ~~all~~ found in ~~the M2_~~$\cancel{K}$~~, M2_~~$\cancel{AI_{ET}}$~~, M2_~~$\cancel{AI_{ET}}$ ~~and M2_~~$\cancel{T}$ ~~model~~ GEV_M2b_*IAR*, GEV_M2b_*IAR*, PIII_M2b_*IAR* and GEV_M2b_*IAR*, respectively. These results indicated that ~~in~~ for explaining nonstationarity of low flow in Huaxian station, IAR is the most dominant HA variable~~s~~, and AI_K is the most dominant TCCCs variable ~~causing nonstationarity in~~ $\cancel{AM_1}$~~,~~ $\cancel{AM_7}$~~,~~ $\cancel{AM_{15}}$ ~~and~~ $\cancel{AM_{30}}$; while in Xianyang, the most dominant HA variable~~s~~ is IAR, the most dominant TCCCs variables causing nonstationarity in AM_1, AM_7, AM_{15} and AM_{30} are K, AI_{ET}, AI_{ET} and T, respectively. ~~Table 4 summarizes the above analysis.~~

<Figure ~~6~~7>

Figure 8~~7~~ shows the diagnostic assessment of ~~the best M2 model~~ the GA_M2 model (~~GA_M2~~ with the optimal explanatory variable) for AM_{30} in both Huaxian and Xianyang stations. The centile curve~~s~~ plots of GA_M2 (Figs. ~~7a~~ 8a and ~~7b~~8b) show the observed values of AM_{30}, the estimated median and the areas between the 5th and 95th centiles. Figure ~~7a~~ 8a shows the response relationship between AM_{30} and AI_K in Huaxian: the increase of AI_K means the smaller magnitude of low-flow events because a high value of AI_K (faster stream recession or fewer rainy days) may lead to faster water loss or less supply. In Fig. ~~7b~~8b, the higher values of $IAR\,\cancel{T}$ 域代码已更改 means the smaller magnitude of low flow events, which suggests that $IAR\,\cancel{T}$ 域代码已更改 plays an important role in driving low-flow generation in Xianyang. Figs ~~7c~~ 8c and ~~7d~~ 8d show that the worm points are within the 95% confidence intervals, thereby indicating a good model fit and a reasonable model construction.

<Figure ~~7~~8>

4.2.2 Multiple covariate models

Figure ~~8~~ 9 shows ~~that~~ the AIC values of stationary model (M0), time covariate model (M1), physical covariate models (M2a, M2b, M3, M4, M5 and M6) for AM_{30}. ~~(M2, M3 and M4 with the corresponding optimal explanatory variables) for~~ $\cancel{AM_1}$, $\cancel{AM_7}$, $\cancel{AM_{15}}$ ~~and~~ $\cancel{AM_{30}}$ ~~in both Huaxian and Xianyang stations.~~ As shown in Fig. 9, M4 (nonstationary GA distribution with the optimal TCCCs variables) has a good performance; after adding the HA variables, M6 with the lowest AIC value~~s~~ is attained; it can be found that the combination of multiple TCCCs variables ~~is~~plays a~~ the~~ major role in changing the low flows of Weihe River, but the influence of HA variables shouldn't be ignored.~~For all low flow series, the lowest AIC values are always found in the M4 models, suggesting that it is necessary to consider multiple explanatory variables for nonstationary modeling.~~

<Figure ~~8~~9>

A summary of frequency analysis based on~~ five types of models (M0, M1, M2, M3 and M4) for both Huaxian and Xianyang gauging stations~~ nonstationary GA distribution AM_{30} is presented in Table 5~~ and Table 6, respectively~~. We choose to focus on M4, M5 and M6. When only using TCCCs variables to model nonstationary low-flow frequency distribution, the results of M4 show the optimal combination of explanatory variables for all low-flow series contains more than three variables. For example, for AM_{30} of Huaxian, the optimal combination of TCCCs variables includes AI_K, BFI and AI_{ET}. When only using HA variables, the results of M5 show IAR is important to the low flows in this area. And M4 has~~ve~~ a better performance than M5. When using both TCCCs variables and HA variables, the results of M6 show the optimal combination contains multiple TCCCs variables and the irrigation area IAR. For Huaxian, the optimal combination of all explanatory variables is AI_K, IAR, BFI and P, while for Xianyang, the optimal combination is IAR, AI_{ET} and BFI. ~~For M4 and M3 models, the relative importance of selected explanatory variables is identified through the stepwise selection method. For instance, for AM_{30} in Xianyang (Table 5), temperature (T) with highest relative importance, followed orderly by P, BFI and K.~~ We can also find that if ~~the candidates~~two TCCCs variables are highly correlated, they do not seem to be selected as the explanatory variables at the same time. For example, ~~one of those variables~~ in terms of ~~only~~ air temperature (T), evapotranspiration (ET) and the climate aridity index (AI_{ET}), only one of them will appear in the optimal combination ~~a best subset of eight candidates in the final optimum model~~. This suggests that multicollinearity problem in multiple variables analysis can be reduced, which will help obtain more reliable GLMs parameters for contribution analysis.

The diagnostic assessment of the ~~best M4 model (GA_M4)~~ GA_M6 model for AM_{30} at two stations is presented by Fig. ~~9~~10. The centile curve~~s~~ plots of GA_M~~4~~6 (Figs. ~~9~~10a and ~~9~~10b) show the more sophisticated nonstationary modeling than GA_M2 (Fig ~~7~~8). When using GA_M~~4~~6 to model AM_{30} in Huaxian (Fig. 9a), similar to GA_M2, the lower low flows are found to also correspond to higher value of AI_K, but GA_M~~4~~6 ~~are~~ is able to identify the more complex variation patterns of low flows through the incorporation of IAR, BFI and P. Figures ~~9~~10c and ~~9~~10d show that the data points of worm plots of GA_M~~4~~6 are almost within the 95% confidence intervals, thereby indicating an acceptable model fit and a reasonable model construction.

<Figure ~~9~~10>

Figure ~~10~~ 11 presents the contribution of each selected explanatory variable to $\ln\left(\theta_1^t\right)-\ln\left(\bar{\theta}_1\right)$ in observation year based on GA_M~~4~~6 for AM_{30} in Huaxian and Xianyang. We can find that for Huaxian, the simulation value of $\ln\left(\theta_1^t\right)$ frequently occur below $\ln\left(\bar{\theta}_1\right)$ during the two periods of about 1970-1982 and 1993-2003, which is in accordance with the observed decrease in AM_{30} of Huaxian station during these periods. In the former period 1970-1982, ~~the largest negative contribution is found in~~ both AI_K and BFI contribute a lot of negative amount to $\ln\left(\theta_1^t\right)-\ln\left(\bar{\theta}_1\right)$, whereas during 1993-2003, the contribution of both AI_K and BFI becomes much less. However, IAR has almost equal negative contribution to $\ln\left(\theta_1^t\right)-\ln\left(\bar{\theta}_1\right)$ in both periods. Unlike the former ~~there~~three variables, the significant negative contribution of AI_{ET} is only found in 1993-2003. For AM_{30} of Xianyang, the contribution of IAR, AI_{ET} and BFI is similar to that at Huaxian station in two periods, however AI_K is not included in the final model. ~~In the latter period 1993-2003, the largest negative contribution was found in AI_{ET}. These results suggest that the significant change of AI_K (mainly because of faster streamflow recession after nearly 1971) dominates the decrease in AM_{30} of Huaxian during 1970-1982, while after 1993, the significant change of AI_{ET} (due to decreasing precipitation and increasing evapotranspiration) has a main effect on the decrease in AM_{30} of Huaxian.~~

<Figure 11>

4.3. Discussion

The impacts of both human activities and climate change on low flows of the study area~~ of the Weihe basin~~ led to time-varying climate and catchment conditions (TCCCs). Nonstationary modeling for annual low flow series ~~considering ~~using TCCCs variables and/or HA variables as explanatory variables is clearly different from either the stationary model (M0) or the time covariate model (M1). The result demonstrates that considering multiple drivers (e.g. the variability in catchment conditions), especially in such an artificially influenced river, is necessary for nonstationary modeling of annual low flow series.

In this study area, nonstationary modeling considering TCCCs is supported by the following facts and findings. For human activities, an important milestone representative is the completion and operation of the irrigation system on plateau in Baoji Gorge Irrigation Area since 1971 (Sect. 3.1). Figure 5c shows the change of irrigation area in this basin. And ~~T~~the change-point detection test in Sect. 4.1 shows that significant change points of both annual recession constant (K) and low flow series occur exactly ~~in ~~at around 1971. This result demonstrates that changes in both K and AM_{30} may involve a consequence of this project. In addition to human activities, climate change also makes a considerable contribution to nonstationarity of low flows, as suggested by nonstationary modeling using TCCCs variables with stepwise analysis. Actually, climate driving pattern may strengthen after nearly 1990, which is indicated by change-point detection test of both annual mean temperature (T) and annual precipitation (P) as well as the behavior of annual low flow series after nearly 1990. Therefore, the temporal variability in irrigation area, streamflow recession, air temperature and precipitation (the frequency and volume of rain events) should be the main driving factors of generating low flow regimes in this basin. Overall, the causes of nonstationarity in category for two gauging stations have no clear difference, but have some differences in the relative importance. As shown in Table 5, when modeling the low-flow series of Huaxian using TCCCs variables, the optimal model (M4) preferred the variables are related to recession process; however, for Xianyang, the preferred variables ~~is~~are related to temperature. The reason for this may be that as a downstream station, Huaxian station suffers more intensive human activity, so that the importance of temperature change to the low-flow change is reduced meanwhile the importance of streamflow recession (related to the capability of water storage) change is ~~improv~~enhanced.

Ignoring the negative impacts of the errors in estimating annual recession constant (K) which are caused by insufficient data points of extracted stream segments at some wet years may lead to the propagation of high errors in annual recession analysis, and accordingly affect the quality of nonstationary frequency analysis when using K as an explanatory variable. Further study will give more reliable estimation of K through improving annual recession analysis.

The related researches (Jiang et al., 2015; Yang and Yang, 2011; Yang and Yang, 2013; Zhang et al., 2015) have applied the Budyko framework to analyze the impacts of climate change and/or human activity on annual runoff. Indeed, for annual runoff, the Budyko framework is a ~~better~~good method ~~than the regression modeling method using in this study,~~ because it used the mean annual water-energy balance equation to consider generation process of total runoff. Unfortunately, to our knowledge, there is a lack of ~~the controls~~ equation derived from basic physics laws for generation process of low flows. Therefore, we emphasize the importance of TCCCs variables to modeling of low-flow nonstationarity.

5. Conclusion

There is an increasing need to develop an effective nonstationary low-flow frequency model to deal with nonstationarities caused by climate change and time-varying anthropogenic activities. In this study, time-varying climate and catchment conditions (TCCCs) in the Weihe River basin were measured by annual time series of the eight indices, i.e., total precipitation (*P*), mean frequency of precipitation events (λ), temperature (*T*), potential evapotranspiration (*ET*), climate aridity index (AI_{ET}), base-flow index (*BFI*), recession constant (*K*), and the recession-related aridity index (AI_K). The nonstationary distribution model was developed using both these eight TCCCs indices and/or there HA indices as candidate explanatory variables for frequency analysis of time-varying annual low flow series caused by multiple drivers. The main driving forces of the decrease in low flows in the Weihe River include reduced precipitation, warming climate, increasing irrigation area and faster streamflow recession. Therefore, a complex deterioration mechanism resulting from these factors demonstrates that in this arid and semi-arid area, the water resources could be vulnerable to adverse environmental changes, thus portending increasing water shortages. The nonstationary low-flow model considering TCCCs can provide the knowledge of low-flow generation mechanism and give more reliable design of low flows for infrastructure and water supply.

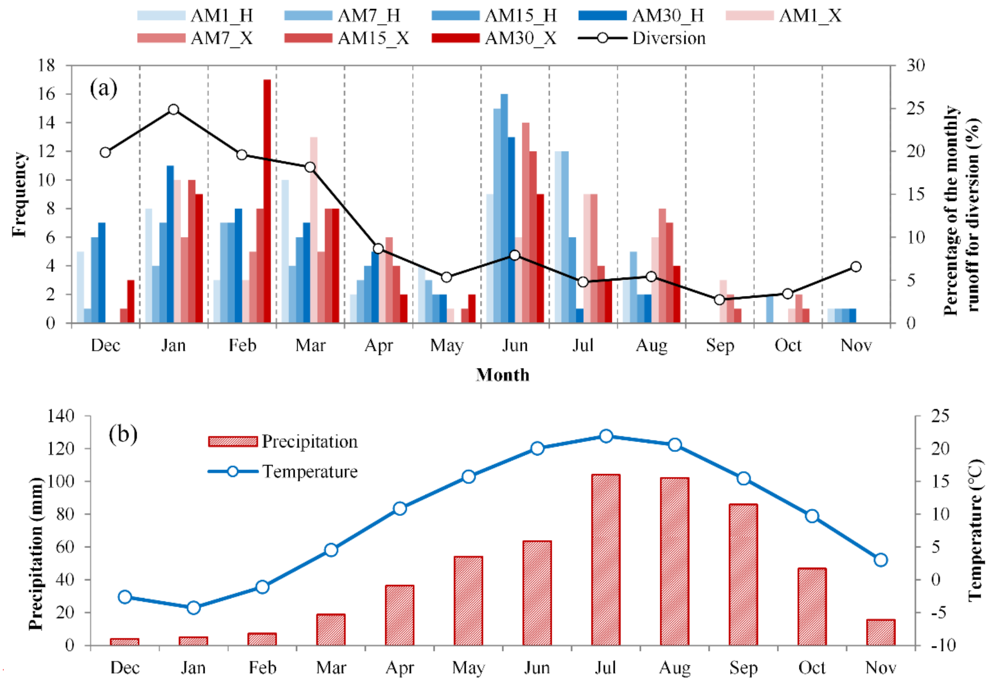
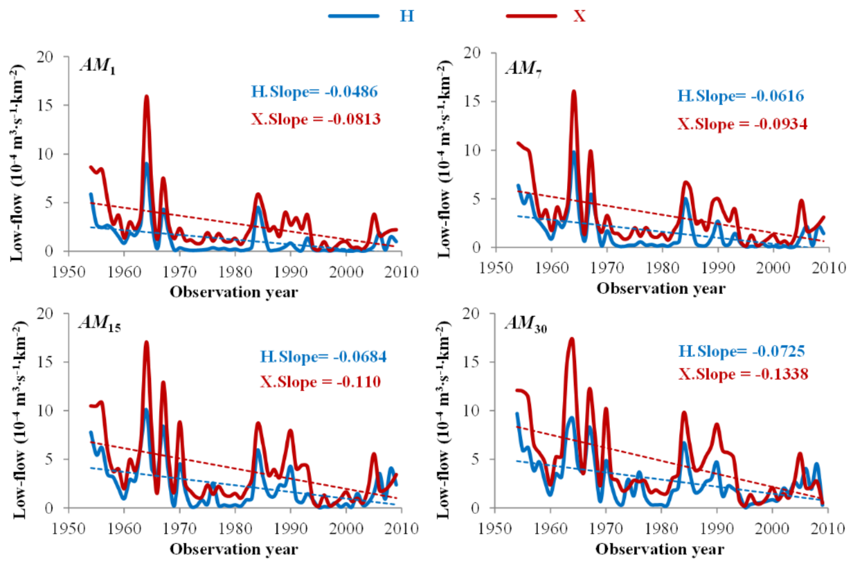
Figure ~~1~~2. Location, topography, hydro-meteorological stations and river systems of the Weihe River basin.



~~Figure 2. Overview of annual low flows and important environment factors using mean monthly data. (a) is frequency distributions of the occurrence time of the annual minimum flows with four durations at Huaxian (H) and Xianyang (X); the black line is mean monthly diversion (1980 to 2005) in Baoji Gorge area. (b) Mean monthly precipitation and temperature from 1954 to 2009.~~



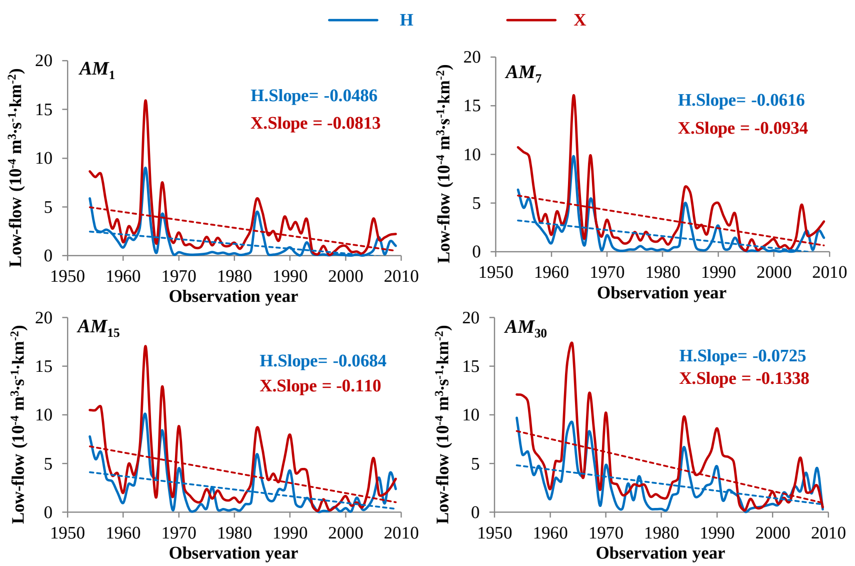


Figure 3. The annual minimum low flows and fitted trend lines in both Huaxian (H) and Xianyang (X) gauging stations.

776 

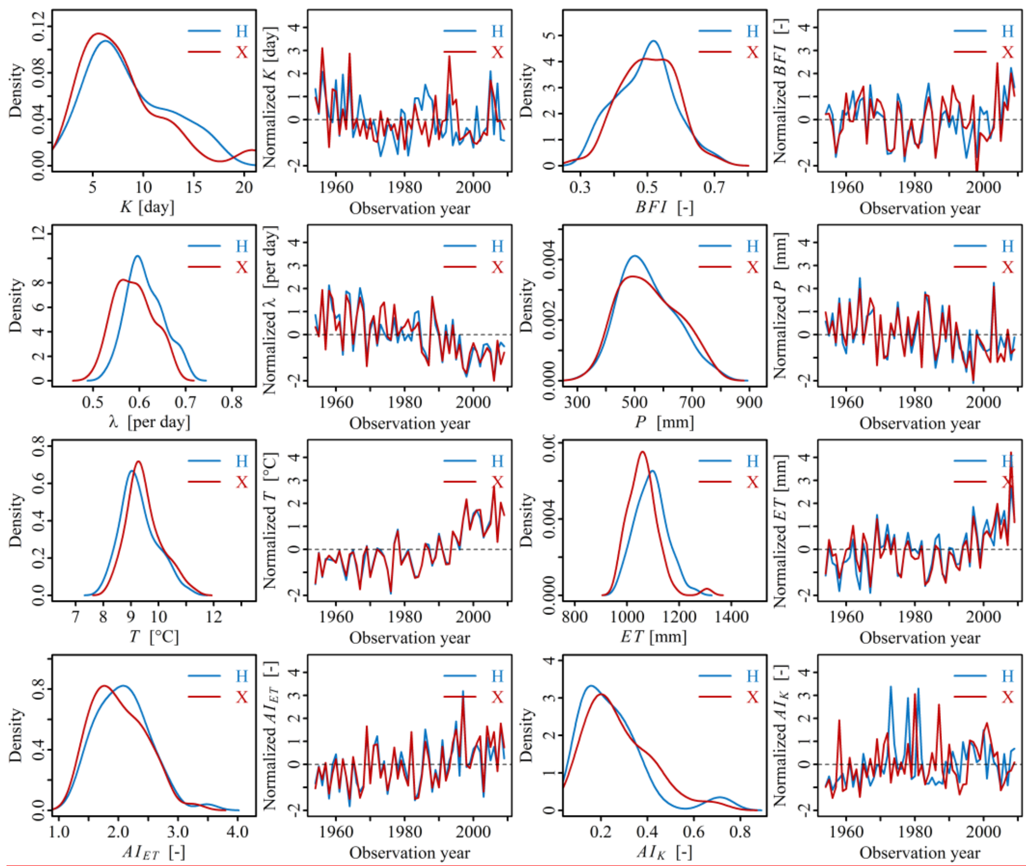

Figure 4. Frequency distributions (using the kernel density estimations) and ~~annual series of eight candidate explanatory variables~~ time series processes of TCCCs variables in both Huaxian (H) and Xianyang (X) stations.

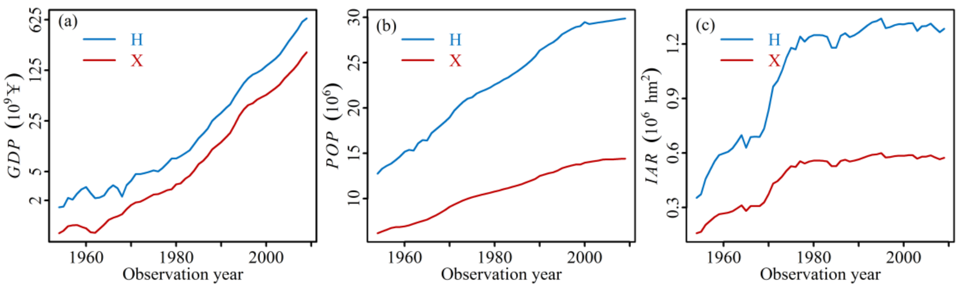

Figure 5. HA indices in both Huaxian (H) and Xianyang (X). (a), (b) and (c) are for population (*POP*), gross domestic production (*GDP*) and irrigated area (*IAR*), respectively.
