**Re: Response to the Comments of Prof. H. Class on Manuscript HESSD-2017--90 (Moment-based Metrics for Global Sensitivity Analysis of Hydrological Systems by A. Dell'Oca, Monica Riva, and Alberto Guadagnini) -**

We would like to thank Prof. Class for the careful and thorough reading of our manuscript and for his insightful comments and constructive suggestions that these have helped to improve the quality of the manuscript. Following is an itemized list of his comments (in italic) and our responses.

- 1) *This manuscript addresses the improvement of GSA (Global Sensitivity Analysis) by using newly introduced metrics based on the evaluation of the first four statistical moments: expectation value, variance, skewedness, tailedness. These metrics allow to extend the analysis beyond variance-based GSA into the details of the shape of the probability density function (pdf). It allows e.g. to detect when a certain model parameter particularly affects the asymmetry or the tailing of a pdf. The authors motivate and outline their idea in the context of GSA very well and nicely explain the expected benefits of their approach.*

We thank Prof. Class for his positive assessment of our work.

- 2) *However, like always, there is no free lunch. The method has the disadvantage that it involves significantly more computational effort, this rendering likely impossible to perform for a complex hydrological scenario of practical relevance. The work-around proposed by Dell'Oca et al is the use of reduced-complexity models or surrogate models; in this case, they use the Polynomial Chaos Expansion technique, which can be viewed as an approximation of a target function by polynomials, where the degree of the polynomials determines (at least up to a certain value) the accuracy of the approximation.*  
*Surrogate models like PCE require some smoothness in the targeted model output parameters with respect to the investigated parameters. Otherwise, discontinuities in the model output is difficult to reproduce. Therefore, I suppose, that this might involve the possibility that sophisticated GSA metrics become biased from errors introduced by the surrogate model. Thus, to give added value through several-moment-based GSA, we must first assure that the pdfs from the (surrogate) models are correct, i.e. the model represents the physics in all aspects. The manuscript addresses this issue quite well by some test cases, although I observe that all three test cases are relatively simple and do not provide huge challenges regarding possibly complex hydrological or geological features. The first test case is rather an academic exercise (which has, of course, value in itself), the second is an example where the results are definitely smooth in the parameter space; only the third one involves a heterogeneity, but still not very challenging for a polynomial approximation. I propose, maybe for future work, for example, a scenario where a fluid is injected into a geologic reservoir which has a fault zone in greater distance and where the response in terms of leakage to this fracture is rather a step-function. Would such a scenario be reflected properly by these new metrics? I guess that yes, but would the PCE provide the appropriate model for it? But clearly, the method proposed here is independent of the choice of the surrogate model.*

We thank Prof. Class for pointing out this very relevant issue. As remarked by the Reviewer, in this manuscript we introduce novel metrics for global sensitivity analysis. These metrics can be evaluated making use of the complete model or (if the CPU time associated with the evaluation of the full model is too high) by a surrogate model. We also investigate the error associated with the evaluation of our novel metrics by replacing the complete system model through a gPCE. As proof of concept, we applied the proposed methodology to 3 (relatively simple) test cases. We agree with Prof. Class that any surrogate model (including gPCE) could fail in interpreting all the details of highly non-linear systems. The application of our methodology of analysis to more complex cases is envisioned as a future step. We will revise the opening statements of Section 3 of the manuscripts to highlight these relevant aspects.

- 3) *What if parameters are not uniformly distributed as assumed e.g. in 221-222? E.g. permeability in a fractured rock. How important is this assumption?*

Varying the probability density function (*pdf*) of uncertain model input parameters does not impact the definition of the novel metrics we propose. Otherwise, it may affect the actual results, depending on the test case considered. In the manuscript, we select uniform distributions for model parameters to mimic a scenario where the only information available is the expected range of variability of the parameters. We will highlight this issue in the revised manuscript.

- 4) *A given acceptable level of accuracy for the PCE-based approximation of the new indices requires increasing polynomial order with the order of the statistical moment. I can comprehend this statement in 3.3 (and in the conclusions with the careful wording "might be") from looking at the corresponding figures. But is there also some comprehensible reasoning or proof why this is the case? The authors are mathematicians and might be able to understand and explain this issue.*

A rigorous and general proof of the findings encapsulated in Figures 2 and 5 and evidenced by Prof. Class requires, for example, deriving (a) the analytical format of the probability density function (*pdf*) of a target model output on the basis of its gPCE based approximation at a given order  $w$ , and (b) the corresponding *pdf* associated with the full system model. We have shown a way to derive the former in a closed-form in a previous work (Riva et al., 2015, already referenced in the manuscript), at least for  $w = 2$ . With reference to the latter, one would need to formulate and solve (either analytically or numerically) appropriate (and exact) system equations satisfied by the *pdf* of interest or by its moments. This step is still an active area of research within which our group has considerable expertise. Approaches which are available in the literature always require approximations and specific assumptions, which are typically problem dependent. In this framework, a generalization of our findings is out of scope of the current study. Here, we rely on the direct solution of the full system model and the associated gPCE approximation to derive quantitative results for the examples considered. We will clarify these concepts in the revised manuscript.

- 5) *I understood that the analysis helps better identifying the relative importance of individual parameters. There is enormous practical relevance for this, e.g. it would help to prioritize*

*exploration efforts for a particular parameter when it becomes clear from the sensitivity analysis that knowledge about this parameter reduces uncertainty drastically. The authors might want to emphasize such examples a bit more prominently if they like.*

We thank Prof. Class for this very interesting comment with which we fully agree. We will add an appropriate paragraph in the revised Introduction.

- 6) *In the first conclusion, line 475, I would write: "The CALCULATED sensitivity of a model output ..."*

We will modify the text accordingly.

- 7) *Very few language issues: 201-202: ... are affected by model uncertain parameters collected in  $x$ . Here is something wrong with the grammar, or I don't understand the meaning.*

The sentence will be rephrased as “are affected by uncertain model parameters collected in the parameter vector  $\mathbf{x}$ ”.

- 8) *326: maybe "characterize" is here not the right wording? What about "control"?*

The key point is to emphasize that the parameters we consider are affected by uncertainty. We will replace the wording ‘characterize experimentally’ by ‘assess experimentally’.

**Re: Response to the Comments of Dr. J. Bensabat on Manuscript HESSD-2017-90 (Moment-based Metrics for Global Sensitivity Analysis of Hydrological Systems by A. Dell’Oca, Monica Riva, and Alberto Guadagnini) -**

We would like to thank Dr. Bensabat for the careful and thorough reading of our manuscript and for the insightful comments and constructive suggestions offered. It is our view that these have helped to improve the quality of the manuscript. Following is an itemized list of his comments (in italic) and our responses.

- 1) *This paper addresses the important topic of Sensitivity analysis of the output produced by hydrological models. The method is novel and provides a more mathematically rigorous framework for the evaluation of parameter sensitivity and a methodology for approximating the output produced by models in case they are demanding in terms of computational resources (PCE).*

We thank Dr. Bensabat for his appreciation of our work and his very positive comments.

- 2) *Three examples are investigated: 1) a synthetic case (the Ishigami function); 2) an analytical solution for seawater intrusion in a coastal aquifer (Pool and Carrera, 2011) and 3) A laboratory scale model of a solute transport. These three cases are all calculated and the relevant measures are presented.*

*Without any doubt this paper is substantial contribution and could lead to a better handling of complex hydrological systems*

We thank Dr. Bensabat for his positive assessment of our work.

- 3) *I would suggest to address a number of issues, which could make the paper attractive to an audience that is less familiar with the mathematical formulation of the method and more sensitive to its impact.*

*The presented cases are for either analytical solutions (cases 1 and 2) or small scale settings (case 3). Therefore it could be of value to discuss how this suggested methodology could be applied to hydrological problems (regional groundwater flow models, flow and transport models and or density dependent seawater intrusion), what would be the steps needed to be taken and what would be the implications in terms of required computational resources.*

We thank Dr. Bensabat for pointing out this very relevant issue. The direct application of our novel metrics for global sensitivity analysis (GSA) to field scale hydrological settings is envisioned as a future study. Such an application should be structured according to the steps detailed in Section 2. A critical limiting factor to any GSA approach is the associated computational burden. The latter is expected to increase according to two features associated with the conceptual and mathematical model used to describe the target variables of interest: (a) the complexity of the hydrological system (in terms of, e.g., hydrogeological heterogeneity, non-linear and/or transient effects), and/or (b) the number of uncertain model input parameters considered. According to the relative weight of these features, there can be some constraints to (i) perform the analysis by relying solely on the full system model, and (ii) construct a sufficiently accurate surrogate model through a number of full model runs which is affordable in terms of computational resources. We will revise the opening statements of Section 3 of the manuscripts to highlight these relevant aspects.

## Abstract

We propose new metrics to assist global sensitivity analysis, GSA, of hydrological and Earth systems. Our approach allows assessing the impact of uncertain parameters on main features of the probability density function, *pdf*, of a target model output,  $y$ . These include the expected value of  $y$ , the spread around the mean and the degree of symmetry and tailedness of the *pdf* of  $y$ . Since reliable assessment of higher order statistical moments can be computationally demanding, we couple our GSA approach with a surrogate model, approximating the full model response at a reduced computational cost. Here, we consider the generalized Polynomial Chaos Expansion (gPCE), other model reduction techniques being fully compatible with our theoretical framework. We demonstrate our approach through three test cases, including an analytical benchmark, a simplified scenario mimicking pumping in a coastal aquifer, and a laboratory-scale conservative transport experiment. Our results allow ascertaining which parameters can impact some moments of the model output *pdf* while being uninfluential to others. We also investigate the error associated with the evaluation of our sensitivity metrics by replacing the original system model through a gPCE. Our results indicate that the construction of a surrogate model with increasing level of accuracy might be required depending on the statistical moment considered in the GSA. Our approach is fully compatible with (and can assist the development of) analysis techniques employed in the context of reduction of model complexity, model calibration, design of experiment, uncertainty quantification and risk assessment.

## 1. Introduction

Our improved understanding of physical-chemical mechanisms governing hydrological processes at multiple space and time scales and the ever increasing power of modern computational resources are at the heart of the formulation of conceptual models which are frequently characterized by marked levels of sophistication and complexity. This is evident when one considers the spectrum of mathematical formulations and ensuing level of model parametrization rendering our conceptual understanding of given environmental scenarios (Willmann et al., 2006; Grauso et al., 2007; Koutsoyiannis, 2010; Wagener et al., 2010; Elshorbagy et al., 2010a,b; Wagener and Montanari, 2011; Hartmann et al., 2013; Herman et al., 2013; Förster et al., 2014; Paniconi and Putti, 2015). Model complexity can in turn exacerbate challenges associated with the need to quantify the way uncertainties associated with parameters of a given model propagate to target state variables.

In this context, approaches based on rigorous sensitivity analysis are valuable tools to improve our ability to (i) quantify uncertainty, (ii) enhance our understanding of the relationships between model input and outputs, and (iii) tackle the challenges of model- and data- driven design of experiments. These also offer insights to guide model simplification, e.g., by identifying model input parameters that have negligible effects on a target output. The variety of available sensitivity methodologies can be roughly subdivided into two broad categories, i.e., local and global approaches. Local sensitivity analyses consider the variation of a model output against variations of model input solely in the neighbourhood of a given set of parameters values. Otherwise, global sensitivity analysis (GSA) quantifies model sensitivity across the complete support within which model parameters can vary. Error measurements and/or lack of knowledge about parameters can be naturally accommodated in a GSA by specifying appropriate parameter intervals and evaluating sensitivity over the complete parameter space. Recent studies and reviews on available sensitivity analysis and approaches are offered by, e.g., Pianosi et al. (2016), Sarrazin et al. (2016), and Razavi and Gupta (2015).

Our study is framed in the context of GSA methods. A broadly recognized strategy to quantify global sensitivity of uncertain model parameters to model outputs relies on the evaluation of the

56 Sobol' indices (Sobol, 1993). These are typically referred to as variance-based sensitivity measures  
57 because the output variance is taken as the metric upon which sensitivity is quantified. A key  
58 limitation of a variance-based GSA is that the uncertainty of the output is implicitly considered to be  
59 fully characterized by its variance. Relying solely on this criterion can provide an incomplete picture  
60 of a system response to model parameters, also considering that probability densities of typical  
61 hydrological quantities can be characterized by highly skewed and tailed distributions (e.g.,  
62 Borgonovo et al., 2011). Recent studies (e.g., Krykacz-Hausmann, 2001; Borgonovo, 2007;  
63 Borgonovo et al., 2011) introduce a sensitivity metric grounded on the complete probability density  
64 function, *pdf*, of the model output. These so-called moment-independent analyses may suffer from  
65 operational constraints, because a robust evaluation of the complete *pdf* may require a number of  
66 model runs which is computationally unaffordable. The PAWN method developed by Pianosi and  
67 Wagener (2015) attempts to overcome this limitation introducing a sensitivity metric based on the  
68 cumulative density function, which can potentially be estimated more robustly than its associated *pdf*  
69 for a given sample size.

70 It is clear that while a variance-based GSA can be favored for its conceptual simplicity and  
71 ease of implementation and variance can be considered in some cases as an adequate proxy of the  
72 spread around the mean, it does not yield a forthright quantification of the way variations of a  
73 parameter can affect the structure of the *pdf* of a target model output. Otherwise, moment-independent  
74 methodologies condense the entire *pdf* in only one index, somehow clouding our understanding of  
75 how the structure of the *pdf* is affected by variations of each uncertain model parameter. Here, our  
76 distinctive objective is to contribute to bridge the gap between these two types of GSA. We do so by  
77 introducing theoretical elements and an implementation strategy which enable us to appraise  
78 parameter sensitivity through the joint use of sensitivity indices based on four (statistical) moments  
79 of the *pdf* of the model output: expected value, variance, skewness and kurtosis. The key idea at the  
80 basis of this strategy is that linking parameter sensitivity to multiple statistical moments leads to  
81 improved understanding of the way a given uncertain parameter can govern key features of the shape

82 of the *pdf* of desired model outputs, which is of interest in modern applications of hydrological and  
83 Earth sciences.

84 Variance-based GSA has also been applied (*a*) to guide reduction of model complexity, e.g.,  
85 by setting the value of a parameter which is deemed as uninfluential to the variance of a target model  
86 output (e.g., Fu et al., 2012; Chu et al., 2015; Punzo et al., 2015), and (*b*) in the context of uncertainty  
87 quantification (Saltelli et al., 2008; Pianosi et al., 2016; Colombo et al., 2016). Only limited attention  
88 has been devoted to assess the relative effects of uncertain model parameters to the first four statistical  
89 moment of the target model output. This information would complement a model complexity analysis  
90 by introducing a quantification of the impact that conditioning the process on prescribed parameter  
91 values would have on the first four statistical moment of the output. Our approach is based on the  
92 joint use of multiple (statistical) moments for GSA. It enables us to address the following critical  
93 questions: When can the variance be considered as a reliable proxy for characterizing model output  
94 uncertainty? Which model parameter mostly affects asymmetry and/or the tailing behavior of a model  
95 output *pdf*? Does a given model parameter have a marked role in controlling some of the first four  
96 statistical moments of the model output, while being uninfluential to others? Addressing these  
97 questions would contribute to prioritize our efforts to characterize model parameters that are most  
98 relevant in affecting important aspects of model prediction uncertainty.

99 Even as the richness of information content that a GSA grounded on the first four statistical  
100 moments might carry can be a significant added value to our system understanding, it may sometimes  
101 be challenging to obtain robust and stable evaluation of the proposed metrics for complex and  
102 computationally demanding models. This can be especially true when considering higher-order  
103 moments such as skewness and kurtosis. To overcome this difficulty, we cast the problem within a  
104 computationally tractable framework by relying on the use of surrogate models, which mimic the full  
105 model response with a reduced computational burden. Amongst the diverse available techniques to  
106 construct a surrogate model (see, e.g., Razavi et al., 2012a,b), we exemplify our approach by  
107 considering the generalized Polynomial Chaos Expansion (gPCE) that has been successfully applied

108 to a variety complex environmental problems (Sudret, 2008; Ciriello et al., 2013; Formaggia et al.,  
 109 2013; Riva et al., 2015; Gläser et al., 2016), other model reduction techniques being fully compatible  
 110 with our GSA framework. In this context, we also investigate the error associated with the evaluation  
 111 of the sensitivity metrics we propose by replacing the original (full) system model through the  
 112 selected surrogate model for three test cases. These include a widely employed analytical benchmark,  
 113 a pumping scenario in a coastal aquifers, and a laboratory-scale transport setting. The remainder of  
 114 the work is organized as follows. Section 2 presents our theoretical framework and developments.  
 115 Section 3 illustrates our results for the three test cases indicated above and conclusions are drawn in  
 116 Section 4.

## 117 **2. Theoretical framework**

118 We start by recalling the widely used variance-based GSA metrics in Section 2.1. These allow  
 119 quantifying the contribution of each uncertain parameter to the total variance of a state variable of  
 120 interest. We also provide a brief overview of the generalized Polynomial Chaos Expansion (gPCE)  
 121 technique, which we use to construct a surrogate of the full system model. We then illustrate in  
 122 Section 2.2 the theoretical developments underlying our approach and introduce novel GSA indices.

### 123 **2.1 Sobol' indices for variance-based GSA and generalized Polynomial Chaos Expansion**

124 We consider a target system state variable,  $y$ , which depends on  $N$  random parameters. These  
 125 are collected in vector  $\mathbf{x} = (x_1, x_2, \dots, x_N)$  and defined in the parameter space  $\Gamma = \Gamma_1 \times \Gamma_2 \times \dots \times \Gamma_N$ ,  
 126  $\Gamma_i = [x_{i,\min}, x_{i,\max}]$  being the support of the  $i$ -th random variable  $x_i$ . Variance-based GSA approaches  
 127 consider variance as the sole metric to quantify the contribution of each uncertain parameter to the  
 128 uncertainty of  $y$ . Iman and Hora (1990) introduce the following index

$$129 \quad HI_{x_i} = V[y] - E[V[y | x_i]] = V[E[y | x_i]], \quad (1)$$

130  $E[-]$  and  $V[-]$  respectively denoting expectation and variance operators. Index  $HI_{x_i}$  quantifies the  
 131 expected reduction of variance due to knowledge of  $x_i$  (the notation  $|x_i$  in Eq. (1) indicates

conditioning on  $x_i$ ). A similar measure is offered by the widely used Sobol' indices (Sobol, 1993). These have been defined starting from the Hoeffding/Sobol decomposition (see, e.g., Sobol, 1993, Le Maître and Knio, 2010) of  $y(\mathbf{x})$  when  $\mathbf{x}$  is a collection of independent random variables as

$$y(\mathbf{x}) = y_0 + \sum_{x_i=1}^N y_{x_i}(x_i) + \sum_{x_i < x_j} y_{x_i, x_j}(x_i, x_j) + \dots + y_{x_1, x_2, \dots, x_N}(x_1, x_2, \dots, x_N), \quad (2)$$

where

$$\begin{aligned} y_0 &= \int_{\Gamma} y(\mathbf{x}) \rho_{\Gamma \mathbf{x}} d\mathbf{x}, \\ y_{x_i}(x_i) &= \int_{\Gamma \sim x_i} y(\mathbf{x}) \rho_{\Gamma \sim x_i} d\mathbf{x}_{\sim x_i} - y_0, \\ y_{x_i, x_j}(x_i, x_j) &= \int_{\Gamma \sim x_i, x_j} y(\mathbf{x}) \rho_{\Gamma \sim x_i, x_j} d\mathbf{x}_{\sim x_i, x_j} - y_{x_i}(x_i) - y_{x_j}(x_j) - y_0, \end{aligned} \quad (3)$$

and so on,  $\rho_{\Gamma \mathbf{x}}$  being the *pdf* of  $\mathbf{x}$ . The integral  $\int_{\Gamma \sim x_i} y(\mathbf{x}) \rho_{\Gamma \sim x_i} d\mathbf{x}_{\sim x_i}$  in Eq. (3) represents integration of  $y(\mathbf{x})$  over the space of all entries of vector  $\mathbf{x}$  excluding  $x_i$ ,  $\rho_{\Gamma \sim x_i}$  being the corresponding *pdf*. The Sobol' index  $S_{x_{i_1}, x_{i_2}, \dots, x_{i_s}}$  is associated with the mixed effect of  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$  on the variance of  $y(\mathbf{x})$ ,  $V[y]$ , and can be computed as

$$S_{x_{i_1}, x_{i_2}, \dots, x_{i_s}} = \frac{1}{V[y]} \int_{\Gamma_{x_{i_1}, x_{i_2}, \dots, x_{i_s}}} y_{x_{i_1}, x_{i_2}, \dots, x_{i_s}}(x_{i_1}, x_{i_2}, \dots, x_{i_s}) \rho_{\Gamma_{x_{i_1}, x_{i_2}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s}. \quad (4)$$

The principal and total Sobol' indices are respectively defined as

$$S_{x_i} = \frac{1}{V[y]} \int_{\Gamma_{x_i}} [y_{x_i}(x_i)]^2 \rho_{\Gamma_{x_i}} dx_i, \quad (5)$$

$$S_{x_i}^T = S_{x_i} + \sum_{x_j} S_{x_i, x_j} + \sum_{x_j, x_k} S_{x_i, x_j, x_k} + \dots \quad (6)$$

Note that  $S_{x_i}$  describes the relative contribution to  $V[y]$  due to variability of only  $x_i$ . Otherwise,  $S_{x_i}^T$  quantifies the total contribution of  $x_i$  to  $V[y]$ , including all terms where  $x_i$  appears. In other words,

148  $S_{x_i}^T$  also includes interactions between  $x_i$  and the remaining uncertain parameters, collected in vector  
 149  $\mathbf{x}_{\sim x_i}$ . Note that according to Eq.s (1)-(2) and Eq. (5)

$$150 \quad S_{x_i} = \frac{V[E[y | x_i]]}{V[y]} = \frac{HI_{x_i}}{V[y]}, \quad (7)$$

151 i.e., the principal Sobol' index represents the relative expected reduction of process variance due to  
 152 knowledge of (or conditioning on) a parameter. Sobol' indices are commonly evaluated via Monte  
 153 Carlo quadrature schemes that can be markedly demanding in terms of computational time, especially  
 154 for complex and highly non-linear settings. Relying on a generalized Polynomial Chaos Expansion,  
 155 gPCE, as a surrogate of the full mathematical model of the system (Ghanem and Spanos, 1991; Xiu  
 156 and Karniadakis, 2002; Le Maitre and Knio, 2010; Formaggia et al., 2013; Ciriello et al., 2013; Riva  
 157 et al., 2015) allows reducing the computational burden associated with GSA techniques. The process  
 158  $y(\mathbf{x})$  is represented as a linear combination of multivariate polynomials,  $\psi_p(\mathbf{x})$ , i.e.,

$$159 \quad y(\mathbf{x}) \cong \beta_0 + \sum_{i=1}^N \sum_{\mathbf{p} \in \mathfrak{I}_i} \beta_{\mathbf{p}} \psi_{\mathbf{p}}(\mathbf{x}) + \sum_{i=1}^N \sum_{j=1}^N \sum_{\mathbf{p} \in \mathfrak{I}_{i,j}} \beta_{\mathbf{p}} \psi_{\mathbf{p}}(\mathbf{x}) + \dots, \quad (8)$$

$$\psi_{\mathbf{p}}(\mathbf{x}) = \prod_{i=1}^N \psi_{i,p_i}(x_i), \quad \beta_{\mathbf{p}} = \int_{\Gamma} y(\mathbf{x}) \psi_{\mathbf{p}}(\mathbf{x}) \rho_{\Gamma\mathbf{x}} d\mathbf{x},$$

160 where  $\mathbf{p} = \{p_1, \dots, p_N\} \in \mathbb{N}^N$  is a multi-index expressing the degree of each univariate polynomial,  
 161  $\psi_{i,p_i}(x_i)$ ;  $\beta_{\mathbf{p}}$  are the gPCE coefficients;  $\mathfrak{I}_i$  contains all indices such that only the  $i$ -th component  
 162 does not vanish;  $\mathfrak{I}_{i,j}$  contains all indices such that only the  $i$ -th and  $j$ -th components are not zero, and  
 163 so on. Note that  $\beta_0 \equiv y_0$ , i.e.,  $\beta_0$  is the unconditional mean of  $y(\mathbf{x})$ . Finally, the Sobol' indices Eq.s  
 164 (4)-(5) and the variance of  $y(\mathbf{x})$  can be computed from Eq. (8) as

$$165 \quad S_{x_{i_1}, \dots, x_{i_s}} = \frac{1}{V[y]} \sum_{\mathbf{p} \in \mathfrak{I}_{i_1, \dots, i_s}} \beta_{\mathbf{p}}^2, \quad S_{x_i} = \frac{1}{V[y]} \sum_{\mathbf{p} \in \mathfrak{I}_i} \beta_{\mathbf{p}}^2, \quad V[y] = \sum_{\mathbf{p} \in \mathbb{N}^N} \beta_{\mathbf{p}}^2 - \beta_0^2. \quad (9)$$

## 166 **2.2 New metrics for multiple-moment GSA**

167 We introduce new metrics to quantify the expected relative change of main features of the *pdf*  
 168 of  $y$  due to variability of model input parameters. In contrast with traditional variance-based GSA  
 169 techniques of the kind described in Section 2.1, we quantify changes in the *pdf* of  $y$  through its first  
 170 four statistical moments, i.e., mean,  $E[y]$ , variance,  $V[y]$ , skewness,  $\gamma[y]$ , and kurtosis,  $k[y]$ . The  
 171 latter is an indicator of the behavior of the tails of the *pdf* of  $y$  and is particularly useful in the context  
 172 of risk analysis,  $\gamma[y]$  quantifying the asymmetry of the *pdf* of  $y$ .

173 The effect of changes of  $x$  on the mean of  $y$  cannot be systematically analyzed by the metrics  
 174 currently available in the literature. We therefore introduce the following quantity

$$175 \quad AMAE_{x_i} = \begin{cases} \frac{1}{|y_0|} \int_{\Gamma_{x_i}} |y_0 - E[y | x_i]| \rho_{\Gamma_{x_i}} dx_i = \frac{1}{|y_0|} E[|y_0 - E[y | x_i]|] & \text{if } y_0 \neq 0 \\ \int_{\Gamma_{x_i}} |E[y | x_i]| \rho_{\Gamma_{x_i}} dx_i = E[|E[y | x_i]|] & \text{if } y_0 = 0 \end{cases}, \quad (10)$$

176  $y_0$  being defined in Eq. (3). Extension of Eq. (10) to consider the joint effect of  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$  on the  
 177 mean of  $y$  is straightforward, leading to the following index

$$178 \quad AMAE_{x_{i_1}, \dots, x_{i_s}} = \begin{cases} \frac{1}{|y_0|} \int_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} |y_0 - E[y | x_{i_1}, \dots, x_{i_s}]| \rho_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s} \\ \quad = \frac{1}{|y_0|} E[|y_0 - E[y | x_{i_1}, \dots, x_{i_s}]|] & \text{if } y_0 \neq 0 \\ \int_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} |E[y | x_{i_1}, \dots, x_{i_s}]| \rho_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s} = E[|E[y | x_{i_1}, \dots, x_{i_s}]|] & \text{if } y_0 = 0 \end{cases} \quad (11)$$

179 Note that index  $AMAE_{x_i}$  quantifies the expected relative variation of the mean of  $y$  due to variations  
 180 of only  $x_i$ , while  $AMAE_{x_{i_1}, \dots, x_{i_s}}$  also includes all interactions amongst parameters  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$ .

181 Along the same lines, we introduce the following index

$$182 \quad AMAV_{x_i} = \frac{1}{V[y]} \int_{\Gamma_{x_i}} |V[y] - V[y | x_i]| \rho_{\Gamma_{x_i}} dx_i = \frac{E[|V[y] - V[y | x_i]|]}{V[y]}, \quad (12)$$

183 quantifying the relative expected discrepancy between unconditional and conditional (on  $x_i$ ) process

184 variance. Note that Eq. (12) does not generally coincide with the principal Sobol' index  $S_{x_i}$  in Eq.  
 185 (7) that quantifies the expected relative reduction of the variance due to knowledge of  $x_i$  (or, in other  
 186 words, the relative contribution to the variance arising from uncertainty in  $x_i$ ). Index  $AMAV_{x_i}$   
 187 reduces to  $S_{x_i}$  only if the conditional variance,  $V[y | x_i]$ , is always (i.e., for each value of  $x_i$ ) smaller  
 188 than (or equal to) its unconditional counterpart  $V[y]$ . The difference between  $AMAV_{x_i}$  and  $S_{x_i}$ , as  
 189 well as advantages of using  $AMAV_{x_i}$ , will be elucidated through the numerical examples illustrated  
 190 in Section 3. Extension of Eq. (12) to consider the joint effect of  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$  reads

$$191 \quad \begin{aligned} AMAV_{x_{i_1}, \dots, x_{i_s}} &= \frac{1}{V[y]} \int_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} |V[y] - V[y | x_{i_1}, \dots, x_{i_s}]| \rho_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s} \\ &= \frac{1}{V[y]} E[|V[y] - V[y | x_{i_1}, \dots, x_{i_s}]|] \end{aligned} \quad (13)$$

192 Index  $AMAV_{x_{i_1}, \dots, x_{i_s}}$  quantifies the expected relative discrepancy between  $V[y]$  and the variance of  
 193 the process conditional to joint knowledge of  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$ .

194 We then quantify the relative expected discrepancy between unconditional,  $\gamma[y]$ , and  
 195 conditional,  $\gamma[y | x_i]$ , skewness through the index

$$196 \quad AMA\gamma_{x_i} = \begin{cases} \frac{1}{|\gamma[y]|} \int_{\Gamma_{x_i}} |\gamma[y] - \gamma[y | x_i]| \rho_{\Gamma_{x_i}} dx_i = \frac{1}{|\gamma[y]|} E[|\gamma_y - \gamma[y | x_i]|] & \text{if } \gamma_y \neq 0 \\ \int_{\Gamma_{x_i}} |\gamma[y | x_i]| \rho_{\Gamma_{x_i}} dx_i = E[|\gamma[y | x_i]|] & \text{if } \gamma_y = 0 \end{cases} \quad (14)$$

197 Extension of Eq. (14) to consider the joint effect of  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$  gives

$$198 \quad AMA\gamma_{x_{i_1}, \dots, x_{i_s}} = \begin{cases} \frac{1}{|\gamma[y]|} \int_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} |\gamma[y] - \gamma[y | x_{i_1}, \dots, x_{i_s}]| \rho_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s} \\ \quad \quad \quad = \frac{1}{|\gamma[y]|} E[|\gamma[y] - \gamma[y | x_{i_1}, \dots, x_{i_s}]|] & \text{if } \gamma[y] \neq 0 \\ \int_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} |\gamma[y | x_{i_1}, \dots, x_{i_s}]| \rho_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s} = E[|E[y | x_{i_1}, \dots, x_{i_s}]|] & \text{if } \gamma[y] = 0 \end{cases} \quad (15)$$

199 The relative variation of the kurtosis of  $y$  due to variations of a parameter  $x_i$  or of the  
 200 parameter set  $x_{i_1}, x_{i_2}, \dots, x_{i_s}$  can be respectively quantified through

$$201 \quad AMAk_{x_i} = \frac{1}{k[y]} \int_{\Gamma_{x_i}} |k[y] - k[y | x_i]| \rho_{\Gamma_{x_i}} dx_i = \frac{1}{k[y]} E[|k[y] - k[y | x_i]|], \quad (16)$$

$$202 \quad \begin{aligned} AMAk_{x_{i_1}, \dots, x_{i_s}} &= \frac{1}{k[y]} \int_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} |k[y] - k[y | x_{i_1}, \dots, x_{i_s}]| \rho_{\Gamma_{x_{i_1}, \dots, x_{i_s}}} dx_{i_1} \dots dx_{i_s} \\ &= \frac{1}{k[y]} E[|k[y] - k[y | x_{i_1}, \dots, x_{i_s}]|] \end{aligned} \quad (17)$$

203 Relying jointly on Eq.s (10)-(17) enables one to perform a comprehensive GSA of the target  
 204 process  $y(\mathbf{x})$  quantifying the impact of  $\mathbf{x}$  on the first four (statistical) moments of the *pdf* of  $y(\mathbf{x})$ .  
 205 This strategy yields information about the way important elements of the distribution of  $y(\mathbf{x})$ , such  
 206 as mean, spread around the mean, symmetry, and tailedness, are affected by uncertain model  
 207 parameters collected in the parameter vector  $\mathbf{x}$ . This analysis is not feasible through a classical  
 208 variance- based GSA.

209 Calculation of the indices we propose entails evaluation of conditional moments of  $y(\mathbf{x})$ . This  
 210 step can be computationally very demanding. Along the lines of our discussion about Sobol' indices  
 211 in Section 2.1, the new metrics Eq.s (10)-(17) can be evaluated via a surrogate model, as we illustrate  
 212 through our examples in Section 3.

### 213 3. Illustrative Examples

214 The theoretical framework introduced in Section 2 is here applied to three diverse testbeds:  
 215 (a) the Ishigami function, which constitutes an analytical benchmark typically employed in GSA  
 216 studies; (b) a pumping scenario in a coastal aquifer, where the state variable of interest is the critical  
 217 pumping rate, i.e. the largest admissible pumping rate to ensure that the extraction well is still not  
 218 contaminated by seawater; and (c) a laboratory-scale setting associated with non-reactive transport in  
 219 porous media. In the first two examples the relatively low computational costs associated with the  
 220 complete mathematical description of the target outputs enables us to assess also the error associated

221 with the evaluation of indices Eq. (10), Eq. (12), Eq. (14) and Eq. (16) through a gPCE representation  
 222 of the output. In the third case, due to the complexity of the problem and the associated computational  
 223 costs, we relay on the gPCE representation for the target quantity of interest. We emphasize that the  
 224 use of a gPCE as a surrogate model is here considered only as an example, our GSA approach being  
 225 fully compatible with any full model and/or model order reduction technique. A critical limiting factor  
 226 to our and any GSA approach could be the associated computational burden. The latter is expected to  
 227 increase according to the following two features, which are mainly associated with the conceptual  
 228 and mathematical model used to describe the target variables of interest: (a) the complexity of the  
 229 hydrological system (in terms of, e.g., hydrogeological heterogeneity, non-linearity and/or transient  
 230 effects), and/or (b) the number of uncertain model input parameters considered. According to the  
 231 relative weight of these features, some computational constraints might arise limiting our ability to  
 232 (i) perform the analysis by relying exclusively on the full system model, or (ii) construct a sufficiently  
 233 accurate surrogate model through a number of full model runs that can be affordable in terms of  
 234 available computational resources. Application of our GSA methodology to scenarios of increased  
 235 level of complexity will be the subject of a future study.

236 In all of the above scenarios, uncertain parameters  $x_i$  collected in  $\mathbf{x}$  are considered as  
 237 independent and identically distributed, *i.i.d.*, random variables, each characterized by a uniform  
 238 distribution within the interval  $\Gamma_i = [x_{i,\min}, x_{i,\max}]$ . Note that varying the *pdf* of the uncertain model  
 239 input parameters does not impact the definition of the GSA indices proposed in Section 2. Otherwise,  
 240 it may affect the actual results, depending on the test case considered. All results are grounded on  
 241  $5 \times 10^5$  Monte Carlo realizations, enabling convergence of all statistical moments analyzed. Series  
 242 appearing in the gPCE Eq. (8) are evaluated up to a given order of truncation in all three examples.  
 243 Here, we apply the total-degree rule and construct a polynomial of order  $w$  through a sparse grid  
 244 technique (see, e.g., Formaggia et al., 2013 and references therein). We then analyze the way the  
 245 selected order  $w$  influences the results. Note that the optimal choice of the polynomial  $\psi_p(\mathbf{x})$  in Eq.

(8) depends on the *pdf* of the random variables collected in  $\mathbf{x}$  (Xiu and Karniadakis, 2002). In our exemplary settings we use the multidimensional Legendre polynomials which are orthonormal with respect to the uniform *pdf*.

### 3.1 Ishigami function

The non-linear and non-monotonic Ishigami function

$$y(\mathbf{x}) = ISH(\mathbf{x}) = \sin(2\pi x_1 - \pi) + a \sin^2(2\pi x_2 - \pi) + b(2\pi x_3 - \pi)^4 \sin(2\pi x_1 - \pi) \quad (18)$$

is widely used in the literature (e.g., Homma and Saltelli, 1996; Chun et al., 2000; Borgonovo, 2007; Sudret, 2008; Crestaux et al., 2009; Borgonovo et al. 2011) to benchmark GSA methods. Here,  $x_i$  ( $i = 1, 2, 3$ ) are *i.i.d.* random variables uniformly distributed within the interval  $[0, 1]$ . Unconditional mean  $E[ISH]$ , variance,  $V[ISH]$ , skewness,  $\gamma[ISH]$ , and kurtosis,  $k[ISH]$ , of Eq. (18) can be evaluated analytically as

$$E[ISH] = \frac{a}{2}, \quad V[ISH] = \frac{1}{2} + \frac{a^2}{8} + b\pi^4 \left( \frac{1}{5} + \frac{b\pi^4}{18} \right), \quad \gamma[ISH] = 0, \quad (19a)$$

$$k[ISH] = \frac{1}{2V^2[ISH]} \left\{ \frac{3}{4} + b\pi^4 \left[ \frac{3}{5} + b\pi^4 \left( \frac{1}{2} + 3b\pi^4 \left( \frac{1}{13} + \frac{\pi^4 b}{68} \right) \right) \right] + \frac{3}{2} a^2 \left[ \frac{1}{2} + \frac{a^2}{32} + \pi^4 b \left( \frac{1}{5} + \frac{\pi^4 b}{18} \right) \right] \right\}. \quad (19b)$$

Equation (19) reveals that the unconditional *pdf* of *ISH* is symmetric with tails that increase with  $|b|$  and decrease with  $|a|$ , as quantified by  $k[ISH]$ . The conditional mean  $E[ISH | x_i]$ , variance  $V[ISH | x_i]$ , skewness  $\gamma[ISH | x_i]$  and kurtosis  $k[ISH | x_i]$  can be evaluated analytically as

$$E[ISH | x_1] = \frac{a}{2} - \frac{1}{5} (5 + b\pi^4) \sin(2\pi x_1), \quad E[ISH | x_2] = a \sin^2(2\pi x_2), \quad E[ISH | x_3] = \frac{a}{2}, \quad (20)$$

$$V[ISH | x_1] = \frac{a^2}{8} + \frac{8b^2\pi^8}{225} (1 - \cos(4\pi x_1)), \quad V[ISH | x_2] = \frac{1}{2} + b\pi^4 \left( \frac{1}{5} + \frac{b}{18} \pi^4 \right), \quad (21)$$

$$V[ISH | x_3] = \frac{a^2}{8} + \frac{1}{2} \left( 1 + b\pi^4 (1 - 2x_3)^4 \right)^2,$$

$$\gamma[ISH | x_1] = -\frac{128b^3\pi^{12}\sin^3(2\pi x_1)}{4875(V[ISH | x_1])^{3/2}}, \quad \gamma[ISH | x_2] = 0, \quad ISH[y | x_3] = 0, \quad (22)$$

$$\begin{aligned} k[ISH | x_1] &= \frac{1}{V^2[ISH | x_1]} \left\{ \frac{3}{128}a^4 + \frac{4}{75}b^2\pi^8\sin^2(2\pi x_1) \left[ a^2 + \frac{1849}{5525}b^2\pi^8\sin^2(2\pi x_1) \right] \right\}, \\ k[ISH | x_2] &= \frac{1}{2V^2[ISH | x_2]} \left\{ \frac{3}{4} + b\pi^4 \left[ \frac{3}{5} + b\pi^4 \left( \frac{1}{2} + 3b\pi^4 \left( \frac{1}{13} + \frac{1}{68}b\pi^4 \right) \right) \right] \right\}, \\ k[ISH | x_3] &= \frac{3}{128V^2[ISH | x_3]} \left\{ a^4 + 16 \left( 1 + b\pi^4(1-2x_3)^4 \right)^2 \left[ a^2 + \left( 1 + b\pi^4(1-2x_3)^4 \right)^2 \right] \right\}. \end{aligned} \quad (23)$$

For the sole purpose of illustrating our approach, here and in the following we set  $a = 5$  and  $b = 0.1$ , which corresponds to  $E[ISH] = 2.50$ ,  $V[ISH] = 10.84$  and  $k[ISH] = 4.18$ . Figure 1 depicts the first four moments of  $ISH$  conditional to values of  $x_1$  (blue curves),  $x_2$  (red curves) and  $x_3$  (green curves) within the parameter space. The corresponding unconditional moments (black curves) are also depicted for completeness.

Comparing Eq. (19a) and Eq. (20), it is seen that  $E[ISH | x_3]$  coincides with its unconditional counterpart  $E[ISH]$ , indicating that conditioning on any value of  $x_3$  does not impact the mean of  $ISH$ . Otherwise, setting  $x_1$  or  $x_2$  to a given value clearly affects the mean of  $ISH$  in a way which is governed by Eq. (20) and shown in Fig. 1a. It is clear from Eq. (20) that  $E[ISH | x_2]$  has a higher frequency of oscillation within  $\Gamma_{x_2}$  than has  $E[ISH | x_1]$  within  $\Gamma_{x_1}$ . The global index in Eq. (10) can be evaluated analytically as

$$AMAE_{x_1} = \frac{4}{a\pi} \left| 1 + \frac{b}{5}\pi^4 \right|, \quad AMAE_{x_2} = \frac{2}{\pi} \left| \frac{a}{a} \right|, \quad AMAE_{x_3} = 0. \quad (24)$$

Note that  $AMAE_{x_2}$  does not depend on specific values of  $a$  and  $b$ .

Equation (21) shows that all random model parameters influence the variance of  $ISH$ , albeit to different extents, as also illustrated in Fig. 1b. Note that  $V[ISH | x_2]$  is always smaller than  $V[ISH]$  (compare Eq. (19a) and Eq. (21)) and does not depend on  $x_2$ , i.e., conditioning  $ISH$  on  $x_2$

reduces the process variance regardless the conditioning value. Otherwise,  $V[ISH | x_3]$  can be significantly larger or smaller than its unconditional counterpart. Table 1 lists values of  $AMAV_{x_i}$  ( $x_i = x_1, x_2, x_3$ ) computed via Eq. (12) with the  $a$  and  $b$  values selected for our demonstration. The principal Sobol' indices (Sudret, 2008)

$$S_{x_1} = \frac{(5 + b\pi^4)^2}{50 V[ISH]}, \quad S_{x_2} = \frac{a^2}{8 V[ISH]}, \quad S_{x_3} = 0, \quad (25)$$

are also listed for completeness. As expected, values of  $AMAV_{x_i}$  listed in Table 1 suggest that conditioning on  $x_3$  has the strongest impact on the variance of  $ISH$ , followed by  $x_1$  and  $x_2$ . Note that  $S_{x_3} = 0$ , a result which might be interpreted as a symptom that  $ISH$  is insensitive to  $x_3$ . The apparent inconsistency between the conclusions which could be drawn by analysing  $AMAV_{x_3}$  and  $S_{x_3}$  is reconciled by the observation that the function  $V[ISH] - V[ISH | x_3]$  can be positive and negative in a way that its integration over  $\Gamma_{x_3}$  vanishes (see also Fig. 1b). Therefore, the mean reduction of the variance of  $ISH$  due to knowledge of (or conditioning on)  $x_3$  is zero. It is remarked that this observation does not imply that the variance of  $ISH$  does not vary with  $x_3$ , as clearly highlighted by Fig. 1b and quantified by  $AMAV_{x_3}$ .

The symmetry of the *pdf* of  $ISH$  is not affected by conditioning on  $x_2$  or  $x_3$ , as demonstrated by Eq. (22). Otherwise,  $\gamma[ISH | x_1]$  is left (or right) skewed when  $x_1$  is smaller (or larger) than 0.5, as dictated by Eq. (22) and shown in Fig. 1c.

The conditional kurtosis  $k[ISH | x_2]$  does not depend on the conditioning value  $x_2$  (see Eq. (23)). We then note that this conditional moment is always larger than (or equal to) its unconditional counterpart  $k[ISH]$ , regardless the particular values assigned to  $a$  and  $b$ , as we verified through extensive numerical tests. This result implies that the *pdf* of  $ISH$  conditional on  $x_2$  is characterized

304 by tails which are heavier than those of its unconditional counterpart. Figure 1d reveals that  
 305  $k[ISH | x_1]$  and  $k[ISH | x_3]$  are smaller than  $k[ISH]$  for the values of  $a$  and  $b$  implemented in this  
 306 example. Table 1 lists the resulting values of  $AMAk_{x_i}$  ( $x_i = x_1, x_2, x_3$ ) for the selected  $a$  and  $b$   
 307 values.

308 We close this part of the study by investigating the error which would arise when one evaluates  
 309 our GSA indices by replacing  $ISH$  through a gPCE surrogate model. We do so on the basis of the  
 310 absolute relative error

$$311 \quad e_j = \begin{cases} \left| \frac{j_{gPCE} - j_{full\ model}}{j_{full\ model}} \right| & \text{if } j_{full\ model} \neq 0 \\ |j_{gPCE} - j_{full\ model}| & \text{if } j_{full\ model} = 0 \end{cases}, \quad (26)$$

312 where  $j = AMAE_{x_i}, AMAV_{x_i}, AMA\gamma_{x_i}$  or  $AMAk_{x_i}$  ( $x_i = x_1, x_2, x_3$ ); the subscripts *full model* and  
 313 *gPCE* respectively indicate that quantity  $j$  is evaluated via Eq. (18) or through a gPCE surrogate  
 314 model, constructed as outlined in Section 2.1. Figure 2 depicts Eq. (26) versus the total degree  $w$  of  
 315 the gPCE. Note that the lower limit of the vertical axis of Fig. 2 is set to 0.001% for convenience of  
 316 graphical representation. Approximation errors associated with GSA indices related to the mean,  
 317  $AMAE_{x_i}$ , rapidly approach zero as  $w$  increases. Note that  $e_{AMAE_{x_3}}$  is smaller than 0.001% for all tested  
 318 values of  $w$  and it is therefore not included in Fig. 2a. Values of  $e_j$  linked to  $AMAV_{x_i}, AMA\gamma_{x_i}$  and  
 319  $AMAk_{x_i}$  do not show a consistently decreasing trend until  $w \geq 5$ . Values of  $e_j$  associated with the  
 320 variance, skewness and kurtosis decrease with approximately the same average linear rate (in log-log  
 321 scale) for the largest  $w$  considered (Fig.s 2b, 2c and 2d). This example reinforces the need for reliably  
 322 testing the accuracy of a gPCE-based model approximation as a function of the total degree desired,  
 323 depending on the statistical moment of interest. Note that a generalization of our findings about the  
 324 error (26) is outside the scope of the current study. This would require the derivation of (a) the  
 325 analytical format of the *pdf* of a target model output through its gPCE based approximation at a given

order  $w$  (see, e.g., Riva et al., 2015), and (b) the corresponding  $pdf$  resulting from the full system model (e.g., by formulating and solving exact equations for the target  $pdf$ , or its moments, typically invoking problem specific assumptions).

329

### 3.2 Critical Pumping Rate in Coastal Aquifers

The example we consider here is taken from the study of Pool and Carrera (2011) related to the analysis of salt water contamination of a pumping well operating in a homogenous confined coastal aquifer of uniform thickness  $b'$ . The setting is sketched in Fig. 3. A constant discharge,  $Q_w'$  [ $L^3 T^{-1}$ ], is pumped from a fully penetrating well located at a distance  $x_w'$  [L] from the coastline and a constant freshwater flux,  $q_f'$  [ $L T^{-1}$ ], flowing from the inland to the coastline, is set. Pool and Carrera (2011) introduced a dimensionless well discharge  $Q_w = Q_w' / (b' x_w' q_f')$  and defined the critical pumping rate  $Q_c$  as the value of  $Q_w$  at which a normalized solute concentration monitored at the well exceeds 0.1%. A key result of the study of Pool and Carrera (2011) is that  $Q_c$  can be approximated through the following implicit equation

$$\lambda_D = 2 \left[ 1 - \frac{Q_c}{\pi} \right]^{1/2} + \frac{Q_c}{\pi} \ln \frac{1 - (1 - Q_c / \pi)^{1/2}}{1 + (1 - Q_c / \pi)^{1/2}} \quad \text{with} \quad \lambda_D = \frac{\Delta \rho'}{\rho_f'} \frac{1 - (Pe_T)^{-1/6}}{x_w' J}. \quad (27)$$

Here,  $x_w = x_w' / b'$ ;  $J = q_f' / K$ ;  $Pe_T = b' / \alpha_T'$ ;  $K$  [ $L T^{-1}$ ] is the uniform hydraulic conductivity;  $\alpha_T'$  [L] is transverse dispersivity;  $\Delta \rho' = \rho_s' - \rho_f'$ ,  $\rho_f'$  and  $\rho_s'$  being fresh- and salt-water densities, respectively. The quantity  $Pe_T$  is a measure of the intensity of dispersive effects,  $J$  is the natural head gradient of the incoming freshwater, and  $x_w$  is the dimensionless distance of the well from the coastline. Pool and Carrera (2011) demonstrated the accuracy of Eq. (27) in predicting the critical pumping rate when  $\lambda_D \in (0-10]$ . Additional details about the problem setting, boundary and initial conditions, as well as geometrical configuration of the system can be found in Pool and Carrera

(2011). Here, we focus on the main result of Eq. (27) which represents the complete mathematical description of the problem we analyze. We perform a sensitivity analysis of  $Q_c$  with respect to  $Pe_T$ ,  $J$ , and  $x_w$ . While the first two quantities are difficult to assess experimentally in practical applications, the well location can be considered as an operational/design variable. Table 2 lists the intervals of variation we consider for  $Pe_T$ ,  $J$  and  $x_w$ . These are designed to (a) resemble realistic field values and (b) obey the above mentioned constraint about  $\lambda_D$ .

Numerical evaluation of the first four unconditional statistical moment of  $Q_c$  yields a mean value  $E[Q_c]=1.65$ , variance  $V[Q_c]=0.17$ , skewness  $\gamma[Q_c]=-0.30$  (which indicates a light asymmetry in the *pdf*), and kurtosis  $k[Q_c]=2.51$  (i.e., *pdf* tails decrease faster than those of a Gaussian distribution). Figure 4 depicts the first four moments of  $Q_c$  conditional to values of  $Pe_T$  (blue curves),  $J$  (green curves), and  $x_w$  (red curves) within the parameter space. The corresponding unconditional moments (black curves) are also depicted for completeness. Note that each parameter interval of variation has been normalized to span the range  $[0, 1]$  for graphical representation purposes. Table 3 lists the values of indices  $AMAE_{x_i}$ ,  $AMAV_{x_i}$ ,  $S_{x_i}$ ,  $AMA\gamma_{x_i}$  and  $AMAk_{x_i}$  ( $x_i = Pe_T, J, x_w$ ) associated with  $Q_c$ . As in our first example, it is clear that sensitivity of  $Q_c$  with respect to  $Pe_T, J, x_w$  depends on the statistical moment of interest.

Inspection of Fig. 4a reveals that the mean of  $Q_c$  is more sensitive to conditioning on  $J$  or  $x_w$  than to conditioning on  $Pe_T$ . Note that increasing  $Pe_T$ , i.e., considering advection-dominated scenarios, leads to an increase of the mean value of  $Q_c$ . This is so because the dispersion of the intruding saltwater wedge is diminished and the travel time of solutes to the well tends to increase. High values of the natural head gradient of the incoming freshwater,  $J$ , are associated with high mean values of  $Q_c$ . This is consistent with the observation that the inland penetration of the wedge is contrasted by the effect of freshwater which flows in the opposite direction. As expected, decreasing

371  $x_w$  (moving the pumping well towards the coast) leads to a reduction of the mean value of  $Q_c$ . Figure  
 372 4a shows that mean  $Q_c$  varies with  $x_w$  and  $J$  in a similar way. This outcome is consistent with Eq.  
 373 (27) where  $Q_c$  depends on the product  $x_w J$ , i.e., increasing  $x_w$  or  $J$  has the same effect on  $Q_c$ .

374 It can be noted (see Tab. 3) that  $AMAE_{Pe_T}$  is smaller than  $AMAE_J$  and  $AMAE_{x_w}$ , consistent  
 375 with Fig. 4a. Figure 4b shows that the variance of  $Q_c$  decreases as  $Pe_T$ ,  $J$ , or  $x_w$  increase. This trend  
 376 suggests that the uncertainty on  $Q_c$ , as quantified by the variance, decreases as (i) the intruding wedge  
 377 sharpens or is pushed toward the seaside boundary by the incoming freshwater or (ii) the well is  
 378 placed at increasing distance from the coastline. Inspection of Fig. 4c and 4d shows that conditioning  
 379 on  $Pe_T$ ,  $J$ , or  $x_w$  causes the *pdf* of  $Q_c$  to become less asymmetric and less tailed than its unconditional  
 380 counterpart. This behavior suggests that the relative frequency of occurrence of (high or low) extreme  
 381 values of  $Q_c$  tends to decrease as additional information about the model parameters become  
 382 available.

383 Figure 5 depicts error,  $e_j$ , Eq. (26) versus total degree,  $w$ , of the gPCE representation of  $Q_c$ ,  
 384 for  $j =$  (a)  $AMAE_{x_i}$ , (b)  $AMAV_{x_i}$ , (c)  $AMAY_{x_i}$  and (d)  $AMAK_{x_i}$  ( $x_i = Pe_T$  (blue curves),  $J$  (red  
 385 curves),  $x_w$  (green curves)). These results indicate that: (i)  $e_j$  associated with  $AMAE_{x_i}$  is negligible  
 386 ( $\approx 1\%$ ) even for low  $w$ ; (ii)  $e_{AMAV_{Pe_T}} \approx 10\%$  for  $w = 2$  and rapidly decreases to values below 1% for  
 387 increasing  $w$ ; (iii)  $e_{AMAV_J}$  and  $e_{AMAV_{x_w}}$  are always smaller than 1%; and (iv) the trend of  $e_{AMAY_{x_i}}$  is  
 388 similar to that of  $e_{AMAK_{x_i}}$  for all  $x_i$ , with values of the order of 10% or higher for  $w = 2$  and displaying  
 389 a decrease with increasing  $w$  to then stabilize around values smaller than 1% when  $w \approx 4$  or 5. We  
 390 note that the absolute relative error (26) for  $AMAE_{x_i}$  with a given value of  $w$  is always lower than  
 391 errors associated with higher order moments. Similar to our results in Section 3.1, it is clear from Fig.  
 392 5 that attaining a given level of accuracy for the gPCE based indices for  $Q_c$  requires considering a

diverse total order  $w$  of the gPCE depending on the order of the statistical moment considered. As such, following the typical practice of assessing the reliability of a gPCE surrogate model solely on the basis of the variance or of a few random model realizations does not guarantee a satisfactory accuracy of the uncertainty analysis of a target model output which should consider higher-order statistical moments.

### 3.3 Solute transport in a laboratory-scale porous medium with zoned heterogeneity

As a last exemplary showcase, we consider the laboratory-scale experimental analysis of nonreactive chemical transport illustrated by Esfandiar et al. (2015). These authors consider tracer transport within a rectangular flow cell filled with two types of uniform sands. These were characterized by diverse porosity and permeability values, which were measured through separate, standard laboratory tests. A sketch of the experimental set-up displaying the geometry of the two uniform zones respectively formed by coarse and fine sand is illustrated in Fig. 6.

After establishing fully saturated steady-state flow, a solution containing a constant tracer concentration is injected as a step input at the cell inlet. The tracer breakthrough curve is then defined in terms of the temporal variation of the spatial mean of the concentration detected along the flow cell outlet. Esfandiar et al. (2015) modeled the temporal evolution of normalized (with respect to the solute concentration of the injected fluid) concentration at the outlet,  $\bar{C}(t)$  ( $t$  denoting time), by numerically solving within the flow domain the classical Advection-Dispersion Equation implementing an original and accurate space-time grid adaptation technique. Unknown longitudinal dispersivities of the two sands ( $a_{L,i}$ ,  $i = 1, 2$  respectively denoting the coarse and fine sand) were considered as uncertain system parameters to be estimated against the available experimental solute breakthrough data. To minimize the computational costs in the model calibration process, Esfandiar et al. (2015) relied on a gPCE approximation of  $\bar{C}(t)$ . The authors constructed a gPCE of total degree  $w = 3$  by considering  $\log_{10}(a_{L,i})$  to be two *i.i.d.* random variables uniformly distributed within

417  $\Gamma_{\log_{10}(a_{L,i})} = [-6, -2]$ ,  $a_{L,i}$  being expressed in [m]. Further details about the problem set-up, numerical  
 418 discretization and grid adaptation technique as well of the construction of the gPCE representation  
 419 can be found in Esfandiar et al. (2015). Here, we ground the application of our new GSA metrics on  
 420 the gPCE surrogate model already constructed by Esfandiar et al. (2015) to approximate  $\bar{C}(t)$ .

421 Figure 7 depicts the temporal evolution of the unconditional expected value,  $E[\bar{C}(t)]$ ,  
 422 variance,  $V[\bar{C}(t)]$ , skewness,  $\gamma[\bar{C}(t)]$ , and kurtosis,  $k[\bar{C}(t)]$ , of normalized  $\bar{C}(t)$ . Time steps  
 423  $t_{0.02}$ ,  $t_{0.4}$ , and  $t_{0.96}$ , i.e., the times at which  $E[\bar{C}(t)] = 0.02, 0.4$ , and  $0.96$ , respectively, are  
 424 highlighted in Fig. 7a. Figure 7a reveals a pronounced tailing of  $E[\bar{C}(t)]$  at late times, the short  
 425 time mean breakthrough being associated with a rapid temporal increase of  $E[\bar{C}(t)]$ . A local  
 426 minimum at  $t_{0.4}$  and two local peaks and are recognized in  $V[\bar{C}(t)]$  (Fig. 7b). The variance peaks  
 427 at times approximately corresponding to the largest values of  $\partial^2 E[\bar{C}(t)] / \partial t^2$ . This outcome is  
 428 consistent with the results of numerical Monte Carlo (MC) simulations depicted in Fig. 8 of Esfandiar  
 429 et al. (2015) where the largest spread of the MC results is observed around these locations. The local  
 430 minimum displayed by  $V[\bar{C}(t)]$  suggests that  $\bar{C}(t)$  at observation times close to  $t_{0.4}$  is mainly  
 431 driven by advection, consistent with the observation that advective transport components are the main  
 432 driver of the displacement of the center of mass of a solute plume. The late time variance  $V[\bar{C}(t)]$   
 433 tends to vanish because the normalized breakthrough curve is always very close to unity irrespective  
 434 of the values of  $a_{L,1}$  and  $a_{L,2}$ . Joint inspection of Figs 7c and 7d reveals that the *pdf* of  $\bar{C}(t)$  tends to  
 435 be symmetric around the mean (Fig. 7c) and characterized by light tails (Fig. 7d) at about  $t_{0.4}$ .  
 436 Otherwise, the *pdfs* of  $\bar{C}(t)$  tends to display heavy right or left tails, respectively for observation  
 437 times shorter or longer than  $t_{0.4}$ . These observations suggest that the relative frequency of rare events

438 (i.e., very low or high solute concentrations, which can be of some concern in the context of risk  
 439 assessment) is lowest at intermediate observation times across the duration of the experiment.

440 Figure 8 depicts the temporal evolution of (a)  $AMAE_{x_i}$ , (b)  $AMAV_{x_i}$ , (c)  $AMAG_{x_i}$ , and (d)  
 441  $AMAK_{x_i}$  ( $x_i = \log_{10}(a_{L,1}), \log_{10}(a_{L,2})$ ) of  $\bar{C}(t)$ . Results embedded in Fig. 8 show that statistical  
 442 moments of  $\bar{C}(t)$  are more sensitive to  $\log_{10}(a_{L,1})$  than to  $\log_{10}(a_{L,2})$  at early times. The opposite  
 443 occurs when  $t > t_{0.4}$ . Our set of results suggests that the overall early time pattern of solute  
 444 breakthrough is mainly dictated by the value of  $a_{L,1}$ , the late time behavior being chiefly influenced  
 445 by  $a_{L,2}$ . These conclusions are supported by the results of Figs 9-11, where we depict the expected  
 446 value, variance, skewness, and kurtosis of  $\bar{C}(t)$  conditional to  $\log_{10}(a_{L,1})$  (blue curves) and  
 447  $\log_{10}(a_{L,2})$  (red curves), at times  $t = t_{0.02}$  (Fig. 9),  $t_{0.4}$  (Fig. 10), and  $t_{0.96}$  (Fig. 11). The corresponding  
 448 unconditional moments are also depicted (black curves) for ease of comparison. Figure 9 shows that  
 449 the first four statistical moments of  $\bar{C}(t_{0.02})$  are practically insensitive to the value of the fine sand  
 450 dispersivity,  $a_{L,2}$ . As one could expect by considering the relative size and geometrical pattern of the  
 451 two sand zones, Fig. 9a shows that the average amount of solute reaching the cell outlet at early times  
 452 increases with  $a_{L,1}$ , because dispersion of solute increases through the coarse sand which resides in  
 453 the largest portion of the domain. Figure 9b shows  $V[\bar{C}(t_{0.02})]$  is negligible when  $a_{L,1}$  is known.  
 454 Consistent with this result, Figs 9c and 9d respectively show a reduction in the asymmetry and in the  
 455 tailing behavior of the *pdf* of  $\bar{C}(t_{0.02})$  when  $a_{L,1}$  is fixed. These results are a symptom of a reduced  
 456 process uncertainty, which is in line with the observation that the bulk of the domain is filled with the  
 457 coarse sand whose dispersive properties become deterministic when  $a_{L,1}$  is known.

458 Inspection of the first four unconditional statistical moments of  $\bar{C}(t_{0.4})$  (black curves in Fig.  
 459 10) indicates that the unconditional *pdf* of  $\bar{C}$  at this intermediate time is closely resembling a

460 Gaussian distribution. Conditioning  $\bar{C}(t_{0.4})$  on dispersivity causes a variance reduction, an increase  
 461 of the tailing and the appearance of a negative (left) or positive (right) skewness, respectively when  
 462 conditioning is performed on  $a_{L,1}$  or  $a_{L,2}$ . The latter behavior suggests that in the type of experimental  
 463 setting analyzed the variability of  $a_{L,1}$  promotes the appearance of values of  $\bar{C}(t_{0.4})$  larger than the  
 464 mean, the opposite occurring when solely  $a_{L,2}$  is considered as uncertain.

465 Figure 11 shows that all four statistical moment of  $\bar{C}(t_{0.96})$  are chiefly sensitive to the  
 466 dispersivity of the fine sand box, which is placed near the cell outlet. One can note that knowledge of  
 467  $a_{L,2}$  yields a diminished variance of  $\bar{C}(t_{0.96})$ , which drops almost to zero, an increased degree of  
 468 symmetry and a reduce tailing of the *pdf* of  $\bar{C}(t_{0.96})$ , all these evidences being symptoms of  
 469 uncertainty reduction.

470 Results depicted in Figs 9-11 and our earlier observations about Fig. 7 are consistent with the  
 471 expected behavior of transport in the system and the relative role of the dispersivities of the two sand  
 472 regions. The high level of sensitivity of  $\bar{C}(t)$  to  $a_{L,1}$  at the early times of solute breakthrough is in  
 473 line with the observation that solute particles are mainly advected and dispersed through the coarse  
 474 sand. Both dispersivities affect the behavior of  $\bar{C}(t)$  at intermediate times, when solute is traveling  
 475 through both sands. The dispersivity of the coarse sand plays a minor role at late times, because  
 476 virtually no concentration gradients arise in this portion of the domain. Otherwise, concentration  
 477 gradients persist in the fine sand zone close to the outlet and the solute breakthrough is clearly  
 478 controlled by the dispersive properties of the fine sand.

#### 479 **4. Conclusions**

480 We introduce a set of new indices to be employed in the context of global sensitivity analysis,  
 481 GSA, of hydrological and Earth systems. These indices consider the first four (statistical) moments  
 482 of the probability density function, *pdf*, of a desired model output,  $y$ . As such, they quantify the

483 expected relative variation, due to the variability in one (or more) model input parameter(s) of the  
484 expected value, variance, skewness and kurtosis of  $y$ . When viewed in the current research trend, our  
485 work is intended to bridge the gap between variance-based and *pdf*-based GSA approaches since it  
486 embeds the simplicity of the former while allowing for a higher-order description of how the structure  
487 of the *pdf* of  $y$  is affected by variations of uncertain model parameters. We cope with computational  
488 costs, which might be high when evaluating higher-order moments, by coupling our GSA approach  
489 with techniques approximating the full model response through a surrogate model. For the sake of  
490 our study, we consider the generalized Polynomial Chaos Expansion (gPCE), other model reduction  
491 techniques being fully compatible with our approach. Our new indices can be of interest in  
492 applications in the context of current practices and evolution trends in factor fixing procedures (i.e.,  
493 assessment of the possibility of fixing a parameter value on the basis of the associated output  
494 sensitivity), design of experiment, uncertainty quantification and environmental risk assessment, due  
495 to the role of the key features of a model output *pdf* in such analyses.

496 We test and exemplify our methodology on three testbeds: (a) the Ishigami function, which is  
497 widely employed to test sensitivity analysis techniques, (b) the evaluation of the critical pumping rate  
498 to avoid salinization of a pumping well in a coastal aquifer, and (c) a laboratory-scale nonreactive  
499 transport experiment. Our theoretical analyses and application examples lead to the following major  
500 conclusions.

- 501 1. The **calculated** sensitivity of a model output,  $y$ , with respect to a parameter depends on the selected  
502 global sensitivity index, i.e., variability of a model parameter affects statistical moments of  $y$  in  
503 different ways and with different relative importance, depending on the statistical moment  
504 considered. Relying on the indices we propose allows enhancing our ability to quantify how  
505 model parameters affect features of the model output *pdf*, such as mean, degree of spread,  
506 symmetry and tailedness, in a straightforward and easily transferrable way.
- 507 2. Joint inspection of our moment-based global sensitivity indices and of the first four statistical  
508 conditional and unconditional moments of  $y$  increases our ability to understand the way the

structure of the model output  $pdf$  is controlled by model parameters. As demonstrated in our examples, classical variance-based GSA methods cannot be used for this purpose, leading, in some cases, to the unwarranted conclusion that a given parameter have a limited impact on a target output.

3. Analysis of the errors associated with the use of a surrogate model for the evaluation of our moment-based sensitivity indices suggests that: (a) attaining a given level of accuracy for the gPCE based indices associated with a target variable,  $y$ , might require considering a diverse total order  $w$  of the gPCE, depending on the target statistical moment considered in the GSA of  $y$ ; and (b) in our examples, the absolute relative error (26) for  $AMAE_{x_i}$  based on a given total degree  $w$  of the gPCE approximation is always lower than its counterpart associated with higher order moments (see Fig. 2 and 5).

631 **Table 1.** Global sensitivity index  $AMAE_{x_i}$  Eq. (10),  $AMAV_{x_i}$  Eq. (12),  $AMA\gamma_{x_i}$  Eq. (14), and  
 632  $AMAk_{x_i}$  Eq. (16) associated with the Ishigami function Eq. (18). Principal Sobol' indices,  $S_{x_i}$  Eq.  
 633 (7), are also listed;  $x_i = x_1, x_2, x_3$ .

	$AMAE_{x_i}$	$AMAV_{x_i}$	$S_{x_i}$	$AMA\gamma_{x_i}$	$AMAk_{x_i}$
$x_1$	0.75	0.40	0.40	0.45	0.37
$x_2$	0.64	0.29	0.29	0.00	0.33
$x_3$	0.00	0.84	0.00	0.00	0.53

634

635

636 **Table 2.** Intervals of variations of  $Pe_T, J, x_w$ .

	$\Gamma_n = [x_{n,\min} - x_{n,\max}]$
$\Gamma_{Pe_T}$	$[0.01 - 0.1]$
$\Gamma_J$	$[8e^{-4} - 2.5e^{-3}]$
$\Gamma_{x_w}$	$[10 - 33]$

637

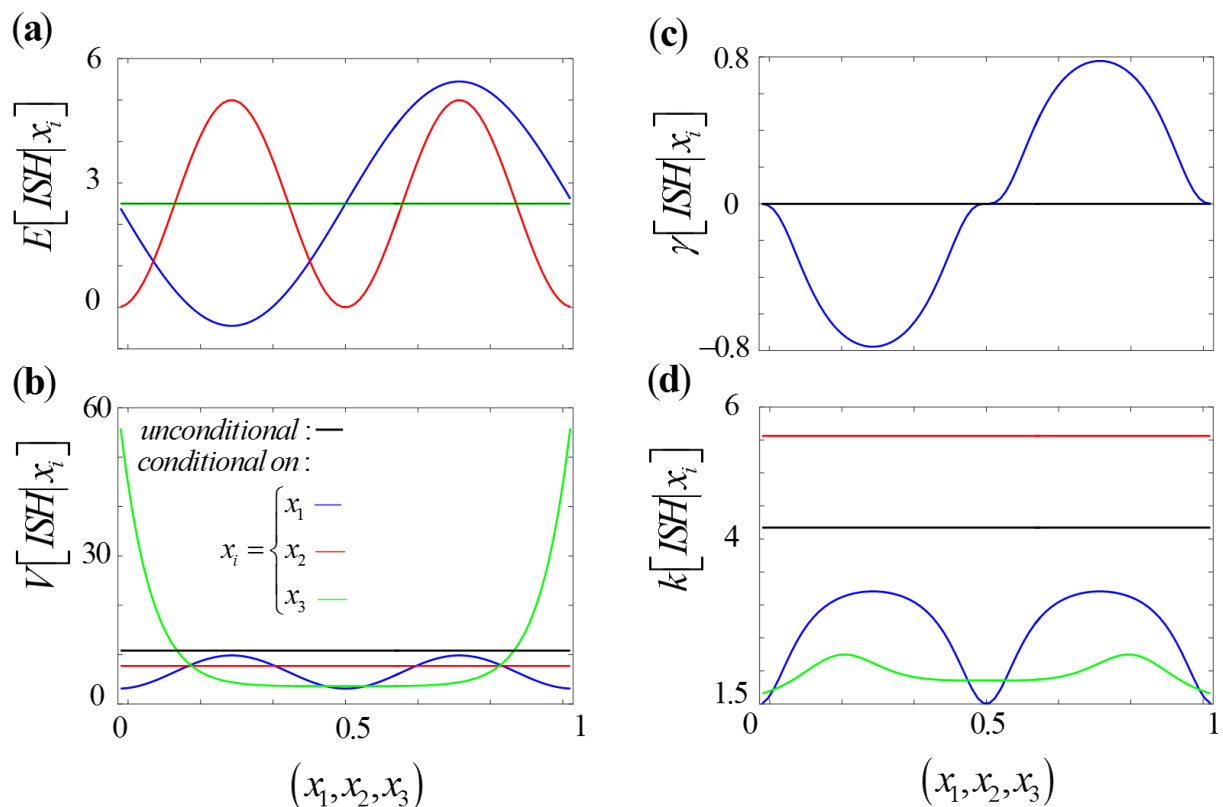

638

639 **Table 3.** Global sensitivity index  $AMAE_{x_i}$  Eq. (10),  $AMAV_{x_i}$  Eq. (12),  $AMAY_{x_i}$  Eq. (14), and  
640  $AMAK_{x_i}$  Eq. (16) associated with the critical pumping rate  $Q_c$  (25). Principal Sobol' indices,  $S_{x_i}$  Eq.  
641 (7) , are also listed;  $x_i = Pe_T, J, x_w$ .

	$AMAE_{x_i}$	$AMAV_{x_i}$	$S_{x_i}$	$AMAY_{x_i}$	$AMAK_{x_i}$
$Pe_T$	0.07	0.14	0.09	0.35	0.09
$J$	0.14	0.41	0.41	0.88	0.12
$x_w$	0.15	0.48	0.48	0.78	0.11

**Figure 1.** Variation of the first four moments of  $ISH$  Eq. (18) conditional to values of  $x_1$  (blue curves),  $x_2$  (red curves) and  $x_3$  (green curves) within the parameter space: (a) expected value,  $E[ISH | x_i]$ , (b) variance,  $V[ISH | x_i]$ , (c) skewness,  $\gamma[ISH | x_i]$ , and (d) kurtosis,  $k[ISH | x_i]$ , ( $i = 1, 2, 3$ ). The corresponding unconditional moments (black curves) are also depicted.

650

651 **Figure 2.** Error  $e_j$  Eq. (26) versus the total degree  $w$  of the gPCE representation of  $ISH$  for  $j =$  (a)  
 652  $AMAE_{x_i}$ , (b)  $AMAV_{x_i}$ , (c)  $AMA\gamma_{x_i}$  and (d)  $AMAk_{x_i}$ , with  $x_i = x_1$  (blue curves),  $x_2$  (red curves),  
 653  $x_3$  (green curves). Note that  $AMAE_{x_3}$  is always smaller than 0.001%. Average slope of the rate of  
 654 decrease of  $e_j$  for the largest  $w$  values considered are indicated as a reference in (a)-(d).

655

656

**Figure 3.** Sketch of the critical pumping scenario taking place within a coastal aquifer of thickness  $b'$ . A constant freshwater (in blue) flux,  $q'_f$ , flows from the inland to the coastline (saltwater in red). A constant discharge,  $Q'_w$ , is pumped from a fully penetrating well located at a distance  $x'_w$  from the coastline. Color scale indicating variable concentration of salt is only qualitative for illustration purposes.
