Abstract

Hydrological disturbances could increase dissolved organic carbon (DOC) exports through changes in runoff and leaching, reducing the potential carbon sink function of peatlands. The objective of this study was to assess the impact of hydrological restoration on hydrological processes and DOC dynamics in a rehabilitated *Sphagnum*-dominated peatland. A conceptual hydrological model calibrated on the water table and coupled with a biogeochemical module was applied to La Guette peatland (France), which experienced a rewetting action on February 2014. The model (eight calibrated parameters) reproduced water table ($0.1 < NS < 0.61$) and pore water DOC concentration ($2 < RMSE < 11 \text{ mg L}^{-1}$) time series (01/04/2014 to 15/12/2017) in two contrasted locations (rewetted and control) of the peatland. Hydrological restoration was found to impact the water balance through a decrease in slow deep drainage and an increase in fast superficial runoff. Observed DOC concentrations were higher in summer in the rewetted location compared to the control area and were linked with a difference in dissolved organic matter composition analyzed by fluorescence. Hydrological conditions, especially the severity of the water table drawdown in summer, were identified as the major factor controlling DOC concentration dynamics. The results of the simulation suggest that the hydrological restoration did not affect DOC loads, at least on a short-term period (3 years). However, it impacted the temporal dynamics of DOC exports, which were the most episodic and mainly transported through fast surface runoff in the area affected by the restoration while slow deep drainage dominated DOC exports in the control area. In relation with dominant hydrological processes, exported DOC is expected to be derived from more recent organic matter in the top peat layer in the rewetted area than in the control area. Since it is calibrated on water table and DOC concentration, the model presented in this study proved to be a relevant tool to identify the main hydrological processes and factors controlling DOC dynamics in different areas of the same peatland. It is also a suitable alternative to a discharge calibrated catchment model when the outlet is not easy to identify or to monitor.

1 Introduction

Sphagnum-dominated peatlands represent a major stock of the global soil carbon (C) pool (Gorham, 1991). Dissolved organic carbon (DOC) exports through runoff and leaching could account for up to 25% of the C fluxes (Yu, 2012), reducing the potential C storage function of peatlands (Billett et al., 2004) and impacting downstream water quality (Ritson et al., 2014). DOC dynamics in peatlands has been found to be strongly controlled by site hydrology, especially by the water table depth (WTD) (e.g. Hribljan et al., 2014; Jager et al., 2009; Strack et al., 2008, 2015). Therefore, hydrological disturbances such as drainage can lead to increased DOC exports in relation with WTD variations (Strack et al., 2008; Worrall et al., 2007). Where disturbances have occurred, hydrological restoration can be undertaken to reestablish peatland functioning (Menberu et al., 2016), with a potential impact on DOC dynamics and exports (Glatzel et al., 2003; Strack et al., 2015; Worrall et al., 2007).

In peatlands, as in many terrestrial ecosystems, DOC dynamics is controlled on the one hand, by its production to consumption ratio in pore water, and, on the other hand, by lateral water fluxes that drive its exports. DOC production through organic matter decomposition is known to increase with temperature (Clark et al., 2009; Freeman et al., 2001) and DOC consumption, mainly due to heterotrophic bacterial activity, is also positively correlated to temperature and can lead to decreased DOC concentrations during drought (Clark et al., 2009; Pastor et al., 2003). The export of the DOC produced in pore water is mainly controlled by peatland hydrology (Pastor et al., 2003; Strack et al., 2008), especially by the partitioning between quick near surface flow and groundwater flow (Birkel et al., 2014). Due to the complexity of the interactions between these factors, field studies can show contradictory results on the effect of rewetting on DOC dynamics, with some studies reporting increasing concentrations (Hribljan et al., 2014; Strack et al., 2015) while others report decreasing concentrations (Höll et al., 2009; Wallage et al., 2006).

While changes in DOC net production resulting from WTD drawdown can be assessed through field monitoring, the relative contributions of DOC production and consumption cannot be evaluated (Strack et al., 2008). Process-based biogeochemical models can be relevant tools to understand DOC dynamics (Evans et al., 2005) and can help to identify factors controlling its production and consumption in such environments. In particular, conceptual models are appropriate because they are parsimonious in terms of their number of parameters, avoiding overparametrization issues (Birkel et al., 2017; Seibert et al., 2009). Nevertheless, these parameters have to be adjusted to every condition through calibration and validation phases when a more physically model would only require adjusting boundary conditions. In addition, conceptual models are valid for a specific range of input data and should not be used for prediction where conditions lie out of their validation range. However, another advantage of using conceptual models is that they usually require commonly measured data (e.g. precipitation and water discharge or water level) so they can be applied to numerous study sites where such data are available, making them a suitable tool to compare sites with different settings.

When studying DOC dynamics in peatlands, existing conceptual models are composed of a DOC module combined with a hydrological model (Birkel et al., 2014; Futter et al., 2007; Lessels et al., 2015). In these studies, the hydrological model is

usually adapted to the catchment and calibrated on stream discharge. However, stream discharge in peatlands is difficult to monitor because the diffuse runoff that occurs in these flat areas can result in multiple outlets. Furthermore, while WTD is a key parameter to explain DOC dynamics (Strack et al., 2008), it is usually not considered for calibration, and water discharge is preferred instead. Therefore, while these models have proven to be well adapted when modelling a catchment containing a peatland area (Birkel et al., 2014; Futter et al., 2007; Lessels et al., 2015), where the outlet is well defined, they are more difficult to apply when considering a peatland alone. In this case, the model should focus on the simulation of the WTD, especially when studying DOC dynamics in peatland pore water. Furthermore, a model based on WTD can also provide interesting information about the spatial variability of the dominant hydrological processes when applied to different locations within the same peatland. Models simulating DOC dynamics are usually based on a simple mass balance and DOC production and consumption rates, usually expressed as first order rate processes (Birkel et al., 2014; Futter et al., 2007; Lessels et al., 2015). In these cases, DOC production and consumption rates are modified using terms related to temperature and soil moisture as these two parameters control the microbial activity and peat decomposition that regulate the production and consumption of DOC in peat water.

In this study, we propose to couple an existing WTD dependent hydrological model specially developed for simulating peatland hydrology (Binet et al., 2013) with a biogeochemical module simulating DOC production and consumption as first order rate processes. The hydrological model was calibrated on WTD, which is an important driver of the DOC dynamics in peatland. The model was applied to two sites of a *Sphagnum*-dominated peatland, one of them having experienced a rewetting action. The objectives of this study were 1) to identify the dominant hydrological processes in both a rewetted and undisturbed peatland locations, 2) to understand how these hydrological processes affect the DOC dynamics in each of these two locations, and 3) to assess the impact of the rewetting on DOC export in a *Sphagnum*-dominated peatland.

2 Material and methods

2.1 Study area and data collection

2.1.1 Site description

The La Guette peatland (150 m.a.s.l., 47°19N, 2°16'E, 20 ha), located in the Sologne forest (Neuvy-sur-Barangeon, France) is an acidic fen with a homogeneous plant cover mainly composed of moss patches (*Sphagnum cuspidatum*, *S. rubellum* and *S. palustre*), and ericaceous shrubs (*Calluna vulgaris* and *Erica tetralix*). The peatland has been invaded by *Molinia caerulea* and *Betula spp* for 70 years with an acceleration of the invasion in recent decades (Gogo et al., 2011). This was partly caused by a road ditch located near the outlet that accelerated the peatland drainage (Fig. 1). In February 2014, hydrological restoration was undertaken in the road ditch to raise the WTD and reduce its fluctuations in order to promote soil rewetting. The site is an oligotrophic fen that has not developed any abundant hummock and hollow microtopography, such as is found in a typical ombrotrophic site.

2.1.2 Data collection and analysis

WTD and DOC concentrations ([DOC]) in pore-water were monitored in two locations of the peatland. One is affected by the restoration work and is called “rewetted” while the other is not and is called “control” (Fig. 1). WTD were recorded in piezometers since February 2014 at a 15 min time step using vented-pressure probes (Orpheus mini, OTT Hydromet). Pore-water was sampled in 4 wells surrounding each piezometer (each of them less than 5m from the piezometer) during 13 campaigns that took place every 1 to 4 months between February 2014 and December 2017. The pipes were emptied before sampling to avoid the presence of rain water and ensure that the water sampled was representative of the peatland water. The water samples were filtered using 0.45 μm PES filters on the field and transported in an ice box to the lab where DOC concentrations were determined with a TOC analyzer (TOC-L, Shimadzu) within 2 days following sampling (samples stored at 4°C). In this study, the measured [DOC] is considered to correspond to [DOC] of the macropore water as pipes are expected to be filled by gravitational water after being emptied (Zsolnay, 2003).

Pore-water dissolved organic matter (DOM) was characterized by its fluorescence properties through three-dimensional excitation emission matrices (EEMs; Fellman et al., 2010) acquired with F-2500 and F-7000 spectrofluorometers (Hitachi). EEMs were recorded using a 10 x 10 mm quartz mirrored cell, at a photomultiplier voltage of 400 V, with a scan speed of 1500 nm/min, over ranges of excitation of 220–500 nm, in 10 nm steps, and emission of 230–550 nm, in 1 nm steps, respectively; the slit widths of both monochromators were set at 5 nm. A parallel factor analysis (PARAFAC) was performed using the drEEM toolbox according to the processing described in Murphy et al. (2013). PARAFAC is a commonly used method to analyze EEMs based on the decomposition of DOM fluorescence signature into individual components that provide estimates of the relative contribution of each component to total DOM fluorescence (Fellman et al., 2010). The method was applied to analyze the samples of two campaigns, those of March 2015 (wet conditions) and September 2015 (dry conditions) in order to compare DOM composition for two contrasted hydrological settings.

Meteorological data were recorded at an hourly time step from a station located within the peatland between the two studied areas (Fig. 1). Rainfall was measured with a tipping bucket rain gauge and potential evapotranspiration (PET) computed with the FAO Penman-Monteith equation at an hourly time step (Allen et al., 1998) using local solar radiation, wind speed, relative humidity and temperature measurements.

The effect of hydrological conditions (dry period from 1st of June to 30th of November and wet period from 1st of December to 31st of May) and location (rewetted or control) on [DOC] and DOM composition were tested using two-way ANOVA and Tukey’s *post hoc* tests were used to identify the significant differences (p-value is referred as p).

2.2 Model description

The modeling approach used in this study combines a conceptual hydrological model with a biogeochemical model simulating DOC dynamics. The hydrological model is based on a conceptual water table dependent hydrological model that has already been successfully applied in the study area (Binet et al., 2013). This model is coupled with a module based on

functions describing DOC production and consumption in pore-water which was developed for this study. The model is described in detail in the following sub sections.

2.2.1 Hydrological model

The hydrological model is based on the model described by Binet et al. (2013). It is a daily time step, reservoir model specifically developed for peatland hydrology integrating a WTD dependent runoff. Compared to the original model, a few modifications were made in this study in order to improve the model. The overall structure of the new model is presented in Fig. 2.

The relation between soil water content and WTD was improved. In the original version the user had to know the relation between WTD and soil water content. Now the model automatically computes the soil water content based on the porosity of the percolation reservoir (Θ_{min}), the porosity at the surface (Θ_{max}), and peat depth (H_{max}) (Fig. 2). The porosity of the percolation reservoir is considered to be constant over the depth and equal to Θ_{min} . The porosity of the S_m reservoir is equal to 0 at the maximum depth (H_{max}) and increases linearly with the storage until the surface where it reaches $\Theta_{max}-\Theta_{min}$, Θ_{max} being the total porosity of the S_e and S_m reservoirs at the surface. The new relation between WTD and soil moisture content is given by

$$15 \quad H(\theta) = \frac{\ln(\theta/\theta_{min})}{\left(\frac{\theta_{max}-\theta_{min}}{S_{max}}\right)} \quad (1)$$

$$S_{max} = \frac{H_{max} (\theta_{max}-\theta_{min})}{\ln(\theta_{max}/\theta_{min})} \quad (2)$$

where H is the WTD (mm), Θ is the sum of the porosities in S_m and S_e at a given H and S_{max} is the maximum amount of water contained in both S_m and S_e (mm).

With this modification, the maximum amount of water stored in the S_e reservoir (S_{emax} in mm), which was a calibrated parameter in the original version of the model, is now automatically computed with

$$20 \quad S_{emax} = \theta_{min} H_{max} \quad (3)$$

Overall, this definition improved the relation between WTD and the water content. In the original version of the model, the porosity of the S_m reservoir was equal to 1, while it now depends on the WTD, to better represent reality (Bourgault et al., 2017).

A third reservoir was added, S_r (overland flow storage), in order to differentiate the overland flow water (S_r) from the water entering the peat macroporosity (S_m), which were not differentiated in the original model. While it might not significantly affect the hydrological model, this was done to prepare for the addition of biogeochemical processes which are different for these two reservoirs. Following the addition of the S_r reservoir, a maximum amount of water contained in the S_m reservoir is defined (S_{mmax} in mm) and is computed according to

$$30 \quad S_{mmax} = S_{max} - S_{emax} \quad (4)$$

The routing was also slightly modified to take into account the addition of the new reservoir (Sr). Water from precipitation first fills the Sm reservoir, and the Sr reservoir starts to be filled only when Sm is full ($S_m = S_{mmax}$). The order of priority in which evapotranspiration is removed from the 3 reservoirs is now Sr, Sm and Se.

Finally a discharge coefficient was added to compute the flow from the new Sr reservoir,

$$5 \quad O = \alpha_o S_r \quad (5)$$

where O is the overland flow from the Sr reservoir (mm), α_o is the discharge coefficient of the Sr reservoir (-) and Sr is the volume of water in the Sr reservoir (mm).

This flux is added to the total discharge which is now computed according to

$$Q = D + R + O \quad (6)$$

10 where Q is the total discharge (mm), D is the percolation rate from the Se reservoir (mm) and R is the runoff rate from the Sm reservoir (mm).

Given the structure of the model, D represents the drainage of the retention reservoir and can be assimilated to slow deep drainage. R and O represent the drainage of the macroporosity and the overland flow and can be assimilated to fast superficial drainage.

15 Concerning evapotranspiration, the crop coefficient used to compute evapotranspiration (ET) from ETP was separated into the dormant (Kcd) and the growing (Kcg) season. The latter runs from May to September with a linear relation between the two coefficients during April and October. This was done to take into account the impact of vascular vegetation growth in peatlands. Finally, a condition was added so that the water level in Sm cannot be lower than the water level in Se.

The computation of the following processes remained unchanged: infiltration from Sm to Se (ISe), percolation (P) and runoff
20 (R). The reader is referred to Binet et al. (2013) for a more detailed description of the computation of these processes.

The modified hydrological model is now controlled by 9 parameters (Tab. 1). Three input parameters describing the peat structure (Hmax, Θ_{min} and Θ_{max}) and 6 calibrated parameters controlling water fluxes in the model: Kcd and Kcg for ET, Imax for the ISe, and a discharge coefficient for each reservoir (α_p , α_r and α_o). The forcing variables remained daily precipitation and PET as in the original model.

25

2.2.2 DOC model

To simulate DOC dynamics, a module was developed based on first order production and loss, and mass balance, similarly to what can be found in the literature (Birkel et al., 2014; Lessels et al., 2015). Production and loss are computed in the Se and Sm reservoirs only since the main biogeochemical processes linked to DOC dynamics occur in soil storage and no
30 reaction takes place in the Sr reservoir. DOC production was based on a production coefficient and two additional modifiers based on soil water content and air temperature, as usually considered in DOC production models (Birkel et al., 2014; Futter et al., 2007; Lessels et al., 2015). The effect of the temperature was based on a Q_{10} formulation (the factor by which the rate of a reaction increases for every 10-degree rise in the temperature) with a value of 2 according to the value commonly used

in DOC production models (Lessels et al., 2015; Michalzik et al., 2003; Tjoelker et al., 2001). The rate modifier based on water content was expressed with a quadratic function to represent the non-linear production of DOC with the variation in soil moisture. DOC production is computed as follows:

$$PDOC = k_{prod} S SOC 2^{T/10} (S / Smax)^2 \quad (7)$$

- 5 where PDOC is the DOC production rate ($\text{mg day}^{-1} \text{m}^{-2}$), k_{prod} is the production constant (day^{-1}), SOC is the amount of organic carbon per mm of peat per square meter ($\text{mg mm}^{-1} \text{m}^{-2}$), T is the air temperature ($^{\circ}\text{C}$), S is the amount of water in the reservoir considered (mm) and Smax is the maximum amount of water in the reservoir considered (mm).

DOC loss, corresponding to mineralization and sorption, was based on a loss coefficient linked to air temperature in the same way as DOC production. DOC loss is computed according to

$$10 \quad LDOC = k_{loss} [DOC] S 2^{T/10} \quad (8)$$

where LDOC is the DOC loss rate ($\text{mg day}^{-1} \text{m}^{-2}$), k_{loss} is the loss constant (day^{-1}), [DOC] is the DOC concentration in pore water (mg L^{-1}) and S is the amount of water in the reservoir considered (mm).

Finally, the mass balance of DOC is computed in the Sm and Se reservoirs at the daily time step

$$DOC_{Sm}^{t+1} = DOC_{Sm}^t + (PDOC_{Sm}^t - LDOC_{Sm}^t + [DOC]_{rain} I_{Sm} - [DOC]_{Sm}^t (I_{Se} + R)) dt \quad (9)$$

$$15 \quad DOC_{Se}^{t+1} = DOC_{Se}^t + (PDOC_{Se}^t - LDOC_{Se}^t + [DOC]_{Sm}^t I_{Se} - [DOC]_{Se}^t D) dt \quad (10)$$

where the upper index represents the time step, the subscript indicates the reservoir considered (Sm or Se), DOC is the mass of DOC in the considered reservoir per unit area (mg m^{-2}), $[DOC]_{rain}$ is the DOC concentration in rain water (mg L^{-1}), I_{Se} is the infiltration from Sm to Se per unit area (mm day^{-1}), I_{Sm} is the infiltration from Sr to Sm (mm day^{-1}) and dt is the time step (here chosen as one day).

- 20 The DOC model is controlled by 4 parameters (Tab. 1). Two input parameters (SOC and $[DOC]_{rain}$) and two calibrated parameters controlling DOC dynamics (k_{loss} and k_{prod}). The additional forcing variable is air temperature.

2.2.3 Model setup

- The hydrological and biogeochemical model parameters were calibrated for each piezometer of the peatland for the wettest period (01/04/2014 to 01/04/2015) and the driest period (01/10/2016 to 15/12/2017) considering available data. The model
 25 was validated over a period with a more intermediate condition (01/04/2015 to 01/04/2016). The period from 01/05/2016 to 30/09/2016 was not simulated because exceptionally heavy rainfall (return period of about 50 years) occurred on 31/05/2016, causing extensive flooding in the whole region. The definition of the model is not suitable for these exceptional events because the water coming from the river during the flood is not taken into account in the model. However, the flood was not expected to impact [DOC] in the peat profile since it was already saturated with rain water when the flood of the
 30 river reached the peatland. In addition, it has to be noted that the model is able to represent less exceptional events as long as the flood does not reach the peatland (estimated at a 10 to 20 years return period in our case). Θ_{min} and Θ_{max} were set at 0.2 and 1, respectively, and Hmax at 0.6 m, based on field data. $[DOC]_{rain}$ was 2 mg L^{-1} according to measurements

performed on rain water and SOC was set at $833 \cdot 10^3 \text{ mg mm}^{-1} \text{ m}^{-2}$ following measurements performed on peat samples. Initial conditions were set to observed values for water table depth and to 15 mg L^{-1} for [DOC].

2.2.4 Model calibration and evaluation

The parameters were calibrated with a Nelder-Mead algorithm (Varadhan et al., 2016) implemented in the R software (R Core Team, 2012) using the Nash-Sutcliffe coefficient on the water table depth (NS, Nash and Sutcliffe, 1970) as the objective function for the hydrological module and the root-mean-square error (RMSE) for the DOC concentrations in Sm. NS was chosen for the hydrological model because it can take the large variation of the water table into account while RMSE was chosen for the DOC model because [DOC] variations are not very large and it provides a quantitative estimate of the error. In addition, the coefficient of determination multiplied by the slope of the regression (Br2, Krause et al., 2005) was computed for both the hydrological and DOC model, to better assess the quality of the simulations. The hydrological model was calibrated following a multi-site strategy. The parameters independent of the location within the peatland were kept similar for both sites (Kcd, Kcg and Imax) and only the parameters expected to differ between sites were set free for each site (α , α_{sr} and α_p). This was done in order to prevent an overfitting of the model. The hydrological module was calibrated first because substantially more water table data were available than DOC concentrations. The DOC module was then calibrated after the calibration of the hydrological model. The ranges allowed for the calibrated parameters are indicated in Tab. 3. A sensitivity analysis was performed using a latin-hypercube one-factor-at-a-time (LHOAT) procedure (Zambrano-Bigiarini and Rojas, 2014) implemented in the R software. The sensitivity analysis was based on NS for the hydrological model. The sensitivity analysis was not performed for the DOC model since it contains only 2 parameters, both considered as sensitive. Finally, an uncertainty analysis of the hydrological model was performed based on a GLUE analysis (Beven and Freer, 2001) with 50 000 runs, using a criteria of $NS > 0$ for both locations to select behavioral simulations. Parameters ranges were the same than the one used for the calibration (Table 3). Uncertainty boundaries on fluxes are presented as the 5th and 95th of the fluxes obtained from the weighted behavioral parameter sets. The main objective of the uncertainty analysis was to better assess the confidence in the simulated fluxes for which no data were available.

3 Results

3.1 Observed hydrology and DOC

The mean annual precipitation (P) of the area was 787 mm yr^{-1} and the mean annual PET 935 mm yr^{-1} for the period ranging from 01/04/2014 to 10/12/2017 (Tab. 2). WTD and DOC exhibited different dynamics between rewetted and control areas (Fig. 3, 4 and 5). The water table was close to the surface level in each piezometer during the wet season but the length of this season depended on the severity of the water table drawdown that occurred during the previous drier season. In 2014, a particularly wet year ($P=906 \text{ mm}$ and $PET=904 \text{ mm}$ from 01/04/2014 to 01/04/2015), the water table reached the surface in December 2014 while for the following season, which was relatively dry ($P=736 \text{ mm}$ and $PET=960 \text{ mm}$ from 01/04/2015 to

01/06/2016), it reached the surface in May 2016. The WTD was lower on average and with a greater variability in the control than in the rewetted area but the main difference between the sites was the severity of the maximum water table drawdown which was 26 cm in the rewetted and more than 43 cm in the control site, with the same climatic conditions for both locations.

- 5 The average of [DOC] measurements was 13.3 ± 4.6 mg L⁻¹ in the control site and 21.6 ± 7.2 mg L⁻¹ in the rewetted one. [DOC] were globally higher in the rewetted than in the control site (p-value<0.001) but this was especially true in the dry period. Overall, [DOC] were higher in dry periods than in wet periods for the rewetted site while this difference was not observed in the control site (Fig. 4a). Finally, when considering the temporal evolution of [DOC], the main difference was observed between April and October 2015 where [DOC] rose in the rewetted but decreased in the control site (Fig. 5).
- 10 The PARAFAC analysis revealed three main components characterizing the DOM (Fig. 4b). According to the review by Fellman et al. (2010), the first component (ex 360, em 466) can be described as high-molecular-weight and humic and is referred to here under its original name as C. The second component (ex 330, em 407) can be described as low-molecular-weight and is referred to here as M. The third component (ex 250, em 446) can be described as high molecular weight and humic and is referred to here as A. Component A is known to be more aromatic than C (Fellman et al., 2010), even if in our
- 15 case, the shorter emission wavelength for component A than for C may also indicate that C is more aromatic than A (McKnight et al., 2001). The ratio of the contribution of component C over the contribution of A and of the contribution of component M over the contribution of A in pore water samples of the wet and dry campaigns are presented in Fig. 4 (c and d). A large increase in the contribution of C relative to the contribution of A was observed in dry conditions in the rewetted area (p<0.001) while the ratio was similar for control and rewetted sites in wet conditions. Similarly, a significant increase in
- 20 the contribution of M relative to the contribution of A was observed during dry conditions in the rewetted site compared to wet conditions in control and rewetted areas (p<0.001).

3.2 Hydrological modeling

- The best simulated and the observed WTD dynamics are shown in Fig. 3. NS and Br2 were greater than 0.10 and 0.24 for calibration periods and reached values greater than 0.10 and 0.39 for validation periods, respectively. The RMSE ranged
- 25 between 1 and 9 cm and no drop in the model performance was observed for the validation period, compared to the calibration ones (Tab. 3). The model performed better for the wettest year in the control area and better for the intermediate and the driest years in the rewetted area. The important point is that the model was able to reproduce two different WTD dynamics using the same input data (i.e. rainfall and PET). These differences are explained by the modification in calibrated parameter values. As the evapotranspiration coefficient and maximum infiltration rates were the same for each site, the
- 30 differences are driven by the discharge coefficients. The values of the three discharge coefficients (α_p , α_r and α_{sr}), corresponding to the intensity of the drainage of the three reservoirs (Se, Sm and Sr), were higher in the control site than in the rewetted one (Tab. 3). These differences were reflected in the water balance of each location with a lower water discharge (Q) in the rewetted site than in the control one (Tab. 2). However, fast superficial drainage (O) was higher in the

rewetted site than in the control one, in contrast to the slow deep drainage (R+D). This is confirmed by the uncertainty analysis, which showed that despite large uncertainties in flows (80 to 250 mm) the difference between overland flow and drainage flow in the two sites can be considered significant as the ranges provided by the uncertainty analysis do not overlap. Finally, sensitivity analysis indicated that the model is the most sensitive to the evapotranspiration coefficient in the growing season and the Se discharge coefficient, and the least sensitive to the evapotranspiration coefficient in the dormant period and the Sr discharge coefficient for both locations (Tab. 4).

3.3 DOC dynamics modeling

Simulated and observed pore water [DOC] are shown in Fig. 5. The simulations presented a RMSE $< 9 \text{ mg L}^{-1}$ for calibration and RMSE $< 11 \text{ mg L}^{-1}$ for validation in both rewetted and control sites, and with no systematic overestimations or underestimations. The model performed better for the control than for the rewetted site, except for the driest year (Tab. 5). The model was able to reproduce [DOC] dynamics in both locations, especially the rising concentrations in the rewetted site and the decreasing concentrations in the control site during summer 2015 (Fig. 5). The DOC balance was computed for each location and is shown in Tab. 2. Overall, DOC exports were slightly higher but and in the same order of magnitude for each location. Nevertheless, a difference can be observed for the partitioning between exports from the Se and Sm reservoirs. While 44% of the total DOC exports originated from Se in the control site, exports from Se only account for 0.02% of the total DOC exported in the rewetted site (Tab. 2). Fig. 6 shows the temporal dynamics of simulated daily DOC exports for each location. DOC exports were episodic in both locations with the highest peaks for the control site during the wettest year and the highest peaks in rewetted for the driest year. The minimum daily export rates were higher in the control than in the rewetted site.

20 4 Discussion

4.1 Hydrological processes

In this study, observed water table dynamics were used to better understand the dominant hydrological processes taking place in two locations of a restored peatland (rewetted and control), by calibrating a conceptual model. Though simple (6 calibrated parameters), the model was able to reproduce the specific water table dynamics in each location of the studied area, using the same input data (precipitation and potential evapotranspiration). This difference in observed water table dynamics (17 cm of difference for the maximum water table drawdown) is reflected in the calibrated parameter values for each location (Tab. 3). In addition, and in order to better assess the dominant processes, a sensitivity analysis of the model was performed for each location (Tab. 4). The results indicate that the most sensitive parameters are Kcg and α_p which are related to the evapotranspiration during the growing season and the deep drainage of the retention reservoir (Se), respectively, meaning that these processes are the most important ones to explain the peatland hydrology. While evapotranspiration coefficients are the same for both sites, the drainage coefficient of the retention reservoir is the highest for

the control location and this difference may explain the dissimilarity in the severity of the observed water table drawdown and simulated water table balance in the two locations. Overland flow (O) accounts for 56% of the total discharge in the rewetted site while it represents less than 1% of the total discharge in the control one. At the contrary, deep drainage (D) represents less than 1% of the total discharge in the rewetted site and 24% in the control one it. This difference in the partitioning between fast superficial and slow deep discharge can be related to the restoration work, since the blockage of the drain could have reduced the deep drainage and increased the amount of surface drainage in the rewetted area. While the difference in water table dynamics between the two locations can be explained by other factors than restoration (e.g. geomorphological settings and vegetation cover), observations showed that the restoration work created an inundated area in its vicinity, in agreement with the results of Wilson et al. (2010) indicating that the frequency of full saturation of the peat increases markedly after a drain blocking operation. In addition, microtopography and vegetation cover are very homogenous over the area and these factors cannot explain the observed differences in water table dynamics between the two locations. Therefore, in this case, the model can help to characterize the impact of restoration as seen in the simulated water balance and the value of the deep drainage coefficients. It enables deep drainage dominated (control) and surface drainage dominated (rewetted) systems to be identified within the same peatland, in relation with hydrological restoration work. However, these results can only be considered an interpretation as there are no measurements of fluxes.

4.2 DOC dynamics control factors

4.2.1 Simulation results

A module simulating DOC production and loss was added to the hydrological model in order to better understand DOC dynamics in the two peatland locations, with RMSE between 1.6 and 10.8 mg L⁻¹ for the different calibration and validation periods. However, the quality of the results is more difficult to assess than for the hydrological model because few data were available for the calibration and validation steps. Nevertheless, it is noteworthy that the model, based on only 2 calibrated parameters, is able to capture the two different dynamics recorded in each location, i.e. rising [DOC] in the downstream location in summer 2015 and a decreasing [DOC] in the upstream location in the same period.

4.2.2 DOC concentrations and control factors

Long-term studies have reported decreasing pore water [DOC] more than 10 years after a restoration operation took place (Höll et al., 2009; Wallage et al., 2006), while others observed increasing [DOC] after restoration (Hribljan et al., 2014; Strack et al., 2015). Glatzel et al. (2003) observed an increase in pore water [DOC] following a drain blocking operation but predicted a decrease in [DOC] with time due to a depletion of easily decomposable organic matter in the peat. In this study, the results indicate that, during the three years following a restoration operation, [DOC] were higher in the rewetted than in the control location during the dry period (from 1st of June to 30th of November), while they were similar during the wet period. In addition, the difference in [DOC] dynamics is also reflected in DOM quality inferred from its fluorescence

properties, with a greater increase in low molecular weight compounds (component M) and fewer aromatic high molecular weight compounds (component C) in the rewetted location during the dry season compared to the control area. These findings are in agreement with the studies by Höll et al. (2009), Hribljan et al. (2014) and Strack et al. (2015) who observed that wetter sites would result in a pore water with smaller and fewer aromatic dissolved organic molecules (likely sourced from inputs of fresh litter from growing vegetation) than the sites with a lower water table.

The main difference in [DOC] is observed during the dry period, when the water table dynamics is different between the two locations. This would confirm that hydrology, and especially the magnitude of the water table drawdown, might be a major factor controlling [DOC] dynamics in the peatland. Indeed, the higher WTD in the dry period in the rewetted site is related with a higher [DOC] than in the control site where the WTD is lower. A larger proportion of low aromatic DOC is also observed during the same period in the rewetted than in the control site. Therefore, we propose to explain the differences in [DOC] by the difference in water table drawdown in the dry period. When the water table drawdown is small (high water table), more DOC is produced from the top peat layer containing more recent and easily biodegradable organic matter than when the water table drawdown is more severe (low water table). In addition, anaerobic conditions in the rewetted site would lead to less efficient decomposition of organic matter, increasing the production of water-soluble intermediate metabolites (Kalbitz et al., 2000; Strack et al., 2008). An increase in [DOC] in the rewetted location can also be explained by an increase in the photic zone, potentially supporting algae photosynthate production enhancing DOC release into the water column, as suggested by Hribljan et al. (2014). However, the latter hypothesis is the least probable in our case since no ponding water is observed in summer in the study area. The ability of the model to reproduce pore water [DOC] dynamics can be attributed to its consideration of the water table drawdown which is expressed in the model through the use of soil moisture (based on water level in the Sm and Se reservoirs) as a production rate modifier. Finally, while this study focuses on the hydrological control on DOC dynamics, it is important to note that other factors not directly integrated in the model are also known to affect DOC exports such as pH and redox state (e.g. Grybos et al., 2009; Knorr, 2013).

4.2.3 DOC exports

The model enables DOC exports to be estimated for each location (Tab. 2). The results (values) are in the range reported in the literature (from 4.2 to 18.9 g-C m² yr⁻¹, Birkel et al., 2014, 2017 and Jager et al., 2009). DOC exported from the control site is slightly higher than that from the rewetted but in the same order of magnitude for both sites. Therefore, taking into account the simplicity of the model, the difference in DOC exports between both sites was not considered significant. The reduction in DOC exports, for the best fit simulation, has to be related to the increase of the amount in quick surface overflow in the rewetted site which is characterized by a low [DOC], and therefore low DOC exports. In the rewetted site, the water does not infiltrate in the already saturated peat porosity and while [DOC] increases, DOC exports decreases. In addition, the partitioning between DOC exports from the two production reservoirs is clearly different for each location. According to the water balance, DOC exports are mainly driven by the drainage from the Sm reservoir in the rewetted site while the amount of DOC exported through deep drainage and runoff is more balanced in the control site. This clearly

reflects the dominant hydrological processes in each location and can be seen in the temporal variability in DOC exports (Fig. 6). DOC exports are more episodic in the rewetted site, with 75% of the DOC exported during only 13% of the total simulated period length (47% of the total DOC export for the same period in the control site). These results are consistent with the results of Birkel et al. (2017) who highlighted the non-linearity of DOC exports in a peatland catchment and reported that 60% of the DOC was exported in 30% of the time through rapid near-surface runoff in a small peat catchment. However, in the control site, DOC exports are less episodic than in the rewetted one in accordance with the dominance of a slow but regular deep drainage of the Se reservoir in this site. These results confirm that hydrology has a major impact on DOC load dynamics (Birkel et al., 2017; Tunaley et al., 2016), since it is the partitioning between superficial quick flow and slow deep drainage that controls the temporal dynamics of DOC exports (Birkel et al., 2014). This study also suggests that this hydrological control on DOC fluxes also affects the source of DOC exported from the peatland, in relation with the difference in DOM composition observed with the fluorescence analysis. Therefore, in the rewetted area the DOC exported will exhibit characteristics of top peat layer recent organic matter (less aromatic) while it is likely derived from older and deeper organic matter (more aromatic) in the control area. These findings indicate that, while its impact on DOC loads can be negligible, restoration work might have an impact on stream ecosystems by releasing a less aromatic DOM, especially during the dry season. However, these findings are valid for a three-year period following the restoration and might be different for the future, underlining the need for long term monitoring to correctly assess the impact of hydrological restoration on DOC dynamics.

4.3 Perspectives for application of the model

The model developed in this study follows a parsimonious coupled hydrology-biogeochemistry model philosophy (Birkel et al., 2014, 2017; Lessels et al., 2015). By keeping parametrization to a minimum, it was able to identify factors controlling WTD and DOC dynamics in the two contrasted sites of the studied peatland with a relatively low requirement in input data (precipitation, potential evapotranspiration and temperature). Contrary to similar models, hydrology is here calibrated on WTD instead of on stream discharge. This way, the model proves to be a relevant tool to be applied in flat areas where catchment delineation is highly uncertain and outlets difficult to monitor. It is also useful to explore the hydrology of areas located within the same peatland by performing a multi-site calibration. However, it is necessary to perform an uncertainty analysis to better assess confidence in the computed fluxes when no data are available. The careful application of the model highlights the impact of hydrological restoration on hydrology and DOC dynamics that would have been difficult to study with models calibrated on stream discharge and applicable at the catchment scale only. In addition, the DOC model developed in this study has shown good results in modeling pore water [DOC] dynamics, meaning that the 2 calibrated parameters model is adapted to simulate DOC dynamics in peatland ecosystems. Therefore, if applied to several WTD time series, it could provide spatial information by identifying the main areas of DOC production within a peatland. This model

could also be applied to longer time series and different study sites to assess the effect of hydrological restoration over longer periods, and the dominant controlling factors in peatlands with different settings.

5 Conclusions

- 5 A conceptual hydrological model, especially developed for peatland and calibrated on WTD, has been combined with a simple DOC production/loss model and applied to two locations of a peatland, one of them affected by hydrological restoration. The application of this model has shown the following:
- The hydrological restoration was found to impact water balance, by increasing fast superficial drainage compared to slow deep drainage.
 - 10 • The intensity of the maximum water table drawdown was found to be the main factor controlling pore water [DOC] dynamics in the peatland.
 - Higher [DOC] in the rewetted location was linked to differences in DOM composition
 - Simulated DOC exports were in the same order of magnitude for rewetted and control locations, in a short-term period (3 years).
 - 15 • Water partitioning between fast superficial drainage and slow deep drainage controls DOC sources as well as the temporal dynamics of DOC exports

These results suggest that hydrological restoration does not affect short term DOC fluxes in peatland. In addition, this study has shown that the proposed conceptual hydrological and biogeochemical model can provide relevant information about water balance and the factors controlling element cycling processes in peatlands. The application of a WTD based model is a relevant alternative to a discharge calibrated catchment model when the outlet is not easily identifiable or when seeking for within-peatland spatial information.

Tables

Table 1: List of the parameters used in the hydrological and in the DOC model. The hydrological flux associated to each parameter is in parenthesis. Calibrated parameters and boundary condition independent (BCI) parameters are indicated.

	Symbol	Process	Description	Units	Calibrated
<i>Hydrological model</i>	Hmax	WTD-moisture relation	Peat depth	mm	no
	Θmin	WTD-moisture relation	Porosity at maximum depth	m ³ .m ⁻³	no
	Θmax	WTD-moisture relation	Porosity at the surface	m ³ .m ⁻³	no
	Kcd	Evapotranspiration (ET)	Crop coefficient for dormant season	-	yes (BCI)
	Kcg	Evapotranspiration (ET)	Crop coefficient for growing season	-	yes (BCI)
	Imax	Infiltration Sm to Se (ISe)	Maximum infiltration rates in Se	mm day ⁻¹	yes (BCI)
	αp	Percolation rate from Se (D)	Discharge coefficient of Se	day ⁻¹	yes
	αr	Runoff rate from Sm (R)	Discharge coefficient of Sr	day ⁻¹	yes
	αo	Overland flow from Sr (O)	Discharge coefficient of So	day ⁻¹	yes
<i>DOC model</i>	SOC	DOC module	Mass of TOC in peat profile	mgC mm ⁻¹	no
	DOCrain	DOC module	DOC concentration in rain water	mg L ⁻¹	no
	kprod	DOC module	DOC production coefficient	day ⁻¹	yes
	kloss	DOC module	DOC loss coefficient	day ⁻¹	yes

5 **Table 2: Water and DOC balance computed for the simulated period (01/04/2016 to 01/04/2016 and 01/10/2016 to 10/12/2017) in rewetted and control areas. P is precipitation, ET is evapotranspiration, Q is total discharge, O is overland flow, R is macroporosity runoff, D is deep drainage. Best fit is indicated and 5th and 95th percentiles of the behavioural runs are between bracket.**

	Rewetted (5 th – 95 th)	Control (5 ^h – 95 ^h)
P (mm yr ⁻¹)	787	787
ET (mm yr ⁻¹)	357 (284 – 374)	357 (284 – 374)
Q (mm yr ⁻¹)	417 (399 – 489)	466 (370 – 494)
O (mm yr ⁻¹)	233(188 – 394)	4 (0 – 40)
R (mm yr ⁻¹)	183 (42 – 220)	352 (20 – 355)
D (mm yr ⁻¹)	2 (1 – 79)	111 (102 – 444)
DOC exports total (g C m ⁻² yr ⁻¹)	3.6 (3.5 – 7.2)	8.6 (8.5– 25.5)
DOC exports Se (g C m ⁻² yr ⁻¹)	0.1 (0.1 – 3.6)	3.8 (3.8 – 14.3)
DOC exports Sm (g C m ⁻² yr ⁻¹)	3.5(3.1 – 3.6)	4.8(0.9– 11.5)

Table 3: Calibrated parameters and efficiency criteria for the different periods of calibration and validation. Ranges of parameters used for autocalibration are also indicated.

	Rewetted	Control	Range
Kcd	0.37	0.37	0.01 – 0.5
Kcg	0.40	0.40	0.4 – 0.8
Imax	0.84	0.84	0.2 – 5
α_p	1.6E-05	1.9E-03	0 – 0.01
α_r	0.20	0.37	0 – 0.5
α_{sr}	0.20	0.27	0 – 0.5
<i>Calibration (2014/15)</i>			
NS	0.10	0.61	
Br2	0.52	0.67	
RMSE (m)	0.01	0.01	
<i>Calibration (2016/17)</i>			
NS	0.25	0.16	
Br2	0.26	0.24	
RMSE (m)	0.065	0.080	
<i>Validation (2015/16)</i>			
NS	0.10	0.30	
Br2	0.54	0.39	
RMSE (m)	0.02	0.09	

Table 4: Sensitivity rank of the parameters of the hydrological model

Parameter	<i>Sensitivity rank</i>	
	Rewetted	Control
Kcg	1	1
α_p	2	2
α_r	4	3
Imax	3	4
α_o	6	5
Kcd	5	6

Table 5: Calibrated parameters and efficiency of the DOC model

	Rewetted	Control
kprod	5.0E-08	9.0E-07
kloss	5.0E-04	1.2E-02
<i>Calibration (2014/15)</i>		
RMSE (mg.L ⁻¹)	5.4	1.6
Br2	0.003	0.89
<i>Calibration (2016/17)</i>		
RMSE (mg.L ⁻¹)	8.6	8
Br2	0.18	0.03
<i>Validation (2015/16)</i>		
RMSE (mg.L ⁻¹)	8.9	10.8
Br2	0.34	0.31
