

Dear reviewers and dear Editor,

We uploaded a new version of the paper. We inserted modifications answering to most of the reviewers requests

We hope the paper is now suitable for publication.

Answers to the reviewer comments are reported in the following and we briefly described how we modified the manuscript.

The authors.

Reviewer1

Material and Methods

- P7,L6: I don't think that a 1000 km² basin can be considered small

We changed the sentence: "... characterized by small /medium sized (drainage area in the range 10-1000 km²) and steep slope (10 - 20 %) basins"

- P7,L14: what do you mean by "rigid" winters?

We changed the sentence: ". Winter seasons are generally not very cold being in a Mediterranean environment but,...."

- P7,L5: why did you chose CDF among other approaches, can you name pros and cons (support your decision)?

Done, in the text, section 2.2, it is already explained why the CDF matching was chosen. We also added some more information as requested, we report part of the text:

"The described procedure allowed to obtain a 3-hourly maps dataset in which the model bias was eliminated by keeping the characteristics of the modelled output in terms of seasonality and inter-annual variability. Furthermore, the procedure allows to avoid alterations of possible temporal trends, at both full-domain and single-cell spatial scale.

The CDF approach allows maintaining the most possible quantity of information furnished by the observations, namely the distribution of the monthly cumulative rainfall, this is not possible with simpler methods (like the simple correction of the average). On the other side, the temporal structure of the rainfall events at sub-monthly scale is the one derived from the model, that can bring some kind of distortion with respect to the actual meteorology of the region; the latter constitute the main limitation of the methodology."

- P7,L24: "seamlessly" I'm not sure if this is the adverb you want to use. Do you mean "continuously"?

Changed Seamlessly with continuously

- P8,L10: Add units.

We added the unit in the sentence before the formula: "...of rainfall p (3-hours cumulate in mm).."

- There is no information about the parameters that requires no calibration, how were they obtained? For example, where is the Leaf Area Index (LAI) parameter coming from? Same for all the other parameters that are not mentioned in the manuscript (these are as important as calibrated parameters). This needs to be included.

We added an Appendix where we show values of parameters which are not involved in calibration.

- P11,L16: Incoming shortwave?

Corrected

- Still unclear the use of the term "section" in the manuscript, if you mean

gauge station, sub-basin or basins, please use that instead, it is confusing.
Corrected with gauge station or sub-basins along the manuscript

- I don't understand why the authors perform model calibration and validation using observed meteorological records, but then they move forward and do the analysis using the reanalysis product. In my opinion this is flawed and wrong, you should use the reanalysis to perform calibration/validation to prove that the model represent reasonably well the streamflow regime, and then, you can argue that the model is appropriate for the long-term analysis using reanalysis. Authors should reconsider this. If the reanalysis is really close to the observed meteorology (after all the corrections), results will show a good streamflow representation, but you need you show this.

We do not agree with the referee, we also explained why we performed the calibration with observations in our previous review, we report it in the following. Synthetically: a) performing calibration with observations is the best option because it is not affected by the errors of reanalysis and there is consistency between input (rain, ...) and output (streamflow) b) reanalysis reproduces a possible realistic meteorological history but timing e location (and also magnitude) of the events are not detailed enough so they are inconsistent with observed streamflow c) Continuous observed streamflow for periods comparable with reanalysis are not available (reliable observed streamflow are generally available for recent years)

This is the old answer:

....It is not possible calculating the statistics like Nash-Sutcliffe, REHF...etc., for 1979-2008 period, for 2 reasons: 1) no observed discharge time series are available 2)The ExpressHydro Reanalysis can not reproduce the exact sequence and timing of the real events in period 1979-2008, but only a reasonable climatology of the area. Theoretically it could be also reproduce particular events but with very high errors in geolocation and timing and large uncertainty from a quantitative point of view. As a consequence even in the case we had 1979-2008 observed discharge time series they could not be directly compared with simulated ones (both with and without downscaling)

We added a paragraph in section 2.4.2 to explain the reasons of adopted approach.

"Model calibration was performed using observed input and output data without considering reanalysis. This is in the authors opinion that best approach for several reasons: i) EXPRESS-HYDRO reanalysis data are not involved because they are affected by errors larger than observations ones ii) meteorological data at high time resolution are available iii) EXPRESS-HYDRO reanalysis are too uncertain in terms of geo-location, timing and magnitude of real events, as a consequence streamflow simulations can not be compared with observations iv) no reliable streamflow data are available for the period covered by the reanalysis."

- P13,L13: It is unclear why you introduce Curve Number here? If its a parameters that the model requires it should be in a section describing the model parameters (with all the other parameters as well), otherwise explain.

We added a sentence also in section 2.4.1:".. Curve Number maps are used to estimate some of the subsurface flow parameters (Gabellani et al., 2008)..."

- P14,L3-7: reword.

Reworded: "Even if the calibration of the model did not encompass all the study region due to the lack of data, the hydrological model (as well) was proven to give good performances as well as similar models specifically developed for the same study area (Giannoni et al., 2000, 2005; Gabellani et al., 2008; Silvestro et al. 2013, 2015; Cenci et al 2016), even in not calibrated basins (Regione Marche, 2016)"

Results

- P19,L20-23: The authors blame calibration for all the mismatches they found. This is only one part of the problem. See comment below.

- P20: 10-16 (figure 11): I think this is also the result of errors compensating and the authors should at least mention it (see the previously shown mismatches in figures 8 to 10 and table 5, to support the errors compensating). I can see that this can be useful for ungauged basins, but you have to keep in mind that there are a lot of uncertainties here that are not properly addressed in my opinion (not everything can be attributed to errors in parameter calibration, there are also uncertainties in model structure, non-calibrated parameters and input data). You should include a paragraph with a more comprehensive assessment (discussion) of the uncertainties and problems with the model. There is a lot of literature about this; here are some examples that you could look at:

Liu and Gupta, 2007: Uncertainty in hydrologic modeling: Toward an integrated data assimilation framework, Water Resources Research, 10.1029/2006WR005756.

Wagener and Gupta, 2005: Model identification for hydrological forecasting under uncertainty: Stochastic Environmental Research and Risk Assessment, 10.1007/s00477-005-0006-5.

Walker et al., 2003: Defining Uncertainty: A Conceptual Basis for Uncertainty Management in Model-Based Decision Support, Integrated Assessment, 10.1076/iaij.4.1.5.16466.

Beven, K., 2007: A manifesto for the equifinality thesis, Journal of Hydrology, 10.1016/j.jhydrol.2005.07.007.

We added a paragraph in section 3.2 discussing the point of various sources of uncertainty (different from calibration) "...There are other sources of uncertainty that can explain the mismatches, hydrological model can lead to errors (Walker et al., 2003; Liu and Gupta, 2007) due to both its internal structure and to those parameters which are not calibrated but set by literature or by territorial information; furthermore the input variables are affected by uncertainty, not only rainfall, so they can be cause of errors."

We added a paragraph in section 3.3 to discuss the point of error compensation: "...It is anyway important to highlight that good results in terms of growth curve could be also partially due to the effect of error compensation..."

In the results chapter in different parts a deep discussion is done, we know that calibration is not the only source of uncertainty. The manuscript mentions the problem of meteorological input and also the problem of spatial and time scale of the precipitation, moreover the possible effect of bias correction.

- Explicit the value of A_{th} in page 20 and figure 11.
Done, inserted value in the caption

- P21,L15: This potential relationship between Ratio (T) and area is biased because the size of the sample is biased too (only few large basins and many small ones) and it should be stated in the text (not only here, but in other sections in the manuscript).

In section 3.3 we highlighted this point. "The first consideration is that a relation between Ratio(T) and A appears to exist even if it is supposedly biased because the size of the sample is biased: the number of small basins is hugely higher than large ones"

- Include a table with the details about the observed streamflow and meteorological data used in the study (period, gaps and official ID – if available-). This table should be included as supplementary material.

We included a table with periods of availability of annual discharge maxima data. The other meteorological input (data for calibration and reanalysis) are continuous and periods are already mentioned in the text.

The table should be included in supplementary materials

Other minor comments:

- Figure1: Add scale. Avoid acronyms (everywhere in the text too, unless previously defined). Such as FR, MC and IT. There is no curve number in the figure (see caption).

Done

- Figure3: group the subplot in boxes by season and add an identifier, such as (a) for summer, etc. and describe it in the caption.

Done

- Figure4: can probably be removed as the numbers are in Table 4 already (too many figures).

This figure was requested by a previous reviewer, it is in our opinion interesting to a visual check of results. If both editor and reviewer retain it must be removed we are open to do that.

- Y-axis label figure 5 and 6: change to "mean monthly cumulative rainfall"

- Include legend in figure 5 and 6.

Done

- Include axis units in figure 2, 3(ANTO), 5, 6 and 16.

Done

- Figure 8, 9 and 10: Change units format to "m³ s⁻¹".

Done

- I still think that 16 figures is too much and some figures can be either merged, simplified or moved to supplement material.

The number of figures is quite high but the analysis is wide involving both rainfall and discharge. We would maintain the proposed figures to maintain a good readability, and even because they are derived after various reviews and merging process.

- Table1: Include official ID number for the sub-basins (sections?). Don't capitalize "Slope". Typo in "height".

Corrected. We do not have specific ID

- Table2: What is "AP". Are these values for calibration or validation? Unclear.

Include the period of analysis in the caption.

Done

CP: calibrated parameters AP: average parameters. We added the information in the caption

- Table5: What are the first “p-values” and “K-S test” associated with? Avoid using B.C. unless defined in the table caption.

We inserted the definition and modified the table. Results are reported for the two cases: with (B.C.) and without (No B.C.) rainfall bias correction.

- Table 6: What’s “N. Program”. Too many acronyms not defined throughout the text, avoid them unless explicitly defined.

Removed

- Abstract: What’s “inter alia” streamflow?

Removed and changed the sentence

- Many typos (more than previous version actually). Just to name a few examples:

- Peri et al (2015) instead of Pieri et al (2015)
- Krog et al (2015) instead of Krogh et al (2015)
- Page7, L5: “et c” instead of “etc”
- Page7, L9: there is a “.” in the middle of the sentence.
- Page 7, L22: “:” in the middle of the sentence.

Corrected

1 **Analysis of the streamflow extremes and long term water balance**
2 **in Liguria Region of Italy using a cloud permitting grid spacing**

8 **Abstract**

9 Characterizing the hydrometeorological extremes, in terms of both rainfall and streamflow, as
10 well as the estimation of long-term water balance indicators are essential issues for flood alert
11 and water management services. In recent years, simulations carried out with meteorological
12 models are getting available at increasing spatial and temporal resolutions (both historical
13 reanalysis and near real-time hindcast studies): thus, these meteorological datasets can be
14 used as input for distributed hydrological models to drive long-period hydrological reanalysis.
15 In this work we adopted a high resolution (4 km-spaced grid, 3-hourly) meteorological
16 reanalysis dataset that covers Europe as a whole for the period between 1979 and 2008. This
17 reanalysis dataset was used together with a rainfall downscaling algorithm and a rainfall bias
18 correction technique in order to feed a continuous and distributed hydrological model. The
19 resulting modelling chain allowed to produce long time series of distributed hydrological
20 variables for Liguria Region (N-W Italy) which have been impacted by severe hydro-
21 meteorological events.

22 The available raingauges were compared with the rainfall estimated by the dataset, and then
23 used to perform a bias correction in order to match the observed climatology. An analysis of
24 the annual maxima discharges derived by simulated streamflow time series was carried out by
25 comparing the latter with the observations (where available) or a regional statistical analysis

1 (elsewhere). Eventually, an investigation of long-term water balance was performed by
2 comparing simulated runoff ratios with the available observations.

3 The study highlights the limits and the potentialities of the considered methodological
4 approach in order to undertake an hydrological analysis in study areas mainly featured by
5 small basins, thus allowing to overcome the limits of observations which are punctual and in
6 some cases not fully reliable.

7 **1 Introduction**

8 The estimation of the magnitude and the probability of occurrence of a certain streamflow is
9 an important task for a number of purposes: risk assessment, design of structural protections
10 against flooding, civil protection, and early warning.

11 The standard approach based on the use of streamflow observations to carry out a statistical
12 analysis on a specific outlet (Kottegoda and Rosso, 1997) is not always possible because of
13 the lack of measurements: this problem can be tackled by means of a frequency
14 regionalization approach (De Michele and Rosso, 2002) exploiting both observed and
15 modelled streamflow (Boni et al., 2007).

16 On the other hand, studies and methodologies regarding the management of water resources
17 and droughts also have an important role, especially in the perspective of possible future
18 changes in climate and water needs (Calanca et al., 2006; Fu et al., 2007; Döll and Müller,
19 2012; Asadieh and Krakauer, 2017). In this case, the analysis of long-term water balance
20 components is of primary importance and the evaluation of total runoff and
21 evapotranspiration becomes crucial.

22 In the last decades, the use of meteorological reanalyses to study basins behaviour in different
23 hydrological regimes has become quite frequent, due to the increased reliability and space-
24 time resolution of NWP models. Among many others, Choi et al. (2008) investigated the
25 feasibility of temperature and precipitation data of the North American Regional Reanalysis

1 (NARR, about 32 km grid spacing) for hydrological modelling in northern Manitoba
2 watersheds, while Bastola and Misra (2013) showed that reanalysis products outperformed
3 other four meteorological datasets, when used as a large-scale precipitation proxy for
4 hydrological response simulations.

5 Furthermore, Krogh et al. (2015) used ECMWF interim reanalysis (ERA-Interim, about 70
6 km grid spacing) as input to model the hydrological response of one of the largest rivers in
7 Patagonia; similarly, Nkiaka et al. (2017) investigated the potential of using global reanalysis
8 datasets in the data-scarce Sudan-Sahel region.

9 The CORDEX (COordinated Regional climate Downscaling Experiment, Giorgi et al. 2009)
10 initiative is aiming at producing regional climate change projections worldwide to be fed into
11 impact, adaptation and disaster risk reduction studies using fine-scaled regional climate
12 models (RCM) forced by different GCMs of the CMIP5 (Coupled Model Intercomparison
13 Project Phase 5, CMIP5) archive. Along these lines, Kotlarski et al. (2014) confirmed, with
14 simulations on grid-resolutions up to about 12 km (0.11°), the capability of RCMs to correctly
15 reproduce the main features of the European climate for the period 1979-2008. However they
16 also exhibit relevant modeling errors concerning some metrics, certain regions and seasons: as
17 an example, precipitation biases are in the $\pm 40\%$ range while seasonally and regionally
18 averaged temperature biases are generally smaller than 1.5°C . Building on these findings,
19 Pieri et al. (2015) moved one step further, in the framework of the EXtreme PREcipitation
20 and Hydrological climate Scenario Simulations (EXPRESS-Hydro) project, by dynamically
21 downscaling at a finer space-time resolution (4 km, 3-hourly) the ERA-Interim dataset using
22 the state-of-the-art non-hydrostatic Weather Research and Forecasting (WRF) regional
23 climate model.

24 In this work the high-resolution ($\Delta t=3$ h, $\Delta x=4$ km) EXPRESS-HYDRO regional dynamical
25 downscaling of historical climate scenarios is used as input to a hydro-meteorological chain

1 including a rainfall downscaling algorithm (RainFARM, Rebora et al. 2006a, 2006b) and a
2 continuous distributed hydrological model (Continuum, Silvestro et al. 2013). As a result, a
3 30-year long high resolution ($\Delta t=1$ h, $\Delta x=< 500$ m) hydrological dataset (e.g. Streamflow and
4 Evapotranspiration) was generated for a reference Mediterranean region. It is noteworthy to
5 highlight that both Continuum model and RainFARM downscaling algorithm have been
6 already widely employed and tested in the very same study area (Gabellani et al., 2008;
7 Silvestro et al., 2014; Laiolo et al., 2015; Davolio et al., 2017).

8 The distributed nature of the variables allowed to investigate the possibility of using the
9 hydrological modelling chain for extreme streamflow statistical analysis (e.g. distribution of
10 annual discharge maxima) and long-term water balance (e.g. long-term runoff ratio) with a
11 fully distributed approach. Furthermore, the fine space-time resolution of the forcings,
12 together with the use of a rainfall downscaling model, allowed to evaluate such a high
13 resolution reanalysis in regions featured with small hydrological watersheds (Silvestro et al.,
14 2011), complex topography and frequently flash-flooded (Altinbilek et al., 1997; Cassola et
15 al., 2016). The aforementioned elements, together with the analysis of the distribution of
16 flood extremes, are the main novel contributions of the presented analysis in respect to other
17 works that employ a similar modelling cascade: it is in fact mandatory to use high resolution
18 reanalysis since coarser ones cannot reproduce the small-scale rainfall structures that usually
19 trigger such local hydro-meteorological processes.(Buzzi et al., 2013; Marta-Almeida, 2016;
20 Pontoppidan et al. 2017; Schwitalla et al. 2017).

21 The study shows the capabilities and the limits of the considered modelling chain to
22 reproduce low-frequency streamflow and long-term water balance as an alternative to
23 observations in a scarce data environment or whenever a finer spatial distribution of hydro-
24 meteorological processes is essential.

1 The manuscript is organized as follows: section 2 describes the study area, hydro-
2 meteorological data set and models, section 3 shows the results, and in section 4 the
3 discussion and conclusions are reported.

4 **2 Materials and Methods**

5 **2.1 Study Area and Case study**

6 Liguria Region is located in northern Italy (Figure 1) and it is characterized by small/medium
7 sized (drainage area in the range 10-1000 km²) and steep slope (10 - 20 %) basins (Table 1).
8 The response time to precipitation is short, ranging between 0.5 and 10 hours (Maidment,
9 1992; Giannoni et al., 2005). The maximum elevation of mountains is around 2500 m, and
10 most of the region is covered with forest or other types of vegetation like meadows and
11 shrubs; usually the catchments mouths are densely urbanized. The hydrological regime is
12 prevalently torrential and the entire study area is frequently hit by flash floods (Rebora et al.,
13 2013): as a consequence, the variability of annual discharge maxima is high. Winter seasons
14 are generally not very cold being in a Mediterranean environment but, as the elevation varies
15 from sea level to more than 2000 m, below-zero temperatures are rare (a few days a year)
16 along the coast and at low altitude but they can easily drop even below -10 °C inland. Snow
17 occurs only few days a year and normally does not reach the coastal areas.
18 During warm season peak temperature hardly rises over 31-32 °C. The local rain gauge
19 network (OMIRL – “Osservatorio Meteo-Idrologico della Regione Liguria”) is managed by
20 the Environmental Agency of Liguria Region (ARPAL) and is quite dense (more than 150
21 gauges; 1 rain gauge/40 km² on the average) ,with a 5-10 minute resolution and an
22 homogeneous distribution with respect to the elevation. Temperature, radiation, wind, air
23 humidity gauges are also part of the observational network, even though their density is
24 lower, about 1/50, 1/200, 1/200, 1/60 km² respectively. Data from 2011 to 2014 were
25 collected for calibrating/validating the hydrological model.

1 Besides, for a subset of 95 raingauge stations (see Figure 1), ARPAL hosts a web-based free-
2 access validated database of historical (1978 - 2010) daily precipitation measurements
3 (ARPAL, 2010) that were used in the present study for the bias correction of the EXPRESS-
4 Hydro reanalysis rainfall estimation.

5 For 11 level gauge stations seamless hourly data are available from 2011 to 2014 together
6 with rating curves, while annual discharge maxima (hereafter ADM) time series longer than
7 30 years are available for 15 level gauges (Figure 1); the latter ones cover sub-periods which
8 are not continuous from 1950 to recent years. Moreover, in the Hydrologic Annual Survey
9 (<http://www.arpal.gov.it/homepage/meteo/pubblicazioni/annali-idrologici.html>), an official
10 document published by ARPAL, annual basin-scale runoff ratio (defined as runoff
11 volume/precipitation) are available for 6 stations.

12 In Table 1 the availability of the discharge and discharge-related data is summarized together
13 with hydro-geomorphic characteristics of the basins upstream each station.

14 All the data are checked by ARPAL in compliance with WMO recommendations so as to flag
15 errors and unphysical values.

16

17 **2.2 Bias correction of rainfall fields (B.C.)**

18 Before being used as input for the hydrological simulations, the EXPRESS-Hydro reanalysis
19 rainfall dataset was compared with the climatological precipitation data of the Liguria
20 raingauge dataset (ARPAL, 2010). The observational dataset is constituted by validated time
21 series of about 95 raingauges homogeneously distributed on the Liguria Region territory,
22 covering the whole EXPRESS-Hydro dataset (not for all gauges, though) with a daily
23 timestep.

24 In order to provide hydrological model with the most reliable input data, the EXPRESS-
25 Hydro reanalysis precipitation data were bias-corrected with the actual raingauges so as to

1 assure an accurate reproduction of the local climatology in terms of monthly accumulation.
2 As rainfall was the only available data in the Liguria climatological atlas, the bias correction
3 was not applied to the other variables of the EXPRESS-Hydro dataset.
4 Nevertheless, several methods are available in literature to perform a bias correction
5 (hereafter B.C.) on different variables (e.g., rainfall, temperature, etc.; Fang et al. 2015):
6 amongst many, in this study a CDF-matching approach was selected (Fang et al. 2015).
7 In order to preserve the seasonality and the inter-annual variability which can be found in the
8 observational data as well as in the EXPRESS-Hydro ones, the correction was based on the
9 monthly accumulations computed for both datasets. This led to generate $12 \times N$ (where N is
10 the number of years of the dataset) maps of monthly-cumulated rainfall for EXPRESS-Hydro
11 and $12 \times N_{\text{obs}}$ (being N_{obs} the number of years of the observed dataset) timeseries representing
12 the actual accumulated rainfall for each month and for each of the available raingauges.
13 To allow a direct comparison between the observed data and the modeled dataset, the monthly
14 cumulated data from the raingauges were previously interpolated on the EXPRESS-Hydro
15 spatial grid by using a kriging technique with a Spherical variogram. No regression with other
16 spatialized variables (e.g., elevation) was performed because previous tests showed no
17 significant correlation. Due to the high density of the raingauge network and since the
18 interpolation was applied only to the monthly accumulation, possible errors introduced by the
19 interpolation are assumed to be negligible as short-lived and small-scaled rainfall events ,
20 were addressed (see Boni et al., 2007 and Rebora et al. 2013).
21 For each cell i , the empirical CDF (Cumulative Distribution Function) of both observed and
22 modeled values were computed with the purpose of minimizing the distortions, these CDFs
23 were calculated separately for each month of the year

1 In the CDF-matching process the observations CDF was applied to the EXPRESS-Hydro time
 2 series of a given cell i in order to obtain the corrected time series of the monthly
 3 accumulation:

$$4 \quad PM'_{i,m} = F_{OSS,i}^{-1}(F_{MOD,i}(PM_{i,m})) \quad (1)$$

5 where PM is the EXPRESS-Hydro monthly accumulated rainfall, PM' is the bias-
 6 corrected monthly accumulated rainfall, m is the index of the month of the native series,
 7 $F_{MOD,i}$ and $F_{OSS,i}$ are respectively the CDF of the modeled and observed monthly rainfall in the
 8 cell i .

9 Given these corrected monthly time series, the single instantaneous value of rainfall p
 10 (3-hours cumulate in mm) was corrected as follows:

$$11 \quad p'_{i,t} = p_{i,t} \frac{PM'_{i,m}}{PM_{i,m}} \quad (2)$$

12 where:

- 13 - $p_{i,t}$ is the 3-hourly accumulated rainfall modeled in the cell i at time t
- 14 - $p'_{i,t}$ is the bias-corrected 3-hourly accumulated rainfall modeled in the cell i at time t
- 15 - $PM_{i,m}$ is the monthly accumulated rainfall modeled in the cell i for the month m (in
 16 which the instant t falls)
- 17 - $PM'_{i,m}$ is the monthly accumulated rainfall modeled in the cell i for the month m (in
 18 which the time t is) corrected with the CDF-matching

19 The described procedure allowed to obtain a 3-hourly maps dataset in which the model bias
 20 was eliminated by keeping the characteristics of the modelled output in terms of seasonality
 21 and inter-annual variability. Furthermore, the procedure allows to avoid alterations of possible
 22 temporal trends, at both full-domain and single-cell spatial scale.

23 The CDF approach allows maintaining the most possible quantity of information furnished by
 24 the observations, namely the distribution of the monthly cumulative rainfall, this is not
 25 possible with simpler methods (like the simple correction of the average). On the other side,

1 the temporal structure of the rainfall events at sub-monthly scale is the one derived from the
2 model, that can bring some kind of distortion with respect to the actual meteorology of the
3 region; the latter constitute the main limitation of the methodology.

4 **2.3 Downscaling the rainfall with RainFARM Model**

5 RainFARM (Rebora et al. 2006a, 2006b) is a stochastic mathematical model that can be
6 exploited for generating downscaled rainfall fields consistent with the large-scale forecasts
7 provided by either Numerical Weather Prediction Systems (NWPs) as in Laiolo et al. (2013)
8 and by expert forecasters (Silvestro and Rebora, 2014). The model takes into account the
9 variability of precipitation at small spatial and time scales (e.g. $L \leq 1$ km, $t \leq 1$ hour),
10 preserving the precipitation volume at the scales considered reliable (L_r , and t_r) for
11 quantitative precipitation forecasts. In other words L_r , and t_r are those scales where we expect,
12 on average, a reliable forecast of precipitation volume. RainFARM is able on one side to
13 preserve spatial and time patterns at L_r , t_r , on the other side to produce small-scale structures
14 of rainfall which are consistent with detailed remote sensor observations as meteorological-
15 radar estimation (Rebora et al., 2006a).

16 In the model, the spatial-temporal Fourier spectrum of the precipitation is estimated using the
17 rainfall patterns predicted by a meteorological model and it is mathematically described as
18 follows:

$$19 \quad |\hat{g}(k_x, k_y, \omega)|^2 \propto (k_x^2 + k_y^2)^{-\alpha/2} \omega^{-\beta} \quad (3)$$

20 k_x and k_y are the x and y spatial wavenumbers, ω the temporal wavenumber (frequency),
21 while α and β are two parameters that are calibrated fitting the power spectrum of rainfall
22 derived by a NWPS on the frequencies corresponding to the spatial-time scales L_r , and t_r . By
23 extending the spectrum defined by equation (3) to the larger wave numbers/frequencies it is

1 possible to generate a spatial-time rainfall pattern at high resolution (Rebora et al. 2006b).
2 Since the Fourier phases related with the power spectrum (3) are randomly generated before
3 the backwards transformation in real space, RainFARM provides an ensemble of
4 equiprobable high-resolution fields that are consistent with the large-scale precipitation
5 forecasted by a NWPS. RainFARM was designed to feed flood forecasting systems in small
6 and medium sized basins (drainage area $< 10^3$ - 10^4 km²) and it was widely tested on the study
7 area (Rebora et al., 2006a; Silvestro et al. 2012; Silvestro and Rebora, 2014).
8 In this study the algorithm is used to downscale the bias-corrected EXPRESS-Hydro
9 reanalysis; the nominal grid spacing and temporal resolution of EXPRESS-Hydro
10 precipitation (4 km and 3 hours, Hardenberg et al. 2015 and Pieri et al. 2015) are assumed as
11 reliable spatial and time scales. The downscaling algorithm is not used in probabilistic
12 configuration, but to build a possible rainfall time-spatial pattern at 1 km and 1 hour
13 resolution that is compatible with the runoff at small scales, since most of the catchments in
14 the study area are small-sized (often < 100 - 200 km²) with a response time ranging from 1 to 6
15 hours.

16 **2.4 The hydrological model and its calibration-validation**

17 2.4.1 The model: Continuum

18 The hydrological model used in this study is *Continuum* (Silvestro et al. 2013), a distributed
19 and continuous model that relies on a space-filling approach and uses a robust way for the
20 identification of the drainage network components (Giannoni et al., 2005). Though all the
21 main hydrological processes are mathematically described in a distributed way, Continuum
22 was designed to be a trade-off between complex physically-based models (which describe the
23 physical phenomena with a high detail, often introducing complex parameterization) and
24 models with an empirical approach (easy to implement but not accurate enough). The basin or
25 domain of interest is represented through a regular grid, derived by a Digital Elevation Model

1 (DEM) while the flow directions are defined with an algorithm that calculates the maximum
2 slope using the DEM. An algorithm classifies each cell of the drainage network as hillslope or
3 channel flow depending on the main flow regime; a morphologic filter is defined by the
4 expression $AS^k = C$ where A is the drainage area upstream of each cell [L^2], S is the local
5 slope [-], k and C are constants related to the geomorphology of the catchment (Giannoni et
6 al., 2000) and it is used to determine whether a cell is a hillslope or a channel. The surface
7 flow scheme treats differently channel and hillslope flows: the overland flow (hillslopes) is
8 described by a linear reservoir schematization, while an approach derived by kinematic wave
9 (Wooding, 1965; Todini and Ciarapica, 2001) models the channel flow.

10 Subsurface flows and infiltration are modeled through an adaptation of the Horton equations
11 (Bauer, 1974; Disikin and Nazimov, 1997) that accounts for soil moisture evolution even in
12 conditions of intermittent and low-intensity rainfall as in Gabellani et al. (2008). **Curve**
13 **Number maps are used to estimate some of the subsurface flow parameters (Gabellani et al.,**
14 **2008).**

15 Interception of vegetation is schematized with a reservoir that has a retention capacity S_v
16 estimated by static informative layers of vegetation type or Leaf Area Index data; the flow in
17 deep soil and the water table evolution are modeled with a distributed linear reservoir
18 schematization and a simplified version of Darcy equation.

19 The energy balance uses the “force restore equation” (Dickinson, 1988) that allows to
20 explicitly model the soil surface temperature and to estimate the evapotranspiration from the
21 latent heat flux (Silvestro et al., 2013).

22 Snow melting and accumulation is simulated with simple equations forced with air
23 temperature and solar radiation (Maidment, 1992) as in Silvestro et al. (2015).

24 Continuum needs the following input variables: rainfall, air temperature, short-wave incoming
25 solar radiation, wind velocity, and relative humidity. When the ExpressHYDRO reanalysis

1 are used to feed the model the input variables are: 2m temperature, 10 m wind, rain depth,
2 downward short wave flux at ground surface, and 2 m relative humidity.

3 The parameters that require calibration in Continuum model are six, they are often estimated
4 at basin or sub-basin scale: two for the surface flow (u_h [$m^{0.5}s^{-1}$] and u_c [s^{-1}]), two for the sub-
5 surface flow (c_t [-] and c_f [-]) and two for deep flow and watertable (V_{wmax} [mm] and R_f [-])
6 processes.

7 The parameter u_h affects those hydrograph components which are related to fast surface flow
8 as well as u_c but the impact of the latter depends on the length of the channeled paths; c_f is
9 related to saturated hydraulic conductivity and controls the rate of subsurface flow rate (i.e.,
10 it); c_t identifies the part of water volume in the soil that can be extracted through
11 evapotranspiration only and is thus related to the soil field capacity, while both c_t and c_f
12 regulate the dynamics of saturation of the root-zone. The two parameters V_{wmax} and R_f
13 control the flow in the deep soil and the dynamic of watertable, yet they impact on recession
14 curves and influence flood hydrographs only when large-sized catchments are taken into
15 account (Silvestro et al., 2013).

16 2.4.2 Implementation on the study area

17 In the present work, Continuum was implemented with a time resolution of 60 minutes and a
18 spatial resolution of 0.005 deg (about 480 m). The Shuttle Radar Topographic Mission
19 (SRTM) DEM was employed as a terrain model.

20 Model calibration was performed using observed input and output data without considering
21 reanalysis. This is in the authors opinion that best approach for several reasons: i) EXPRESS-
22 Hydro reanalysis data are not involved because they are affected by errors larger than
23 observations ones ii) meteorological data at high time resolution are available iii) EXPRESS-
24 Hydro reanalysis are too uncertain in terms of geo-location, timing and magnitude of real

1 events, as a consequence streamflow simulations can not be compared with observations iv)
2 no reliable streamflow data are available for the period covered by the reanalysis.

3 The model was calibrated on 11 basins where streamflow observations were available at
4 hourly time resolution (see Table 1); the hourly measurements of rainfall, air temperature,
5 solar radiation, air relative humidity provided by the regional weather stations network were
6 interpolated on a 1-km regular grid through a Kriging method to feed the model. The two
7 parameters V_{Wmax} and R_f were estimated at regional scale based also on Davolio et al. (2017),
8 since they are less sensitive than the other four parameters (Silvestro et al., 2013). The
9 observed streamflow data at 60-minute time resolution were compared with the model output
10 in order to evaluate its performance. The validation period spanned from 01/01/2013 to
11 31/12/2014, the model performance was evaluated through the skill scores, also used in the
12 calibration process (Davolio et al., 2017), as reported in the following.

13 The Nash Sutcliffe (NS) coefficient (Nash and Sutcliffe, 1970):

$$14 \quad NS = 1 - \frac{\sum_{t=1}^{t_{max}} (Q_m(t) - Q_o(t))^2}{\sum_{t=1}^{t_{max}} (Q_m(t) - \overline{Q_o})^2} \quad (4)$$

15 where $Q_m(t)$ and $Q_o(t)$ are the modelled and observed streamflows at time t . $\overline{Q_o}$ is the mean
16 observed streamflow.

17 Relative Error of High Flows (REHF)

$$18 \quad REHF = \frac{1}{t_{max}} \left[\sum_{t=1}^{t_{max}} \frac{|Q_m(t) - Q_o(t)|}{Q_o(t)} \right]_{Q > Q_{th}} \quad (5)$$

19 where Q_{th} is chosen as the 99 percentile of the observed hydrograph along the calibration
20 period.

1 While NS has the purpose of evaluating the general reproduction of streamflow, REHF score
2 aims to give more weight to the highest flows thus leading the calibration to better reproduce
3 the flood events.

4 As in Madsen (2000) the calibration was carried out by combining NS and REHF into a
5 multi-objective function: the space parameter was analyzed using a brute force approach on
6 the time span 2011-2013 in order to optimize the aforementioned multi-objective function.
7 The time resolution of the streamflow data was hourly, while the Curve Number map was
8 derived by the CORINE Land Cover ([http://www.sinanet.isprambiente.it/it/progetti/corine-](http://www.sinanet.isprambiente.it/it/progetti/corine-land-cover-1)
9 [land-cover-1](http://www.sinanet.isprambiente.it/it/progetti/corine-land-cover-1)). The parameters range values considered during the calibration process were
10 defined considering their physical meaning, the mathematical constraints and the experience,
11 they are reported in Table 2 (Silvestro et al., 2015; Cenci et al., 2016), the final parameter
12 configuration is similar to the one used in Davolio et al. (2017). Parameters values not
13 involved in calibration are reported in Appendix.

14 The values of the skill scores were calculated for the validation period and turned out to be
15 satisfactory, as reported in Table 3.

16 For those basins where the calibration was not possible, the parameters are assumed to be
17 equal to the average values obtained by the calibration. This assumption was then verified by
18 carrying out a run of the model using the average parameters even for calibrated basins; the
19 statistics maintain good values supporting the significant assumption done. Table 3 reports the
20 skill scores.

21 Even if the calibration of the model did not encompass all the study region due to the lack of
22 data, the hydrological model (as well) was proven to give good performances as well as
23 similar models specifically developed for the same study area (Giannoni et al., 2000, 2005;
24 Gabellani et al., 2008; Silvestro et al. 2013, 2015; Cenci et al 2016), even in not calibrated
25 basins (Regione Marche, 2016). In fact, when the basins have similar characteristics

1 especially regarding the surface response to intense rainfall and the main genesis of rainfall-
2 runoff process, the parameters have often similar values (Boni et al., 2007).

3 In order to reduce the warm up impacts on the 1979 (first year of EXPRESS-Hydro)
4 simulation, a first run was started with a predefined initial condition setup and the state
5 variables simulated on the 31 of December of every year (from 1979 to 2008) were averaged
6 to estimate a reasonable initial condition for 1th January 1979 to be used in the final
7 simulation.

8 The hydrological model run for the period 1979-2008 provided, a streamflow time series for
9 each pixel of the calculation domain which was, ideally, equivalent to having a gauge every
10 Δx along the hydrological network. Since the spatial resolution of the hydrological model is
11 480 m basins smaller than $A_{th}=15 \text{ km}^2$ were not taken into account, because the surface water
12 motion processes cannot be modeled with a sufficient detail (Giannoni et al., 2005).

13 **2.5 Distribution of the annual discharge maxima**

14 The results of the modeling chain were firstly compared with observations using a typical
15 station-wise comparison approach: 15 gauge stations with at least 30 years of annual
16 discharge maxima (ADM) were identified along the Ligurian territory from east to west.

17 It was not possible to ensure a perfect overlapping between the simulated and the
18 observational timeseries, often observed data are not seamless and they may cover longer
19 periods (in some case 50-60 years) with large timespans of missing data (see the table
20 uploaded as additional material). However, on the basis of the conclusions drawn in the
21 Liguria climatological atlas, major climate change-related trends for the meteorological
22 variables are not evident, thus allowing for the use of the database despite the data gaps.

23 The comparison between observed and reanalysis-driven ADM is firstly based on the analysis
24 of the respective cumulative density function distributions.

1 The reanalysis-driven ADM were fitted with a Generalized Extreme Value (GEV) distribution
2 (see e.g., Hoskin and Wallis, 1993; Piras et al., 2015) that represents a good compromise
3 between flexibility and robustness. Other works based extreme statistical analysis on the Two
4 Components Extreme Value (TCEV) model (Rossi et al., 1984), nevertheless we decided to
5 use GEV since it has a smaller number of parameters and it was widely applied (CIMA
6 Research Foundation, 2015; Piras et al., 2015). Moreover the comparison between observed
7 and modeled ADM was also done using the Kolmogorov-Smirnov test with a 5% significance
8 level, in order to verify if they belonged to the same distribution.

9 **2.6 Regional analysis of the annual discharge maxima**

10 In order to carry out a comparison following a distributed approach we referred to Boni et al.
11 (2007) which is one of the operational reference methods in Liguria Region (used by both
12 public authorities and private engineers) to estimate the ADM quantiles (Provincial Authority
13 of Genoa, 2001; Silvestro et al., 2012). The method was conceived and tested especially for
14 the Tyrrhenian catchments of Liguria Region, so the present analysis was carried out only for
15 this area; the 45-50% of which is located upstream the calibrated basins. The method defines
16 a hierarchical approach based on the analysis of the non-dimensional random variable $X_0 =$
17 X/μ_x , obtained by grouping together all the available data, and making them non-dimensional
18 with respect to each local (gauging station) sample mean, μ_x , taken as the index flood for
19 gauged sites. Index flood is estimated even where observations were not available by taking
20 advantage of the rainfall regional frequency analysis and rainfall-runoff modelling to allow
21 quantile estimation in each point of the region.

22 The final result is a methodology to estimate the index flood that can be formalized as it
23 follows:

$$24 \quad Q_{index} = f(Area, longitude) \quad (6)$$

1 While the quantile is:

$$2 \quad Q(T) = K(T) \cdot Q_{index} \quad (7)$$

3 where T is the return period and K(T) is defined by the non-dimensional regional growth
4 curve, uniquely defined for all the studied region (Boni et al. 2007).

5 In the case of the modelling chain analyzed in this work a large number of reanalysis-driven
6 time series is available because 30 year long ADM series for each pixel of the model grid can
7 be accessed for basins bigger than A_{th} . In practice, using a distributed hydrological model, on
8 one side allows the index flood estimation to be a simple mean of a time series in each point
9 of the domain, on the other side provides a large number of data to build the non-dimensional
10 regional curve.

11 **3 Results**

12 **3.1 Precipitation analysis**

13 The comparison between EXPRESS-Hydro reanalysis and precipitation climatology over
14 Liguria derived from observational data was undertaken at annual, seasonal, monthly and
15 daily scales.

16 Pieri et al. (2015), using EURO4M-APGD reference observational dataset (Isotta et al. 2013,
17 with about 50 daily raingauge stations in Liguria), already showed an overall underestimation
18 of the WRF rainfall depths on annual basis, more evident on the eastern side of the region
19 (Figure 3, panels e-f of Pieri et al. 2015), with differences in the range between -2 and -1
20 mm/day on the eastern coastal part and between -1 and 0 mm/day on the eastern Apennines
21 side.

22 The same analysis was repeated and extended in this study, using 95 raingauges in Liguria:
23 results on annual rainfall depth confirm the findings of Pieri et al. (2015) both on eastern and
24 western Liguria sides (Figure 2).

1 Concerning the seasonal results, EXPRESS-Hydro tends to underestimate average observed
2 rainfall depths during DJF (Figure 3) on eastern Liguria (between 0-100 mm) while generally
3 overestimates them on centre-west (0-100 mm); the same holds also for MAM (Figure 3).
4 During JJA, instead, EXPRESS-Hydro underestimation ranges between 0 and 100 mm over
5 both the western and eastern sides, while ramps up to 100 - 200 mm over the centre. The
6 underestimation deepens over eastern Liguria during SON (Figure 3), with values between -
7 100 and 200 mm inland and up to 200 - 300 mm over the coast. Conversely, on the rest of the
8 region the underestimation drops between 0 -100 mm. In Figure 4 the seasonal comparison
9 between observations and EXPRESS-Hydro is also shown in terms of scatter plots, with a
10 good correlation between reanalysis and observations, while in Table 4 we reported the values
11 of bias and Root Mean Square Error (RMSE).

12 Figure 5 shows the box plot of monthly precipitation averaged at regional scale for both
13 EXPRESS-Hydro and observations, obtained by averaging the maps of accumulated rainfall.
14 The comparison highlights that EXPRESS-Hydro satisfyingly reproduces the variability along
15 the 30 years, but often underestimates the rainfall amount; particularly in January, September
16 and October.

17 Figure 6 shows the same analysis of Figure 5 but at catchment scale on 4 basins whose
18 characteristics are reported in Table 1; the basins locations was spread from east to west side
19 of the region to investigate if different behaviours arise along the study area. It is interesting
20 to evidence that while a general underestimation of rainfall during fall period is found for the
21 rivers located in central-east Liguria (Entella closed at Panesi and Vara closed at Nasceto),
22 the other 2 test basins behave rather differently as the box plots of Argentina closed at Merelli
23 and Arroscia closed at Pogli show an overestimation during spring, especially in April and
24 May.

1 A further analysis was carried out in order to understand how EXPRESS-Hydro reanalysis
2 reproduces the rainfall annual maxima, especially after the application of bias correction;
3 ADM of the region are in fact generally driven by very intense rainfall events that have
4 duration lower or equal to 24 hours. We thus compared the annual maxima of 24 hours
5 accumulated rainfall (ARM) derived by observations with those derived by the reanalysis
6 (with B.C.) again following the approach described in Boni et al. (2007): each series of ARM,
7 observed and modeled, was normalized with its average and a regional non-dimensional
8 distribution function was built. The result is reported in Figure 7 which shows a very good fit
9 between observations and reanalysis, this confirms a general good reproduction of the
10 climatology even in terms of ARM.

11 **3.2 Distribution of the annual discharge maxima**

12 In Figures 8 to 10 a selection of observed and reanalysis-driven ADM CDF distributions, the
13 GEV and the corresponding 95% confidence intervals are shown. Six basins were chosen in
14 order to evidence the variability of results, showing either good and poor performances,
15 moreover the comparisons are referred to hydrological gauging stations where reliable and
16 long-time series of observed ADM are available. For each station the results obtained with
17 and without rainfall B.C. are both reported.

18 The cases in Figure 8 show a shift of the observed distribution with respect to the modeled
19 one especially without B.C. Low ADM observed values lay out of the confidence intervals of
20 the reanalysis-driven ADM GEV distribution, while the most extreme values fall inside the
21 confidence intervals. The distributions without bias correction show an underestimation of
22 ADM; B.C. led to very good results for Entella closed at Panesi and to an overestimation on
23 Bisagno closed at La Presa case.

1 Magra closed at Piccatello (Figure 9) shows an overestimation in both cases, even higher after
2 the B.C; Argentina closed at Merelli benefits of B.C. especially regarding the extreme ADM
3 values.

4 Arroscia closed at Pogli shows an improvement of reanalysis-driven ADM, once B.C. is
5 performed, while Nervia ADM without B.C. well fits the observations and B.C. leads to an
6 overestimation (Figure 10).

7 The Kolmogorov-Smirnov test with a 5% significance level on ADM was applied to all the
8 selected stations and the corresponding results are summarized in Table 5. It is interesting that
9 bias correction does not allow to increase the number of null-hypothesis (data belong to the
10 same distribution) yet: 9 stations out of 15 pass the test either B.C. is applied or not. Changing
11 the significance level does not affect the final findings in a significant way: with a 1% 12
12 stations pass the test with B.C. and 11 without B.C., with 10% 7 stations pass the test with
13 B.C. and 7 without B.C.. This fact could derive on how the B.C. -acting on the monthly
14 volume- affects the short-lived and severe rainfall events that usually are responsible for the
15 ADM in many parts of the study area.

16 The poor reproduction of ADM in some basins may be due to various causes; on one side it
17 was not possible to calibrate the model over the whole study region, on the other side in some
18 periods and in some sub-regions the rainfall reanalysis is probably poorly representative of
19 actual rainfall and B.C. does not correct it enough. Moreover observed peaks and simulated
20 peaks are often referred to different time periods: this, together with the typical hydro-climatic
21 regime of the study region (flash floods with high variability of ADM) could have a
22 significant impact on final results. **There are other sources of uncertainty that can explain the**
23 **mismatches, hydrological model can lead to errors (Walker et al., 2003; Liu and Gupta, 2007)**
24 **due to both its internal structure and to those parameters which are not calibrated but set by**

1 literature or by territorial information; furthermore the input variables are affected by
2 uncertainty, not only rainfall, so they can be causes of errors.

3 We would like also to highlight the fact that simulated ADM distributions have often similar
4 shapes to the observed ones and suffer of a sort of bias (for example Bisagno closed at La
5 Presa, Figure 8), while in other cases the simulated ADM distribution is only partially out of
6 the confidence intervals (example Argentina closed at Merelli, Figure 9). The average
7 hydrologic regime on the study region could be only partially affected by the local bad fittings
8 of ADM.

9 **3.3 Regional analysis of the annual discharge maxima**

10 Figure 11 shows the comparison between the non dimensional regional growth curve obtained
11 fitting a GEV on simulated ADM computed with and without B.C., the observations
12 (available ADM on Liguria Region) and the simulated ADM. The results are quite good even
13 if it seems that the modeling chain without B.C. leads to a small underestimation of high
14 frequency events (low T) and a small overestimation of low frequency events (high T) with
15 respect to the observations. Anyway both observed and modeled ADM lay inside the
16 confidence intervals (95 %) for a large part of the curve.

17 In the Figure we reported the curves built using simulations of all the sub-basins with a
18 drainage area larger than $A_{th}=15 \text{ km}^2$ together with those obtained using only the basins
19 where the hydrological model was calibrated. The curves that used only calibrated basins are
20 really similar to the others, proving that the latter configuration enhances the robustness of the
21 regional curve estimation without introducing evident errors.

22 The main differences in the case of B.C. configuration are that observations lay always inside
23 the confidence intervals and there is a better matching between simulated and observed
24 sample curves. This is a significant finding in fact the regional curve is an important
25 ingredient to deal with quantile estimation in ungauged basins. It is important to highlight that

1 regional approach allows to reduce the errors that can be found for single basins (Boni et al.,
2 2007) and which are shown in section 3.2; on one side the normalization of each ADM series
3 with its average reduces the effects of bias (due for example to a bad hydrological model
4 calibration and other sources of error), on the other side the ADM time series of each outlet
5 section (or grid point) is only a small sub-sample of the entire sample used to build the
6 regional curve. It is anyway important to highlight that good results in terms of growth curve
7 could be also partially due to the effect of error compensation.

8 To compare the quantiles estimated using the modelling chain with those in Boni et al. (2007)
9 the following ratio was considered:

$$10 \quad \text{Ratio}(T) = \frac{Q(T)_{Model}}{Q(T)_{Reg}} \quad (8)$$

11 where Model and Reg respectively stand for modelling chain and regional analysis, T is the
12 return period, Q is the ADM. Ideally, if the modelling chain provided exactly the same results
13 of the benchmark regional analysis, the Ratio(T) value should be around 1, Ratio(T) > 1 (<1)
14 means overestimation (underestimation).

15 Figure 12 shows Ratio(T) for T=2.9 years (Index Flow) as a function of the drainage area (A
16 in km²), while Figure 13 shows the maps of Ratio(T) for T=2.9 years and T=50 years.

17 The first consideration is that a relation between Ratio(T) and A appears to exist even if it is
18 supposedly biased because the size of the sample is biased: the number of small basins is
19 hugely higher than large ones; the chain is not able to reproduce in detail the meteorological
20 and hydrologic processes at very fine time and spatial scales (Siccardi et al., 2005), in fact for
21 $A < 30\text{-}50 \text{ km}^2$ the underestimation seems quite systematic even if B.C. improves results.
22 Ratio(T) is generally underestimated also for $A > 30\text{-}50 \text{ km}^2$ but B.C. generally leads to a
23 better balance between over- and underestimation, despite introducing the overestimation
24 grows on larger basins ($A > 200\text{-}300 \text{ km}^2$). From Figure 13 a general improvement driven by

1 B.C. stands out especially in those areas where the model chain without B.C. underestimates
2 $Q(T)$. Areas where modelling chain is really close to the benchmark are in green/light blue,
3 whereas dark blue and purple point out where under or overestimation is high (absolute
4 difference larger than 70-100%); noticeably, $Ratio(T)$ for $T= 50$ years and $T=2.9$ years
5 (Figure 13) have a similar pattern.

6 In central Liguria the $Ratio(T)$ obtained with EXPRESS-Hydro leads to results comparable
7 with Boni et al. (2007) regardless the use of B.C., while simulations with B.C. are affected by
8 overestimation. This could be due to different causes: i) EXPRESS-Hydro is likely to well-
9 reproduce the events at small time and spatial scales (3-6 hours, 10-100 km²) in that part of
10 the region as well as generally underestimates monthly accumulation, in this case B.C. could
11 lead to streamflow overestimation; ii) the hydrological model may need a better calibration,
12 but it does not seem the most probable option; in fact B.C leads to the overestimation of ADM
13 even in calibrated basins, this occurrence arose even in the site comparison (Bisagno creek,
14 see section 3.2) iii) the quantiles in this area may have been underestimated by Boni et al.
15 (2007). It has to be noticed that overestimation is larger for $T=2.9$ years than for $T=50$ years
16 (see Figure 13, some basins are in purple for $T=2.9$ years and in yellow-orange for $T=50$
17 years), this is probably due to the fact that the shape of the growing curve in the B.C. case
18 leads to a reduction of the overestimation as T increases; the behaviour on western Liguria is
19 similar to the centre even if less stressed and evident for larger basins only.

20 The underestimation on smaller catchments ($A < 30-50$ km²) could be partially due to a not
21 optimal parameterization of the hydrological model (especially where calibration was not
22 possible), but it appears more reasonable that the errors related to parameterization would lead
23 to a uniform-like distribution between over and underestimation. However, the model spatial
24 resolution could play a role since the representativeness of the catchment morphology
25 decreases for small drainage areas with a general smoothing effect that affects the results: this

1 degradation effect is clearly continuous from large to small drainage areas, though a threshold
2 for the analysis (i.e., basins with $\text{Area} < 16 \text{ km}^2$ are neglected) was set.

3 A further cause is presumably that EXPRESS-Hydro cannot always adequately reproduce the
4 rainfall structures at fine spatial and temporal scale, and the downscaling procedure can only
5 partially correct this drawback. Moreover the time resolution (1 hour after downscaling) could
6 be not sufficient when drainage area is small (Silvestro et al., 2016; Rebora et al., 2013): as a
7 consequence, the runoff processes needed to trigger such very small catchments are not
8 properly modelled (Siccardi et al., 2005).

9 The combination of the aforementioned factors leads us to conclude that the underestimation
10 of quantiles for very small catchments (i.e. $A < 30\text{-}50 \text{ km}^2$) is a structural problem of the
11 modelling chain.

12 This fact is supported by the analysis shown in Figure 14, left panel. The Ratio(T) averaged
13 on the target area is plotted as a function of T for all the sub-basins with drainage Area ≥ 16
14 km^2 . Ratio increases with T especially for the B.C. case, meaning that the growth curve
15 values K(T) obtained by EXPRESS-Hydro partially balance the underestimation of average
16 ADM (used as Index Flow) in the estimation of higher quantiles; Ratio(T=2.9 years) changes
17 from 0.47 to 0.71, Ratio(T=50 years) from 0.45 to 0.66. If the threshold area is increased from
18 16 to 50 km^2 (Figure 14, right panel) the underestimation drops for both cases, with and
19 without B.C..

20 As already shown, the general underestimation of Ratio(T) for small catchments is not
21 completely confirmed for all the region, for instance, in part of central Liguria results are
22 quite good even for basins with Area $< 50 \text{ km}^2$ and bias correction leads to an overestimation
23 of Ratio(T). Apparently, in this area EXPRESS-Hydro can produce rainfall with a spatial-
24 temporal structure able to trigger floods compatible with the hydro-climatology of local small
25 basins. This is also the part of the study region that previous studies demonstrated to be

1 characterized by the highest values of rainfall maxima for 1, 3, 6, 12 and 24 hours (Boni et al.,
2 2008).

3 **3.4 Effects of the rainfall downscaling on simulated ADM**

4 In order to assess the influence of the rainfall downscaling, the modelling chain was applied
5 without it. In this way for each pixel of the domain a 30year long time series of ADM was
6 computed by the hydrological model driven with the bias-corrected rainfall reanalysis at
7 EXPRESS-Hydro native resolution. The rainfall field was assumed to have a constant
8 intensity over 3-hourly timestep and resampled from 4 km to 1 km.

9 The 30-year average ADM was computed and compared to the ones obtained by the complete
10 chain by estimating the following ratio for each grid cell:

$$11 \quad RatioDS = \frac{Q_{MeanNoDS}}{Q_{MeanDS}} \quad (9)$$

12 where $Q_{MeanNoDS}$ (Q_{MeanDS}) is the average ADM obtained without (with) downscaling. The
13 RatioDS was then plot versus the drainage area as in Figure 15:the downscaling impact
14 generally increases as the drainage area decreases, and it is crucial to simulate the ADM on
15 small catchment when drainage area is lower than 100-150 km². Moreover RatioDS is always
16 lower than 1, thus confirming that rainfall downscaling enhances the runoff formation as in
17 Siccardi et al. (2005), likewise the analysis evidences how the underestimation of quantiles
18 shown in section 3.3 would worsen without it.

19 **3.5 Water balance and runoff ratio**

20 In this section some considerations about the long-term water balance are shown in order to
21 evaluate how the applied system can reproduce the hydrological cycle and the variables
22 related to water balance and water resources management.

23 Taking advantage of the modelled evapotranspiration maps, the distributed runoff ratio (RR) at
24 cell scale is estimated as:

1 $RR(x, y) = \frac{Rain(x,y)-Evt(x,y)}{Rain(x,y)}$ (10)

2 where $Rain(x,y)$ and $Evt(x,y)$ are the modeled total rainfall and evapotranspiration in the cell
3 with coordinates (x,y) over the 30 years of simulation. The maps of RR are shown in Figure
4 16, together with the maps of mean annual rainfall for both cases with and without B.C..

5 The spatial pattern of RR is strongly correlated to the precipitation one, and the latter is in
6 turn evidently related with orography, especially for the case without B.C..

7 When a single cell has a large number of upstream cells, it tends to be frequently saturated
8 because of the contributions of subsurface flow of the upstream cells: the values in the cells
9 that belong to channel network as simulated by the hydrological model (Giannoni et al., 2005)
10 are not shown because they are hardly representative (generally, the values are very low or
11 even negative).

12 B.C. produces an increasing of both precipitation and runoff ratio on the entire region and a
13 reduction of the differences between coastal and inland areas. In order to estimate how the
14 modeling chain reproduces the available observations the runoff ratio at basin scale on a
15 target gauge station S is computed by:

16 $Rs(s) = \frac{VQ(s)}{Rain(s)}$ (11)

17 where $Rain(s)$ is the accumulated rainfall over the basin laying upstream the gauge station S
18 and $VQ(s)$ is the integral on time of the streamflow volume passed through the gauge station
19 S. We considered some gauge sections where the runoff ratio estimated by observations
20 (rainfall and streamflow) is available (see Table 1) from the Hydrologic Annual Survey
21 (<http://www.arpal.gov.it/homepage/meteo/pubblicazioni/annali-idrologici.html>), an official
22 document published by the Regional Agency for Environment Protection. The observed
23 runoff ratios are not available for the simulation period (1979-2008) but they are estimated as

1 an average of the values measured in non-continuous periods since 1940s to present, thus
2 providing a possible benchmark to assess the performance of the modeling chain.
3 Modeled RRs are compatible with the hydro-climatology of the target area (Barazzuoli and
4 Rigati, 2004; Provincia di Imperia, 2017) but at the same time it is evident a general
5 underestimation in the western part of the region (basins Neva, Arroscia, Argentina); B.C.
6 improves results and RRs are more similar to the benchmark (Table 6.).
7 The rainfall B.C. introduces only small variations in terms of runoff ratio, thus meaning that
8 when the long term water balance is addressed, the increasing or decreasing of rainfall lead on
9 similar percent variation on both runoff and evapotranspiration.
10 For example, in the central and eastern parts of Liguria, B.C. generally increases the
11 precipitation and reduces the orographic features of the spatial pattern, but at the same time
12 the evapotranspiration increases too, consequently RRs rise is small. As shown in sections 3.2
13 and 3.3 the increasing of rainfall leads to larger values of ADM, but the RRs do not change
14 significantly: this could be due to the fact that other EXPRESS-Hydro variables that influence
15 the energy balance (and the long term water balance) like solar radiation or wind speed may
16 benefit a correction, nevertheless no reliable and dense data are available for the entire
17 simulation period. Another approach could be to perform a calibration more focused to
18 preserve long term runoff. In any case we could say that generally the results are good and
19 they highlight the potentialities of using such modeling chain even for water balance
20 purposes.

21 **4 Discussion and conclusions**

22 This work explores the possibility of using EXPRESS-Hydro, a high-resolution regional
23 dynamical downscaling of ERA-Interim dataset by means of the state-of-the-art non-
24 hydrostatic Weather Research and Forecasting (WRF) regional climate model for
25 hydrological purposes on small catchments. This was done by feeding a distributed

1 continuous hydrological model with a subset of the EXPRESS-Hydro meteorological
2 variables to produce streamflow simulations; the rainfall fields were downscaled from the
3 native space-time resolution (4km, 3 hours) to a finer one (1km, 1 hour) before they were
4 used to feed an hydrological model. All the analyses were conducted either applying and not
5 applying a bias correction to rainfall fields. The study area is Liguria, a Region in the north-
6 western Italy, with a particular focus on its Tyrrhenian coast.

7 Firstly we evaluated the performance of the modelling chain in reproducing extreme
8 streamflow statistics by following two methods: i) by comparing statistical distribution of
9 ADM with observations in some gauging points ii) by using as a benchmark the regional
10 analysis presented in Boni et al. (2007) that allows a comparison with a distributed approach.

11 We then evaluated how the modeling chain reproduces the long term water balance by
12 analyzing the modeled runoff ratios and using as a benchmark the estimations based on
13 observations.

14 The results are encouraging even if the modelling chain cannot always meet the considered
15 benchmarks with high accuracy. The ADM statistic is quite good in most of the target region
16 but in some sub-regions the quantiles are sometimes under- or over-estimated. Rainfall B.C.
17 generally improves the underestimation, yet introducing an overestimation in some basins
18 especially in the central part of the region and in the largest basins.

19 A single-site comparison of modelled and observed ADM shows that, for a large number of
20 the gauging sites the time series belong to the same distribution with a 5% significance, the
21 fitting of modelled ADM with GEV distributions is generally good and often the observations
22 lay inside the 95% confidence interval, especially for low-frequency quantiles. It must be
23 noted that anyway in some sites the GEV fitting without B.C. is better than that with B.C.

24 A comparison with the regional analysis shows interesting results as the behaviour
25 remarkably drifts in some parts of the region, depending on how EXPRESS-Hydro generates

1 the spatial-temporal patterns of precipitation and how much rainfall bias correction is
2 effective.

3 Both point and distributed analysis show that there is a general underestimation for basins
4 with drainage area smaller than 30-50 km² but B.C. is able to tackling it largely. This is
5 probably due to structural problems of the modelling chain under the aforementioned size:
6 for those basins it is necessary to further refine the time and spatial scales of the
7 meteorological input (precipitation chiefly, Siccardi et al., 2006; Silvestro et al., 2016), and
8 likely of hydrological model too (Yang et al., 2001). A possible way to deal with very small
9 basins is to better exploit the potentialities of the downscaling algorithm (RainFARM) that is
10 here used in a deterministic way to generate a possible time (1-hour)- and space (1km) pattern
11 with the constraint of maintaining the precipitation volumes and structures generated by
12 EXPRESS-Hydro at its native resolution (3 hours, 4 km).

13 Runoff ratio RR was used to evaluate long term water balance. The RR coefficient evaluated
14 on a 30-year long simulation period at cell scale reasonably meets the climatology of the
15 region (Barazzuoli and Rigati, 2004; Provincia di Imperia 2017) and its pattern is highly
16 correlated with annual mean rainfall distribution. RR at basin scale was compared with
17 observations-based estimates for some gauging points and the values are of the same order of
18 magnitude, however the modelling chain generally underestimates in both configurations
19 even if B.C. results are slightly better. This could be due to the fact that also the variables
20 related to energy balance (for example the solar radiation and wind) modelled by EXPRESS-
21 Hydro probably need a correction, but this analysis was not carried out, mainly for the lack of
22 reliable and sufficiently dense data.

23 To summarize this work, the present modelling chain was proven to reliably simulate the
24 hydro-meteorological statistics in the study area, even if some difficulties and gaps were
25 emphasized by the study. The fully distributed approach allows to reproduce the hydro-

1 climatic characteristics and features in a seamless way over the whole territory. Rainfall B.C.,
2 by helping the system to better model some characteristics not completely captured even by a
3 high-resolution meteorological reanalysis, contributes in a relevant way to improve the results
4 even in very small basins (Area < 30-50 km²) generally affected by structural
5 underestimation.

6 **5 Appendix**

7 The Leaf Area Area index were estimated using a map of vegetation cover
8 (<https://geopotal.region.liguria.it/catalogo/mappe.html>) and linking the vegetation types with
9 literature values (Asner et al., 2003) using the classes reported in Table 7. In this application
10 values does not change in time.

11 In the following we report the values used for those parameters not involved in the
12 calibration, defined referring to literature.

13 Values used to estimate the soil thermal inertia:

14 Soil density: 2700 [kg·m⁻³]

15 Soil specific heat: 733 [J·kg⁻¹·K⁻¹]

16 Soil porosity=0.4 [-]

17 The values of neutral component of the bulk heat transfer coefficient were derived by
18 Caparrini et al. (2004) and assigned differently for each season:

19 Winter: $1 \cdot 10^{-3}$ [-]

20 Spring: $4 \cdot 10^{-3}$ [-]

21 Summer: $5 \cdot 10^{-3}$ [-]

22 Autumn: $3 \cdot 10^{-3}$ [-]

23
