16 Abstract

17 Reading landscapes and developing calibration-free runoff generation models that adequately reflect land
18 surface heterogeneities remains the focus of much hydrological research. In this study, we report a novel
19 and simple topography-driven runoff generation parameterization – the HAND-based Storage Capacity
20 curve (HSC), that uses a topographic index (HAND, Height Above the Nearest Drainage) to identify
21 hydrological similarity and the extent of saturated areas in catchments. The HSC can be used as a module
22 in any conceptual rainfall-runoff model. Further, coupling the HSC parameterization with the Mass Curve
23 Technique (MCT) to estimate root zone storage capacity ($S_{u\text{Max}}$), we developed a calibration-free runoff
24 generation module HSC-MCT. The runoff generation modules of HBV and TOPMODEL were used for
25 comparison purposes. The performance of these two modules (HSC and HSC-MCT) was first checked
26 against the data-rich Bruntland Burn (BB) catchment in Scotland, which has a long time series of field-
27 mapped saturation area extent. We found that HSC, HBV and TOPMODEL all perform well to reproduce
28 the hydrograph, but the HSC module performs better in reproducing saturated area variation, in terms of

29 correlation coefficient and spatial pattern. The HSC and HSC-MCT modules were subsequently tested for
30 323 MOPEX catchments in the US, with diverse climate, soil, vegetation and geological characteristics. In
31 comparison with HBV and TOPMODEL, the HSC performs better in both calibration and validation,
32 particularly in the catchments with gentle topography, less forest cover and arid climate. Despite having
33 no calibrated parameters, the HSC-MCT module performed comparably well with calibrated modules,
34 highlighting the robustness of the HSC parameterization to describe the spatial distribution of the root
35 zone storage capacity and the efficiency of the MCT method to estimate $S_{u\text{Max}}$. This novel and calibration-
36 free runoff generation module helps to improve the Prediction in Ungauged Basins and has great potential
37 to be generalized at the global scale.

38

39 1 Introduction

40 Determining the volume and timing of runoff generation from rainfall inputs remains a central challenge
41 in rainfall-runoff modelling (Beven, 2012; McDonnell, 2013). Creating a simple, calibration-free, but robust
42 runoff generation module has been, and continues to be, an essential pursuit of hydrological modellers.
43 Although we have made tremendous advances to enhance our ability on Prediction in Ungauged Basins
44 (PUB) (Sivapalan et al., 2003; Blöschl et al., 2013; Hrachowitz et al., 2013), it is not uncommon that models
45 become increasingly complicated in order to capture the details of hydrological processes shown by
46 empirical studies (McDonnell, 2007; Sivapalan, 2009; Yu et al., 2014). More detailed process
47 conceptualization normally demands higher data requirements than our standard climatological and
48 hydrological networks can provide, leading to more calibrated parameters and a probable increase in
49 model uncertainty (Sivapalan, 2009).

50 Hydrological connectivity is a key characteristic of catchment functioning, controlling runoff generation.
51 It is a property emerging at larger scales, describing the temporal dynamics of how spatially
52 heterogeneous storage thresholds in different parts of catchments are exceeded to contribute to storm
53 runoff generation and how they are thus “connected to the stream” (e.g. Zehe and Blöschl, 2004;
54 Bracken and Croke, 2007; Lehmann et al., 2007; Zehe and Sivapalan, 2009; Ali et al., 2013; Blume and
55 van Meerveld, 2015). Connectivity is controlled by a multitude of factors (Ali and Roy, 2010), including
56 but not limited to surface (e.g. Jencso et al., 2009) and subsurface topography (e.g. Tromp-van Meerveld
57 and McDonnell, 2006), soils (including preferential flow networks; e.g. Zehe et al., 2006; Weiler and
58 McDonnell, 2007), land cover (e.g. Imeson and Prinsen, 2004; Jencso and McGlynn, 2011; Emanuel et al.,

59 the wetness state of the system (e.g. [Detty and McGuire, 2010](#); [Penna et al., 2011](#); [McMillan et](#)
60 [al., 2014](#); [Nippgen et al., 2015](#)).

61 In detailed distributed hydrological bottom-up models, connectivity emerges from the interplay of
62 topography, soil type and water table depth. For example, TOPMODEL ([Beven and Kirkby, 1979](#); [Beven](#)
63 [and Freer, 2001](#)) uses topographic wetness index (TWI) to distinguish hydrologic similarity; and SHE
64 ([Abbott et al. 1986](#)) and tRIBS ([Ivanov et al. 2004](#); [Vivoni et al. 2005](#)) use partial differential equations to
65 describe the water movement based on pressure gradients obtained by topography; and the
66 Representative Elementary Watershed (REW) approach divides catchment into a number of REWs to
67 build balance and constitutive equations for hydrological simulation ([Reggiani et al., 1999](#); [Zhang and](#)
68 [Savenije, 2005](#); [Tian et al., 2008](#)). As the relevant model parameters such as local topographic slope and
69 hydraulic conductivity can, in spite of several unresolved issues for example relating to the differences in
70 the observation and modelling scales (e.g. [Beven, 1989](#); [Zehe et al., 2014](#)), be obtained from direct
71 observations, they could *in principle* be applied without calibration.

72 Zooming out to the macro-scale, top-down models, in contrast, are based on emergent functional
73 relationships that integrate system-internal heterogeneity ([Sivapalan, 2005](#)). These functional
74 relationships require parameters that are effective on the modelling scale and that can largely not be
75 directly determined with small-scale field observations (cf. [Beven, 1995](#)), thus traditionally determined
76 by calibration. However, frequently the number of observed variables for model calibration is, if
77 available at all, limited to time series of stream flow. The absence of more variables to constrain models
78 results in such models being ill-posed inverse problems. Equifinality in parameterization and in the
79 choice of parameters then results in considerable model uncertainty (e.g. [Beven, 1993, 2006](#)). To limit
80 this problem and to also allow predictions in the vast majority of ungauged catchments, it is therefore
81 desirable to find ways to directly infer effective model parameters at the modelling scale from readily
82 available data ([Hrachowitz et al., 2013](#)).

83 The component that is central for establishing connectivity in most top-down models is the soil moisture
84 routine. Briefly, it controls the dynamics of water storage and release in the unsaturated root zone and
85 partitions water into evaporative fluxes, groundwater recharge and fast lateral storm flow generating
86 runoff ([Gao et al., 2018a](#); [Shao et al., 2018](#)). The latter of which is critical from the aspect of connectivity.
87 In majority regions, Hortonian overland flow (HOF, i.e. infiltration excess overland flow) is of minor
88 importance ([Dunne and Black, 1970](#); [Sklash and Farvolden, 1979](#); [Beven, 2004](#); [Burt and McDonnell,](#)
89 [2015](#)), even in arid regions where often most locally generated HOF is re-infiltrated while flowing on

90 hillslopes (Liu et al., 2012) and never reaches the stream channel network. Thus the term saturation
91 excess flow (SEF) can represent, depending on the model and the area of application, different
92 processes, such as saturation overland flow, preferential flow, flow through shallow, high permeability
93 soil layers or combinations thereof. The interplay between water volumes that are stored and those that
94 are released laterally to the stream via fast, connected flow paths (“connectivity”) is in most top-down
95 models described by functions between water stored in the unsaturated root zone (“soil moisture”) and
96 the areal proportion of heterogeneous, local storage thresholds that are exceeded and thus
97 “connected” (Zhao et al., 1980). In other words, in those parts of a catchment where the storage
98 threshold is exceeded will generate lateral flows, and can alternatively be interpreted as runoff
99 coefficient (e.g. Ponce and Hawkins, 1996; Perrin and Andreassian, 2001; Fenicia et al., 2007; Bergström
100 and Lindström, 2015). Thus the idea goes back to the variable contributing area concept, assuming that
101 only partial areas of a catchment, where soils are saturated and thus storage thresholds are exceeded,
102 contribute to runoff (Hewlett, 1961; Dunne and Black, 1970; Hewlett and Troendle, 1975). Although
103 originally developed for catchments dominated by saturation overland flow, the extension of the
104 concept to subsurface connectivity, posing that surface and subsurface connectivity are “two sides of
105 the same coin” (McDonnell, 2013), proved highly valuable for models such as Xinanjiang (Zhao et al.,
106 1980), HBV (Bergström and Forsman, 1973; Bergström and Lindström, 2015), SCS-CN (Ponce and
107 Hawkins, 1996; Bartlett et al., 2016), FLEX (Fenicia et al., 2008) and GR4J (Perrin and Andreassian et al.,
108 2001).

109 Among these models, connectivity is formulated in a general form as $C_R=f(S_U(t), S_{uMax}, \beta)$, where C_R is the
110 runoff coefficient, i.e. the proportion of the catchment generating runoff, $S_U(t)$ is the catchment water
111 content in the unsaturated root zone at any time t , S_{uMax} is a parameter representing the total storage
112 capacity in the unsaturated root zone and β is a shape parameter, representing the spatial distribution
113 of heterogeneous storage capacities in the unsaturated root zone. The parameters of these functions
114 are typically calibrated. In spite of being the core component of soil moisture routines in many top-down
115 models, little effort was previously invested to find ways to determine the parameters at the catchment-
116 scale directly from available data. An important step towards understanding and quantifying
117 connectivity pattern directly based on observations was recently achieved by intensive experimental
118 work in the Tenderfoot Creek catchments in Montana, US. In their work Jencso et al. (2009) were able to
119 show that connectivity of individual hillslopes in their headwater catchments is highly related to their
120 respective upslope accumulated areas. Using this close relationship, Smith et al. (2013) successfully
121 developed a simple top-down model with very limited need for calibration, emphasizing the value of

122 “enforcing field-based limits on model parameters” (Smith et al., 2016). Based on hydrological landscape
123 analysis, FLEX-Topo model (Savenije, 2010) can dramatically reduce the need for calibration (Gharari et
124 al., 2014), and hold considerable potential for spatial model transferability without the need for
125 parameter re-calibration (Gao et al., 2014a; H. Gao et al., 2016). In a recent development, several
126 studies suggest that S_{uMax} can be robustly and directly inferred from long term water balance data, by
127 the Mass Curve Technique (MCT) (Gao et al., 2014; de Boer-Euser et al., 2016; Nijzink et al., 2016). The
128 MCT is an engineering method for reservoir design, in which the reservoir size is estimated as a function
129 of accumulated inflow and human water demand. The MCT treats the root zone as a reservoir, and
130 estimates catchment-scale S_{uMax} from measurable hydrometeorological data, without the need for
131 further calibration. This leaves shape parameter β as the only free calibration parameter for soil
132 moisture routines of that form. Topography is often the dominant driver of water movement caused by
133 prevailing hydraulic gradients. More crucially, topography usually provides an integrating indicator for
134 hydrological behavior, since topography is usually closely related with other landscape elements, such as
135 soil vegetation climate and even geology (Seibert et al., 2007; Savenije, 2010; Rempe and Dietrich, 2014;
136 Gao et al., 2014b; Maxwell and Condon, 2016; Gomes, 2016). The Height Above the Nearest Drainage
137 (HAND; Rennó et al., 2008; Nobre et al., 2011; Gharari et al., 2011), which can be computed from readily
138 available digital elevation models (DEM), could potentially provide first order estimates of groundwater
139 depth, as there is some experimental evidence that with increasing HAND, groundwater depths
140 similarly increase (e.g. Haria and Shand, 2004; Martin et al., 2004; Molenat et al., 2005, 2008; Shand et
141 al., 2005; Condon and Maxwell, 2015; Maxwell and Condon, 2016). HAND can be interpreted as a proxy
142 of the hydraulic head and is thus potentially more hydrologically informative than the topographic
143 elevation above sea level (Nobre et al., 2011). Compared with the TWI in TOPMODEL, HAND is an
144 explicit measure of a physical feature linking terrain to water related potential energy for local drainage
145 (Nobre et al., 2011). More interestingly, topographic structure emerges as a powerful force determining
146 rooting depth under a given climate or within a biome (Figure 1), revealed by a global synthesis of 2,200
147 root observations of >1000 species (Fan et al., 2017). This leads us to think from ecological perspective
148 to use the topographic information as an indicator for root zone spatial distribution without calibrating
149 the β , and coupling it with the MCT method to estimate the S_{uMax} , eventually create a calibration-free
150 runoff generation module.

151 In this study we are therefore going to test the hypotheses that: (1) HAND can be linked to the spatial
152 distribution of storage capacities and therefore can be used to develop a new runoff generation module
153 (HAND-based Storage Capacity curve, i.e. HSC); (2) the distribution of storage capacities determined by

154 HAND contains different information than the topographic wetness index; (3) the HSC together with water
155 balance-based estimates of S_{uMax} (MCT method) allow the formulation of calibration-free
156 parameterizations of soil moisture routines in top-down models directly based on observations. All these
157 hypotheses will be tested firstly in a small data-rich experimental catchment (the Bruntland Burn
158 catchment in Scotland), and then apply the model to a wide range of larger MOPEX catchments (Model
159 Parameter Estimation Experiment).

160 This paper is structured as follows. In the Methods section, we describe two of our proposed modules, i.e.
161 HSC and HSC-MCT, and two benchmark models (HBV, TOPMODEL). This section also includes the
162 description of other modules (i.e. interception, evaporation and routing) in rainfall-runoff modelling, and
163 the methods for model evaluation, calibration and validation. The Dataset section reviews the empirically-
164 based knowledge of the Bruntland Burn catchment in Scotland and the hydrometeorological and
165 topographic datasets of MOPEX catchments in the US for model comparison. The Results section presents
166 the model comparison results. The Discussion section interprets the relation between rainfall-runoff
167 processes and topography, catchment heterogeneity and simple model, and the implications and
168 limitations of our proposed modules. The conclusions are briefly reviewed in the Summary and
169 Conclusions section.

170 2 Methods

171 Based on our perceptual model that saturation excess flow (SEF) is the dominant runoff generation
172 mechanism in most cases, we developed the HAND-based Storage Capacity curve (HSC) module.
173 Subsequently, estimating the parameter of root zone storage capacity (S_{uMax}) by the MCT method without
174 calibration, the HSC-MCT was developed. In order to assess the performance of our proposed modules,
175 two widely-used runoff generation modules, i.e. HBV power function and TOPMODEL module, were set
176 as benchmarks. Other modules, i.e. interception, evaporation and routing, are kept with identical
177 structure and parameterization for the four rainfall-runoff models (HBV, TOPMODEL, HSC, HSC-MCT,
178 whose names are from their runoff generation modules), to independently diagnose the difference among
179 runoff generation modules ([Clark et al., 2008; 2010](#)).

180 2.1 Two benchmark modules

181 **HBV power function**

182 The HBV runoff generation module applies an empirical power function to estimate the nonlinear
 183 relationship between the runoff coefficient and soil moisture ([Bergström and Forsman, 1973; Bergström](#)
 184 [and Lindström, 2015](#)). The function is written as:

$$185 \quad A_s = \left(\frac{S_u}{S_{uMax}} \right)^\beta \quad (1)$$

186 Where A_s (-) represents the contributing area, which equals to the runoff coefficient of a certain rainfall
 187 event; S_u (mm) represents the averaged root zone soil moisture; S_{uMax} (mm) is the averaged root zone
 188 storage capacity of the studied catchment; β (-) is the parameter determining the shape of the power
 189 function. The prior range of β can be from 0.1 to 5. The S_u - A_s has a linear relation while β equals to 1. And
 190 the shape becomes convex while the β is less than 1, and the shape turns to concave while the β is larger
 191 than 1. In most situations, S_{uMax} and β are two free parameters, cannot be directly measured at the
 192 catchment scale, and need to be calibrated based on observed rainfall-runoff data.

193 **TOPMODEL module**

194 The TOPMODEL assumes topographic information captures the runoff generation heterogeneity at
 195 catchment scale, and the TWI is used as an index to identify rainfall-runoff similarity ([Beven and Kirkby,](#)
 196 [1979; Sivapalan et al., 1997](#)). Areas with similar TWI values are regarded as possessing equal runoff
 197 generation potential. More specifically, the areas with larger TWI values tend to be saturated first and
 198 contribute to SEF; but the areas with lower TWI values need more water to reach saturation and generate
 199 runoff. The equations are written as follow:

$$200 \quad D_i = \bar{D} + S_{uMax} (\bar{I}_{TW} - I_{TW_i}) \quad (2)$$

$$201 \quad \bar{D} = S_{uMax} - S_u \quad (3)$$

$$202 \quad A_s = \sum A_{s_i}; \quad \text{while } D_i < 0 \quad (4)$$

203 Where D_i (mm) is the local storage deficit below saturation at specific location (i); \bar{D} (mm) is the averaged
 204 water deficit of the entire catchment (Equation 2), which equals to $(S_{uMax} - S_u)$, as shown in Equation 3. I_{TW_i}
 205 is the local I_{TW} value. \bar{I}_{TW} is the averaged TWI of the entire catchment. Equation 2 means in a certain soil
 206 moisture deficit condition for the entire catchment (\bar{D}), the soil moisture deficit of a specific location (D_i),
 207 is determined by the catchment topography (I_{TW} and I_{TW_i}), and the root zone storage capacity (S_{uMax}).

208 Therefore, the areas with D_i less than zero are the saturated areas (A_{s_i}), equal to the contributing areas.
209 The integration of the A_{s_i} areas (A_s), as presented in Equation 4, is the runoff contributing area, which
210 equals to the runoff coefficient of that rainfall event.

211 Besides continuous rainfall-runoff calculation, Equations 2-4 also allow us to obtain the contributing area
212 (A_s) from the estimated relative soil moisture ($S_u/S_{u\text{Max}}$), and then map it back to the original TWI map,
213 which makes it possible to test the simulated contributing area by field measurement. It is worth
214 mentioning that the TOPMODEL in this study is a simplified version, and not identical to the original one,
215 which combines the saturated and unsaturated soil components.

216 2.2 HSC module

217 In the HSC module, we assume 1) primarily saturation excess flow as the dominant runoff generation
218 mechanism; 2) the local root zone storage capacity has a positive and linear relationship with HAND, from
219 which we can derive the spatial distribution of the root zone storage capacity; 3) rainfall firstly feeds local
220 soil moisture deficit, and no runoff can be generated before local soil moisture being saturated.

221 Figure 2 shows the perceptual HSC module, in which we simplified the complicated 3-D topography of a
222 real catchment into a 2-D simplified hillslope. And then derive the distribution of root zone storage
223 capacity, based on topographic analysis and the second assumption as mentioned in the preceding
224 paragraph. Figure 3 shows the approach to derive the S_u - A_s relation, which are detailed as follows.

225 I. **Generate HAND map.** The HAND map, which represents the relative vertical distance to the
226 nearest river channel, can be generated from DEM ([Gharari et al., 2011](#)). The stream initiation
227 threshold area is a crucial parameter, determining the perennial river channel network
228 ([Montgomery and Dietrich, 1989](#); [Hooshyar et al., 2016](#)), and significantly impacting the HAND
229 values. In this study, the start area was chosen as 40ha for the BB catchment to maintain a close
230 correspondence with observed stream network. And for the MOPEX catchments, the stream
231 initiation area threshold is set as 500 grid cells (4.05 km^2), which fills in the range of stream
232 initiation thresholds reported by others (e.g. [Colombo et al., 2007](#); [Moussa, 2008, 2009](#)). HAND
233 maps were then calculated from the elevation of each raster cell above nearest grid cell flagged
234 as stream cell following the flow direction ([Gharari et al., 2011](#)).

235 II. **Generate normalized HAND distribution curve.** Firstly, sort the HAND values of grid cells in
236 ascending order. Secondly, the sorted HAND values were evenly divided into n bands (e.g. 20
237 bands in this study), to make sure each HAND band has similar area. The averaged HAND value of

238 each band is regarded as the HAND value of that band. Thirdly, normalize the HAND bands, and
239 then plot the normalized HAND distribution curve (Figure 2b).

240 III. **Distribute $S_{u\text{Max}}$ to each HAND band ($S_{u\text{Max}_i}$)**. As assumed, the normalized storage capacity of each
241 HAND band ($S_{u\text{Max}_i}$) increases with HAND value (Figure 2c). Based on this assumption, the
242 unsaturated root zone storage capacity ($S_{u\text{Max}}$) can be distributed to each HAND band as $S_{u\text{Max}_i}$
243 (Figure 3a). It is worth noting that $S_{u\text{Max}}$ needs to be calibrated in the HSC module, but free of
244 calibration in the HSC-MCT module.

245 IV. **Derive the S_u - A_s curve**. With the number of s saturated HAND bands (Figure 3a-c), the soil
246 moisture (S_u) can be obtained by Equation 5; and saturated area proportion (A_s) can be obtained
247 by Equation 6.

$$248 \quad S_u = \frac{1}{n} [\sum_{i=1}^s S_{u\text{Max}_i} + S_{u\text{Max}_s} (n - s)] \quad (5)$$

$$249 \quad A_s = \frac{s}{n} \quad (6)$$

250 Where $S_{u\text{Max}_s}$ is the maximum $S_{u\text{Max}_i}$ of all the saturated HAND bands. Subsequently, the A_s - S_u
251 curve can be derived, and shown in Figure 3d.

252 The SEF mechanism assumes that runoff is only generated from saturation areas, therefore the proportion
253 of saturation area is equal to the runoff coefficient of that rainfall-runoff event. Based on the S_u - A_s curve
254 in Figure 3d, generated runoff can be calculated from root zone moisture (S_u). The HSC module also allows
255 us to map out the fluctuation of saturated areas by the simulated catchment average soil moisture. For
256 each time step, the module can generate the simulated root zone moisture for the entire basin (S_u). Based
257 on the S_u - A_s relationship (Figure 3d), we can map S_u back to the saturated area proportion (A_s) and then
258 visualize it in the original HAND map. Based on this conceptual model, we developed the computer
259 program and created a procedural module. The technical roadmap can be found in Figure 4.

260 2.3 HSC-MCT module

261 The $S_{u\text{Max}}$ is an essential parameter in various hydrological models (e.g. HBV, Xinanjiang, GR4J), which
262 determines the long-term partitioning of rainfall into infiltration and runoff. [Gao et al., 2014a](#) found that
263 $S_{u\text{Max}}$ represents the adaption of ecosystems to local climate. Ecosystems may design their $S_{u\text{Max}}$ based on
264 the precipitation pattern and their water demand. The storage is neither too small to be mortal in dry
265 seasons, nor too large to consume excessive energy and nutrients. Based on this assumption, we can
266 estimate the $S_{u\text{Max}}$ without calibration, by the MCT method, from climatological and vegetation
267 information. More specifically, the average annual plant water demand in the dry season (S_R) is

268 determined by the water balance and the vegetation phenology, i.e. precipitation, runoff and seasonal
269 NDVI. Subsequently, based on the annual S_R , the Gumbel distribution (Gumbel, 1935), frequently used for
270 estimating hydrological extremes, was used to standardize the frequency of drought occurrence. S_{R20y} , i.e.
271 the root zone storage capacity required to overcome a drought once in 20 years, is used as the proxy for
272 S_{uMax} due to the assumption of a “cost” minimization strategy of plants as we mentioned above (Milly,
273 1994), and the fact that S_{R20y} has the best fit with S_{uMax} . The S_{R20y} of the MOPEX catchments can be found
274 in the map of (Gao et al., 2014a).

275 Eventually, with the MCT approach to estimate S_{uMax} and the HSC curve to represent the root zone storage
276 capacity spatial distribution, the HSC-MCT runoff generation module is created, without free parameters.
277 It is worth noting that both the HSC-MCT and HSC modules are based on the HAND derived S_u - A_s relation,
278 and their distinction lays in the methods to obtain S_{uMax} . So far, the HBV power function module has 2 free
279 parameters (S_{uMax} , β). While the TOPMODEL and the HSC both have one free parameter (S_{uMax}). Ultimately
280 the HSC-MCT has no free parameter.

281 2.4 Interception, evaporation and routing modules

282 Except for the runoff generation module in the root zone reservoir (S_{UR}), we need to consider other
283 processes, including interception (S_{IR}) before the S_{UR} module, evaporation from the S_{UR} and the response
284 routine (S_{FR} and S_{SR}) after runoff generation from S_{UR} (Figure 5). Precipitation is firstly intercepted by
285 vegetation canopies. In this study, the interception was estimated by a threshold parameter (S_{iMax}), set to
286 2 mm (Gao et al., 2014a), below which all precipitation will be intercepted and evaporated (Equation 9)
287 (de Groen and Savenije, 2006). For the S_{UR} reservoir, we can either use the HBV beta-function (Equation
288 12), the runoff generation module of TOPMODEL (Equation 2-4) or the HSC module (Section 2.3) to
289 partition precipitation into generated runoff (R_u) and infiltration. The actual evaporation (E_a) from the soil
290 equals to the potential evaporation (E_p), if S_u/S_{uMax} is above a threshold (C_e), where S_u is the soil moisture
291 and S_{uMax} is the catchment averaged storage capacity. And E_a linearly reduces with S_u/S_{uMax} , while S_u/S_{uMax}
292 is below C_e (Equation 13). The E_p can be calculated by the Hargreaves equation (Hargreaves and Samani,
293 1985), with maximum and minimum daily temperature as input. The generated runoff (R_u) is further split
294 into two fluxes, including the flux to the fast response reservoir (R_f) and the flux to the slow response
295 reservoir (R_s), by a splitter (D) (Equation 14, 15). The delayed time from rainfall peak to the flood peak is
296 estimated by a convolution delay function, with a delay time of T_{lagF} . Subsequently, the fluxes into two
297 different response reservoirs (S_{FR} and S_{SR}) were released by two linear equations between discharge and
298 storage (Equation 19, 21), representing the fast response flow and the slow response flow mainly from

299 groundwater reservoir. The two discharges (Q_f and Q_s) generated the simulated streamflow (Q_m). The
300 model parameters are shown in Table 1, while the equations are given in Table 2. More detailed
301 description of the model structure can be referred to [Gao et al., 2014b and 2016](#). It is worth underlining
302 that the only difference among the benchmark HBV type, TOPMODEL type, HSC, and HSC-MCT models is
303 their runoff generation modules. Eventually, there are 7 free parameters in HBV model, 6 in TOPMODEL
304 and HSC model, and 5 in the HSC-MCT model.

305 2.5 Model evaluation, calibration, validation and models comparison

306 Two objective functions were used to evaluate model performance, since multi-objective evaluation is a
307 more robust approach to quantifying model performance with different criteria than a single one. The
308 Kling-Gupta efficiency ([Gupta et al., 2009](#)) (I_{KGE}) was used as the criteria to evaluate model performance
309 and as an objective function for calibration. The equation is written as:

$$310 \quad I_{KGE} = 1 - \sqrt{(r-1)^2 + (\alpha-1)^2 + (\varepsilon-1)^2} \quad (7)$$

311 Where r is the linear correlation coefficient between simulation and observation; α ($\alpha = \sigma_m / \sigma_o$) is a
312 measure of relative variability in the simulated and observed values, where σ_m is the standard deviation
313 of simulated streamflow, and σ_o is the standard deviation of observed streamflow; ε is the ratio between
314 the average value of simulated and observed data. And the I_{KGL} (I_{KGE} of the logarithmic flows) ([Fenia et](#)
315 [al., 2007; Gao et al., 2014b](#)) is used to evaluate the model performance on baseflow simulation.

316 A multi-objective parameter optimization algorithm (MOSCEM-UA) ([Vrugt et al., 2003](#)) was applied for
317 the calibration. The parameter sets on the Pareto-frontier of the multi-objective optimization were
318 assumed to be the behavioral parameter sets and can equally represent model performance. The
319 averaged hydrograph obtained by all the behavioral parameter sets were regarded as the simulated result
320 of that catchment for further studies. The number of complexes in MOSCEM-UA were set as the number
321 of parameters (7 for HBV, 6 for TOPMODEL and the HSC model, and 5 for HSC-MCT model), and the
322 number of initial samples was set to 210 and a total number of 50000 model iterations for all the
323 catchment runs. For each catchment, the first half period of data was used for calibration, and the other
324 half was used to do validation.

325 In module comparison, we defined three categories: if the difference of I_{KGE} of model A and model B in
326 validation is less than 0.1, model A and B are regarded as “equally well”. If the I_{KGE} of model A is larger

327 than model B in validation by 0.1 or more, model A is regarded as outperforming model B. If the I_{KGE} of
328 model A is less than model B in validation by -0.1 or less, model B is regarded as outperforming model A.

329 3 Dataset

330 3.1 The Bruntland Burn catchment

331 The 3.2 km² Bruntland Burn catchment (Figure 6), located in north-eastern Scotland, was used as a
332 benchmark study to test the model's performance based on a rich data base of hydrological
333 measurements. The Bruntland Burn is a typical upland catchment in North West Europe (e.g. [Birkel et al., 2010](#)),
334 namely a combination of steep and rolling hillslopes and over-widened valley bottoms due to the
335 glacial legacy of this region. The valley bottom areas are covered by deep (in parts > 30m) glacial drift
336 deposits (e.g. till) containing a large amount of stored water superimposed on a relatively impermeable
337 granitic solid geology ([Soulsby et al., 2016](#)). Peat soils developed (> 1m deep) in these valley bottom areas,
338 which remain saturated throughout most of the year with a dominant near-surface runoff generation
339 mechanism delivering runoff quickly via micro-topographical flow pathways connected to the stream
340 network ([Soulsby et al., 2015](#)). Brown rankers, peaty rankers and peat soils are responsible for a flashy
341 hydrological regime driven by saturation excess overland flow, while humus iron podzols on the hillslopes
342 do not favor near-surface saturation but rather facilitate groundwater recharge through vertical water
343 movement ([Tetzlaff et al., 2014](#)). Land-use is dominated by heather moorland, with smaller areas of rough
344 grazing and forestry on the lower hillslopes. Its annual precipitation is 1059 mm, with the summer months
345 (May-August) generally being the driest ([Ali et al., 2013](#)). Snow makes up less than 10% of annual
346 precipitation and melts rapidly below 500m. The evapotranspiration is around 400 mm per year and
347 annual discharge around 659 mm. The daily precipitation, potential evaporation, and discharge data range
348 from January 1 in 2008 to September 30 in 2014. The calibration period is from January 1, 2008 to
349 December 31, 2010, and the data from January 1, 2011 to September 30, 2014 is used as validation.

350 The LiDAR-derived DEM map with 2m resolution shows elevation ranging from 250m to 539m (Figure 6).
351 There are 7 saturation area maps (Figure 7) (May 2, July 2, August 4, September 3, October 1, November
352 26, in 2008, and January 21, in 2009), measured directly by the "squishy boot" method and field mapping
353 by global positioning system (GPS), to delineate the boundary of saturation areas connected to the stream
354 network ([Birkel et al., 2010](#); [Ali et al., 2013](#)). These saturation area maps revealed a dynamic behavior of
355 expanding and contracting areas connected to the stream network that were used as a benchmark test
356 for the HSC module.

357 **3.2 MOPEX catchments**

358 The MOPEX dataset was collected for a hydrological model parameter estimation experiment (Duan et al.,
359 2006; Schaake et al., 2006), containing 438 catchments in the CONUS (Contiguous United States). The
360 longest time series range from 1948 to 2003. 323 catchments were used in this study (see the name list
361 in SI), with areas between 67 and 10,329 km², and excluding the catchments with data records <30 years,
362 impacted by snowmelt or with extreme arid climate (aridity index $E_p/P > 2$). In order to analyze the impacts
363 of catchment characteristics on model performance, excluding hydrometeorology data, we also collected
364 the datasets of topography, depth to rock, soil texture, land use, and stream density (Table 3). These
365 characteristics help us to understand in which catchments the HSC performs better or worse than the
366 benchmark models.

367 **Hydrometeorology**

368 The dataset contains the daily precipitation, daily maximum and minimum air temperature, and daily
369 streamflow. The daily streamflow was used to calibrate the free parameters and validate the models.

370 **Topography**

371 The Digital Elevation Model (DEM) of the CONUS in 90m resolution was download from the Earth Explorer
372 of United States Geological Survey (USGS, <http://earthexplorer.usgs.gov/>). The HAND and TWI map can
373 be generated from DEM. The averaged elevation and HAND are used to as two catchment characteristics.

374 **Soil texture**

375 In this study, soil texture is synthetically represented by the K factor, since the K factor is a lumped soil
376 erodibility factor which represents the soil profile reaction to soil detachment (Renard et al., 2011).
377 Generally, the soils (high in clay and sand) have low K values, and soils with high silt content have larger K
378 values. The averaged K factor for each catchment was calculated from soil survey information available
379 from USGS (Wolock, 1997).

380 **Land use**

381 Land use data was obtained from National Land Cover Database (NLCD, <http://www.mrlc.gov/nlcd.php>).
382 Forest plays an essential role in hydrological processes (Gao et al., 2018a), especially for the runoff
383 generation (Brooks et al., 2010). Forest area proportion was utilized as an integrated indictor to represent
384 the impact of vegetation cover on hydrological processes.

385 **Stream density**

386 Stream density (km/km^2) is the total length of all the streams and rivers in a drainage basin divided by the
387 total area of the drainage basin. Stream density data was obtained from Horizon Systems Corporation
388 (<http://www.horizon-systems.com/nhdplus/>).

389 **Geology**

390 Bedrock is a relative impermeable layer, as the lower boundary of subsurface stormflow in the catchments
391 where soil depth is shallow (Tromp-van Meerveld & McDonnell). The depth to bedrock, as an integrated
392 geologic indicator, was accessed from STATSGO (State Soil Geographic,
393 http://www.soilinfo.psu.edu/index.cgi?soil_data&conus&data_cov&dtb) (Schwarz & Alexander, 1995).
394 The averaged depth to bedrock for each catchment was calculated for further analysis.

395

4 Results of the Bruntland Burn

396

4.1 Topography analysis

397 The generated HAND map, derived also from the DEM, is shown in Figure 6, with HAND values ranging
398 from 0m to 234m. Based on the HAND map, we can derive the S_u - A_s curve (Figure 8) by analyzing the
399 HAND map with the method in Section 2.3. The TWI map of the BB (Figure 6) was generated from its DEM.
400 Overall, the TWI map, ranging from -0.4 to 23.4, mainly differentiates the valley bottom areas with the
401 highest TWI values from the steeper slopes. This is probably caused by the fine resolution of the DEM map
402 in 2 m, as previous research found that the sensitivity of TWI to DEM resolution ([Sørensen and Seibert, 2007](#)). From the TWI map, the frequency distribution function and the accumulative frequency
403 distribution function can be derived (Figure 8), with one unit of TWI as interval.
404

405

4.2 Model performance

406 It is found that all the three models (HBV, TOPMODEL, and HSC) can perform well in reproducing the
407 observed hydrograph (Figure 9). The I_{KGE} of the three models are all around 0.66 in calibration, which is
408 largely in line with other studies from the BB ([Birkel et al, 2010; 2014](#)). And the I_{KGL} are 0.76, 0.72 and 0.74
409 for HSC, HBV and TOPMODEL respectively in calibration. While in validation, I_{KGE} of the three models are
410 also around 0.66, while I_{KGL} are 0.75, 0.70 and 0.65 for the three models. Since the measured rainfall-
411 runoff time series only lasts from 2008 to 2014, which is too short to estimate the S_{R20y} (proxy for S_{uMax})
412 by MCT approach (which needs long-term hydro-meteorological observation data,) the HSC-MCT model
413 was not applied to this catchment.

414 Figure 8 shows the calibrated power curve by HBV (averaged beta=0.98) with the S_u - A_s curve obtained
415 from the HSC module. We found the two curves are largely comparable, especially while the relative soil
416 moisture is low. This result demonstrates that for the BB catchment with glacial drift deposits and
417 combined terrain of steep and rolling hillslopes and over-widened valley bottoms, the HBV power curve
418 can essentially be derived from the S_u - A_s curve of HSC module merely by topographic information without
419 calibration.

420 The normalized relative soil moisture of the three model simulations are presented in Figure 9. Their
421 temporal fluctuation patterns are comparable. Nevertheless, the simulated soil moisture by TOPMODEL
422 has larger variation, compared with HBV and HSC (Figure 9).

423 4.3 Contributing area simulation

424 The observed saturation area and the simulated contributing area from both TOPMODEL and the HSC are
425 shown in Figure 7, 9, 10. We found although both modules overestimated the saturated areas, they can
426 capture the temporal variation. For example, the smallest saturated area both observed and simulated
427 occurred on July-02-2008, and the largest saturated area both occurred on January-21-2009. Comparing
428 the estimated contributing area of TOPMODEL with the HSC module, we found the results of the HSC
429 correlates better ($R^2=0.60$, $I_{KGE}=-3.0$) with the observed saturated areas than TOPMODEL ($R^2=0.50$, $I_{KGE}=-$
430 3.4) (Figure 10). For spatial patterns, the HSC contributing area is located close to the river network and
431 reflects the spatial pattern of observed saturated area. While TOPMODEL results are more scattered,
432 probably due to the sensitivity of TWI to DEM resolution (Figure 7). The HSC is more discriminating in
433 terms of less frequently giving an unrealistic 100% saturation and retaining unsaturated upper hillslopes.

434 5 Results from the MOPEX catchments

435 5.1 Topography analysis of the Contiguous US and 323 MOPEX catchments

436 To delineate the TWI map for the CONUS, the depressions of the DEM were firstly filled with a threshold
437 height of 100m (recommended by Esri). The TWI map of the CONUS is produced (Figure S1). Based on the
438 TWI map of the CONUS, we clipped the TWI maps for the 323 MOPEX catchments with their catchment
439 boundaries. And then the TWI frequency distribution and the accumulated frequency distribution of the
440 323 MOPEX catchments (Figure S2), with one unit of TWI as interval, were derived based on the 323 TWI
441 maps.

442 In Figure 11, it is shown that the regions with large HAND values are located in Rocky Mountains and
443 Appalachian Mountains, while the Great Plains has smaller HAND values. The Great Basin, especially in
444 the Salt Lake Desert, has small HAND values, illustrating its low elevation above the nearest drainage,
445 despite a high elevation above sea level. From the CONUS HAND map, we clipped the HAND maps for the
446 323 MOPEX catchments with their catchment boundaries. We then plot their HAND-area curves, following
447 the procedures of I and II in Section 2.2. Figure 12a shows the normalized HAND profiles of the 323
448 catchments.

449 Based on the HAND profiles and the Step III in Section 2.2, we derived the normalized storage capacity
450 distribution for all catchments (Figure 12b). Subsequently, the root zone moisture and saturated area
451 relationship (A_s - S_u) can be plotted by the method in Step IV of Section 2.2. Lastly, reversing the curve of
452 A_s - S_u to S_u - A_s relation (Figure 12c), the latter one can be implemented to simulate runoff generation by
453 soil moisture. Figure 12c interestingly shows that in some catchments, there is almost no threshold
454 behavior between rainfall and runoff generation, where the catchments are covered by large areas with
455 low HAND values and limited storage capacity. Therefore, when rainfall occurs, wetlands response quickly
456 and generate runoff without a precipitation–discharge threshold relationship characteristic of areas with
457 higher moisture deficits. This is similar to the idea of FLEX-Topo where the storage capacity is distinguished
458 between wetlands and hillslopes, and on wetlands, with low storage capacity, where runoff response to
459 rainfall is almost instantaneous.

460 5.2 Model performance

461 Overall, the performance of the two benchmark models, i.e. HBV and TOPMODEL, for the MOPEX data
462 (Figure 13) is comparable with the previous model comparison experiments, conducted with four rainfall–
463 runoff models and four land surface parameterization schemes (Duan et al., 2006; Kollat et al., 2012; Ye
464 et al., 2014). The median value of I_{KGE} of the HBV type model is 0.61 for calibration in the 323 catchments
465 (Figure 13), and averaged I_{KGE} in calibration is 0.62. In validation, the median and averaged values of I_{KGE}
466 are kept the same as calibration. The comparable performance of models in calibration and validation
467 demonstrates the robustness of benchmark models and the parameter optimization algorithm (i.e.
468 MOSCEM-UA). The TOPMODEL improves the median value of I_{KGE} from 0.61 (HBV) to 0.67 in calibration,
469 and from 0.61 (HBV) to 0.67 in validation. But the averaged values of I_{KGE} for TOPMODEL are slightly
470 decreased from 0.62 (HBV) to 0.61 in both calibration and validation. The HSC module, by involving the
471 HAND topographic information without calibrating the β parameter, improves the median value of I_{KGE} to
472 0.68 for calibration and 0.67 for validation. The averaged values of I_{KGE} in both calibration and validation

473 are also increased to 0.65, comparing with HBV (0.62) and TOPMODEL (0.61). Furthermore, Figure 13
474 demonstrates that, comparing with the benchmark HBV and TOPMODEL, not only the median and
475 averaged values were improved by the HSC module, but also the 25th and 75th percentiles and the lower
476 whisker end, all have been improved. The performance gains on baseflow (I_{KGL}) have been investigated
477 and shown in the supplementary figure S3. These results indicate the HSC module improved model
478 performance to reproduce hydrograph for both peak flow (I_{KGE}) and baseflow (I_{KGL}).

479 Additionally, for HSC-MCT model, the median I_{KGE} value is improved from 0.61 (HBV) to 0.65 in calibration,
480 and from 0.61 (HBV) to 0.64 in validation, but not as well performed as TOPMODEL (0.67 for calibration
481 and validation). For the averaged I_{KGE} values, they were slightly reduced from 0.62 (HBV) and 0.61
482 (TOPMODEL) to 0.59 for calibration and validation. Although the HSC-MCT did not perform as well as the
483 HSC module, considering there is no free parameters to calibrate, the median I_{KGE} value of 0.64 (HBV is
484 0.61) and averaged I_{KGE} of 0.59 (TOPMODEL is 0.61) are quite acceptable. In addition, the 25th and 75th
485 percentiles and the lower whisker end of the HSC-MCT model are all improved compared to the HBV
486 model. Moreover, the largely comparable results between the HSC and the HSC-MCT modules
487 demonstrate the feasibility of the MCT method to obtain the S_{uMax} parameter and the potential for HSC-
488 MCT to be implemented in prediction of ungauged basins.

489 Figure 14 shows the spatial comparisons of the HSC and HSC-MCT models with the two benchmark models.
490 We found that the HSC performs “equally well” as HBV (the difference of I_{KGE} in validation ranges -0.1 ~
491 0.1) in 88% catchments, and in the remaining 12% of the catchments the HSC outperforms HBV (the
492 improvement of I_{KGE} in validation is larger than 0.1). In not a single catchment did the calibrated HBV
493 outperform the HSC. Comparing the HSC model with TOPMODEL, we found in 91% of the catchments that
494 the two models have approximately equal performance. In 8% of the catchments, the HSC model
495 outperformed TOPMODEL. Only in 1% of the catchments (two in the Appalachian Mountains and one in
496 the Rocky Mountains in California), TOPMODEL performed better.

497 In order to further explore the impact of catchment characteristics on model performance, we used
498 topography (averaged HAND, averaged slope, and averaged elevation), soil (K-factor), land cover (forest
499 area proportion), climate (aridity index), stream density, and geology (depth to rock) information to test
500 the impact of catchment features on model performance. Table 4 clearly shows that compared with HBV,
501 the 39 catchments with better performance have lower HAND values (37m), more gentle slopes (4.0
502 degree), and smaller forest area (22%); while the elevation, K-factor, aridity index, stream density and
503 depth to rock are almost similar. Also, in the catchments where HSC outperformed TOPMODEL, the

504 catchments have smaller HAND (27m), more gentle slopes (3.6 degree), moderate elevation (469 m), less
505 forest proportion (14%), and more arid climate (aridity index is 1.3). TOPMODEL performs better in only
506 three catchments with larger HAND (193m), steeper slopes (13.5 degree), higher elevation (740 m), more
507 humid climate (aridity index is 0.8), and larger depth to rock (333 cm). In summary, the HSC showed better
508 performance in catchments with gentle topography and more arid climate.

509 Without calibration of $S_{u\text{Max}}$, as expected, the performance of HSC-MCT module slightly deteriorates
510 (Figure 13). In comparison with HBV, the outperformed percentage reduced from 12% (HSC) to 4% (HSC-
511 MCT), the approximately equal-well simulated catchments dropped from 88% to 79%, and the inferior
512 performance increased from 0% to 17%. Also, in comparison with TOPMODEL, the better performance
513 dropped from 8% (HSC) to 7% (HSC-MCT), the approximately equal catchments reduced from 91% to 72%,
514 and the inferior performance increased from 1% to 21%. The inferiority of the HSC-MCT model is probably
515 caused by the uncertainty of the MCT method for different ecosystems which have different survival
516 strategies and use different return periods to bridge critical drought periods. By using ecosystem
517 dependent return periods, this problem could be reduced ([Wang-Erlandsson et al., 2016](#)).

518 To further explore the reason for the better performance of the HSC approach, we selected the 08171000
519 catchment in Texas (Figure 14), in which both the HSC module and the HSC-MCT module outperformed
520 the two benchmark modules to reproduce the observed hydrograph (Figure S4). The HBV model
521 dramatically underestimated the peak flows, with I_{KGE} as 0.54, while TOPMODEL significantly
522 overestimated the peak flows, with I_{KGE} as 0.30. The HSC-MCT model improved the I_{KGE} to 0.71, and the
523 HSC model further enhanced I_{KGE} to 0.74.

524 Since the modules of interception, evaporation and routing are identical for the four models, the runoff
525 generation modules are the key to understand the difference in model performance. Figure S5 shows the
526 HBV β curve and the S_u - A_s curve of the HSC model, as well the TWI frequency distribution. We found that
527 with a given $S_u/S_{u\text{Max}}$, the HBV β function generates less contributing area than the HSC model, which
528 explains the underestimation of the HBV model. In contrast, TOPMODEL has a sharp and steep
529 accumulated TWI frequency curve. In particular, the region with TWI=8 accounts for 40% of the catchment
530 area, and over 95% of the catchment areas are within the TWI ranging from 6 to 12. This indicates that
531 even with low soil moisture content ($S_u/S_{u\text{Max}}$), the contributing area by TOPMODEL is relatively large,
532 leading to the sharply increased peak flows for all rainfall events.

533 **6 Discussion**

534 **6.1 Rainfall-runoff processes and topography**

535 We applied a novel approach to derive the relationship between soil moisture storage and the saturated
536 area from HAND. The areas with relatively low HAND values are saturated earlier than areas with higher
537 HAND values, due to the larger storage capacity in higher HAND locations. The outperformance of the HSC
538 over the benchmark HBV and TOPMODEL in gentle sloping catchments indicates that the HSC module
539 likely has a higher realism than the calibrated HBV beta-function and the TWI of TOPMODEL in these
540 regions. Very interestingly, [Fan et al., \(2017\)](#) presented an ecological observation in global scale, and
541 revealed the systematic variation of rooting depth along HAND (Fig.1, in [Fan et al., 2017](#)). Since rooting
542 depth can be translated to root zone storage capacity through combination with soil plant-available water
543 ([Wang-Erlandsson et al., 2016](#)). This large sample dataset, from ecological perspective, provides a strong
544 support for the assumption of the HSC model on gentle slopes, i.e. the increase of root zone storage
545 capacity with HAND. More interestingly, on excessively drained uplands, rooting depth does not follow
546 the same pattern, with shallow depth and limited to rain infiltration (Fig.1, in [Fan et al., 2017](#)). This could
547 explain the inferior performance of HSC model to TOPMODEL in three MOPEX catchments with
548 excessively drained uplands (larger HAND, steeper slope, higher elevation, and deeper depth to rock),
549 where Hortonian overland flow is likely the dominant mechanism, and the HSC assumption likely does not
550 work well. This indicates that comparing with TWI, the HAND is closer to catchment realism distinguishing
551 hydrological similarity in gentle topography catchments. The HSC module assumes SEF as the dominant
552 mechanism. But since in a real catchment different runoff generating processes may act simultaneously
553 in different environments ([McDonnell, 2013](#); [Hrachowitz and Clark, 2017](#)). Such SEF dominated
554 catchments, or parts thereof, are typically characterized by a subdued relief and thus gently sloping. In
555 steeper catchments, where the groundwater table is deeper and thus more additional water can be stored
556 in the soil, another conceptual parametrisation would be appropriate.

557 The FLEX-Topo model ([Savenije, 2010](#)) also uses HAND as a topographic index to distinguish between
558 landscape-related runoff processes and has both similarity and differences with the HSC model. The
559 results of the HSC model illustrate that the riparian areas are more prone to be saturated, which is
560 consistent with the concept of the FLEX-Topo model. Another important similarity of the two models is
561 their parallel model structure. In both models it is assumed that the upslope area has larger storage
562 capacity, therefore the upper land generates runoff less and later than the lower land. In other words, in
563 most cases, the local storage is saturated due to the local rainfall, instead of flow from upslope. The most

564 obvious difference between the HSC and the FLEX-Topo is the approach towards discretization of a
565 catchment. The FLEX-Topo model classifies a catchment into various landscapes, e.g. wetlands, hillslopes
566 and plateau. This discretization method requires threshold values to classify landscapes, i.e. threshold
567 values of HAND and slope, which leads to fixed and time-independent proportions of landscapes. The HSC
568 model does not require landscape classification, which reduced the subjectivity in discretization and
569 restricted the model complexity, as well as simultaneously allowing the fluctuation of contributing areas
570 (termed as wetlands in FLEX-Topo).

571 6.2 Catchment heterogeneity and simple models

572 Catchments exhibit a wide array of heterogeneity and complexity with spatial and temporal variations of
573 landscape characteristics and climate inputs. For example, the Darcy-Richards equation approach is often
574 consistent with point-scale measurements of matrix flow, but not for preferential flow caused by roots,
575 soil fauna and even cracks and fissures (Beven and Germann, 1982; Zehe and Fluehler, 2001; Weiler and
576 McDonnell, 2007). As a result, field experimentalists continue to characterize and catalogue a variety of
577 runoff processes, and hydrological and land surface modelers are developing more and more complicated
578 models to involve the increasingly detailed processes (McDonnell et al., 2007). However, there is still no
579 compelling evidence to support the outperformance of sophisticated “physically-based” models in terms
580 of higher equifinality and uncertainty than the simple lumped or semi-distributed conceptual models in
581 rainfall-runoff simulation (Beven, 1989; Orth et al., 2015).

582 But evidence is mounting that a catchment is not a random assemblage of different heterogeneous parts
583 (Sivapalan, 2009; Troch et al., 2013; Zehe et al., 2013), and conceptualising heterogeneities does not
584 require complex laws (Chase, 1992; Passalacqua et al., 2015). Parsimonious models (e.g. Perrin et al.,
585 2003), with empirical curve shapes, likely result in good model performance. Parameter identifiability in
586 calibration is one of the reasons. However, the physical rationale of these parsimonious models is still
587 largely unknown lacking a physical explanation to interpret these empirical curves described by
588 mathematical functions (e.g. Equation 3 in Perrin et al., 2003).

589 The benefits of the new HSC module are two-fold. From a technical point of view, the HSC allows us to
590 make Prediction in Ungauged Basins without calibrating the beta parameter in many conceptual
591 hydrological models. Furthermore, the HSC module, from a scientific point of view, provides us with a new
592 perspective on the linkage between the spatial distribution patterns of root zone storage capacity (long-
593 term ecosystem evolution) with associated runoff generation (event scale rainfall-runoff generation).

594 Asking questions of “why” rather than “what” likely leads to more useful insights and a new way forward
595 (McDonnell et al., 2007). The HSC module provides us with a rationale from an ecological perspective to
596 understand the linkage and mechanism between large-sample hillslope ecological observations and the curve
597 of root zone storage capacity distribution (Figure 1, 2, 3). Catchment is a geomorphological and even an
598 ecological system whose parts are related to each other probably due to catchment self-organization and
599 evolution (Sivapalan and Blöschl, 2015; Savenije and Hrachowitz, 2017). This encourages the hope that
600 simplified concepts may be found adequate to describe and model the operation of the basin runoff
601 generation process. It is clear that topography, with fractal characteristic (Rodríguez-Iturbe and Rinaldo,
602 1997), is often the dominant driver of runoff, as well as being a good integrated indicator for vegetation
603 cover (Gao et al., 2014b), rooting depth (Fan et al., 2017), root zone evaporation and transpiration deficits
604 (Maxwell and Condon, 2016), soil properties (Seibert et al., 2007), and even geology (Rempe and Dietrich,
605 2014; Gomes, 2016). Therefore, we argue that increasingly detailed topographic information is an
606 excellent integrated indicator allowing modelers to continue systematically represent heterogeneities and
607 simultaneously reduce model complexity. The model structure and parameterization of both HSC and
608 TOPMODEL are simple, but not over simplified, as they capture likely the most dominant factor controlling
609 runoff generation, i.e. the spatial heterogeneity of storage capacity. Hence, this study also sheds light on
610 the possibility of moving beyond heterogeneity and process complexity (McDonnell et al., 2007), to
611 simplify them into a succinct and *a priori* curve by taking advantage of catchment self-organization
612 probably caused by co-evolution or the principle of maximum entropy production (Kleidon and Lorenz,
613 2004).

614 6.3 Implications and limitation

615 The calibration-free HSC-MCT runoff generation module enhances our ability to predict runoff in
616 ungauged basins. PUB is probably not a major issue in the developed world, with abundant of
617 comprehensive measurements in many places, but for the developing world it requires prediction with
618 sparse data and fragmentary knowledge. Topographic information with high spatial resolution is freely
619 available globally, allowing us to implement the HSC model in global scale studies. In addition, thanks to
620 the recent development, testing, and validation of remote sensing evaporation products in large spatial
621 scale (e.g. Anderson et al., 2011; Hu and Jia, 2015), the $S_{u\text{Max}}$ estimation has become possible without in
622 situ hydro-meteorological measurements (Wang-Erlansson et al., 2016). These widely-accessible
623 datasets make the global-scale implementation of HSC-MCT module promising.

624 Although the new modules perform well in the BB and the MOPEX catchments, we do not intend to
625 propose “a model fits all”. The assumption of HSC, to some extent, is supported by large-sample ecological
626 field observation ([Fan et al., 2017](#)), but it never means the A_s - S_u curve of HSC can perfectly fit the other
627 existing curves (e.g. HBV and TOPMODEL). Unify all model approaches into one framework is the objective
628 of several pioneer works (e.g. [Clark, et al., 2010](#); [Fenia et al., 2011](#)), but out of the scope of this study.
629 Moreover, while estimating the runoff coefficient by the A_s - S_u relation, rainfall in the early time may cause
630 the increase of $S_u/S_{u\text{Max}}$ and runoff coefficient ([Moore, 1985](#); [Wang, 2018](#)). Therefore, neglecting this
631 influence factor, HBV (Equation 1), TOPMODEL (Equation 2-4) and HSC (Equation 5-6) theoretically
632 underestimate the runoff coefficient, which needs to be further investigated.

633 Finally, we should not ignore the limitations of the new module, although it has better performance and
634 modelling consistency. 1) The threshold area for the initiating a stream was set as a constant value for the
635 entire CONUS, but the variation of this value in different climate, geology and landscape classes
636 ([Montgomery and Dietrich, 1989](#); [Helmlinger et al., 1993](#); [Colombo et al., 2007](#); [Moussa, 2008](#)) needs to
637 be future investigated. 2) The discrepancy between observed and simulated saturation area needs to be
638 further investigated, by utilizing more advanced field measurement and simultaneously refining the
639 model assumption. To our understanding, there are two interpretations. Firstly, the overestimation of the
640 HSC model is possibly because two runoff generation mechanisms – SOF and the SSF occur at the same
641 time. However, the saturated area observed by the “squishy boot” method ([Ali et al., 2013](#)), probably only
642 distinguished the areas where SOF occurred. Subsurface stormflow, also contributing to runoff, cannot be
643 observed by the “squishy boot” method. Thus, this mismatch between simulation and observation
644 probably leads to this saturated area overestimation. The second interpretation might be the different
645 definition of “saturation”. The observed saturated areas are places where 100% of soil pore volume is
646 filled by water. But the modelled saturation areas are located where soil moisture is above field capacity,
647 and not necessarily 100% filled with water, which probably also results in the overestimation of saturated
648 areas. Interestingly, in theory the observed saturated area should be within the simulated contributing
649 area, due to the fact that the saturated soil moisture is always larger than field capacity. From this point
650 of view, the observed saturated area is smaller and within the contributing area simulated by HSC, but
651 TOPMODEL missed this important feature. 4) Only the runoff generation module is calibration free, but
652 the interception and response routines still rely on calibration. Although we kept the interception and
653 response routine modules the same for the four models, the variation of other calibrated parameters (i.e.
654 $S_{i\text{Max}}$, D , K_f , K_s , $T_{\text{lag}F}$) may also influence model performance in both calibration and validation. 5) The
655 computational cost of the HSC is more expensive than HBV, and similar to TOPMODEL, due to the cost of

656 preprocessed topographic analysis. But once the S_u - A_s curve is completed, the computation cost is quite
657 comparable with HBV.

658 7 Summary and conclusions

659 In this study, we developed a simple and calibration-free hydrological module (HAND-based Storage
660 Capacity curve, HSC) based on a relatively new topographic index (HAND), which is not only an excellent
661 physically-based indictor for the hydraulic gradient, but also represents the spatial distribution of root
662 zone storage capacity supported by large-sample ecological observations. Based on HAND spatial
663 distribution pattern, the soil moisture (S_u) - saturated area (A_s) relation for each catchment was derived,
664 which was used to estimate the A_s of specific rainfall event based on continuous calculation of S_u .
665 Subsequently, based on the S_u - A_s relation, the HSC module was developed. Then, applying the mass curve
666 technique (MCT) approach, we estimated the root zone storage capacity ($S_{u\text{Max}}$) from observable hydro-
667 climatological and vegetation data, and coupled it with HSC to create the calibration-free HSC-MCT
668 module. The HBV and TOPMODEL were used as two benchmarks to test the performance of HSC and HSC-
669 MCT on both hydrograph simulation and ability to reproduce the contributing area, which was measured
670 for different hydrometeorological conditions in the Bruntland Burn catchment in Scotland. Subsequently,
671 323 MOPEX catchments in the US were used as a large-sample hydrological study to further validate the
672 effectiveness of our proposed runoff generation modules.

673 In the BB exploratory study, we found that the HSC, HBV and TOPMODEL performed comparably well to
674 reproduce the observed hydrograph. Comparing the estimated contributing area of TOPMODEL with the
675 HSC module, we found that HSC module performed better to reproduce saturated area variation, in terms
676 of the correlation coefficient and spatial patterns. This likely indicates that HAND maybe a better indicator
677 to distinguish hydrological similarity than TWI.

678 For the 323 MOPEX catchments, HSC improved the averaged validation value of I_{KGE} from 0.62 (HBV) and
679 0.61 (TOPMODEL) to 0.65. In 12% of the MOPEX catchments, the HSC module outperforms HBV, and in
680 not a single catchment did the calibrated HBV outperform the HSC. Comparing with TOPMODEL, the HSC
681 outperformed in 8% of the catchments, and in only 1% of catchments TOPMODEL has a better
682 performance. Interestingly, we found that the HSC module showed better performance in the catchments
683 with gentle topography, less forest cover, and larger aridity index. Not surprisingly, the I_{KGE} of HSC-MCT
684 model was slightly reduced to 0.59, due to the non-calibrated $S_{u\text{Max}}$, but still comparably well performed
685 as HBV (0.62) and TOPMODEL (0.61). This illustrates the robustness of both the HSC approach to derive

686 the spatial distribution of the root zone storage capacity (β) and the efficiency of the MCT method to
687 estimate the root zone storage capacity ($S_{u\text{Max}}$).

994

995

996 Table 1. The parameters of the models, and their prior ranges for calibration. (* $S_{u\text{Max}}$ is a parameter in HBV,
 997 TOPMODEL and the HSC model, but HSC-MCT model does not have $S_{u\text{Max}}$ as a free parameter; ** β is a parameter in
 998 HBV model, but not in TOPMODEL, HSC and HSC-MCT models)

Parameter	Explanation	Prior range for calibration
$S_{i\text{Max}}$ (mm)	Maximum interception capacity	2
$S_{u\text{Max}}$ (mm)*	The root zone storage capacity	(10, 1000)
β (-)**	The shape of the storage capacity curve	(0.01, 5)
C_e (-)	Soil moisture threshold for reduction of evaporation	(0.1, 1)
D (-)	Splitter to fast and slow response reservoirs	(0, 1)
T_{lagF} (d)	Lag time from rainfall to peak flow	(0, 10)
K_f (d)	The fast recession coefficient	(1, 20)
K_s (d)	The slow recession coefficient	(20, 400)

999

1000

1001 Table 2. The water balance and constitutive equations used in models. (Function (15)^{*} is used in the HBV model, but
 1002 not used in the TOPMODEL, HSC and HSC-MCT models)

reservoirs	Water balance equations	Constitutive equations
Interception reservoir	$\frac{dS_i}{dt} = P - E_i - P_e \quad (8)$	$E_i = \begin{cases} E_p; S_i > 0 \\ 0; S_i = 0 \end{cases} \quad (9)$
		$P_e = \begin{cases} 0; & S_i < S_{iMax} \\ P; & S_i = S_{iMax} \end{cases} \quad (10)$
Unsaturated reservoir	$\frac{dS_u}{dt} = P_e - E_a - R_u \quad (11)$	$\frac{R_u}{P_e} = \left(\frac{S_u}{S_{uMax}} \right)^\beta \quad (12)^*$
		$\frac{E_a}{E_p - E_i} = \frac{S_u}{C_e S_{uMax}} \quad (13)$
Splitter and Lag function		$R_f = R_u D \quad (17); R_s = R_u (1 - D) \quad (14)$
		$R_{fl}(t) = \sum_{i=1}^{T_{lagf}} c_f(i) \cdot R_f(t-i+1) \quad (15)$
		$c_f(i) = i / \sum_{u=1}^{T_{lagf}} u \quad (16)$
Fast reservoir	$\frac{dS_f}{dt} = R_f - Q_f \quad (17)$	$Q_f = S_f / K_f \quad (18)$
Slow reservoir	$\frac{dS_s}{dt} = R_s - Q_s \quad (19)$	$Q_s = S_s / K_s \quad (20)$

1003

1004 Table 3. Data source of the MOPEX catchments.

Data	Unit	Resources	Website	Reference
Daily precipitation	mm/d	MOPEX	http://www.nws.noaa.gov/oh/d/mopex/mo_datasets.htm	(Duan et al., 2006)
Daily maximum temperature	°C	MOPEX	Same as above	Same as above

Daily minimum temperature	°C	MOPEX	Same as above	Same as above
Daily runoff	mm/d	MOPEX	Same as above	Same as above
Aridity index	-	MOPEX	Same as above	Same as above

1005

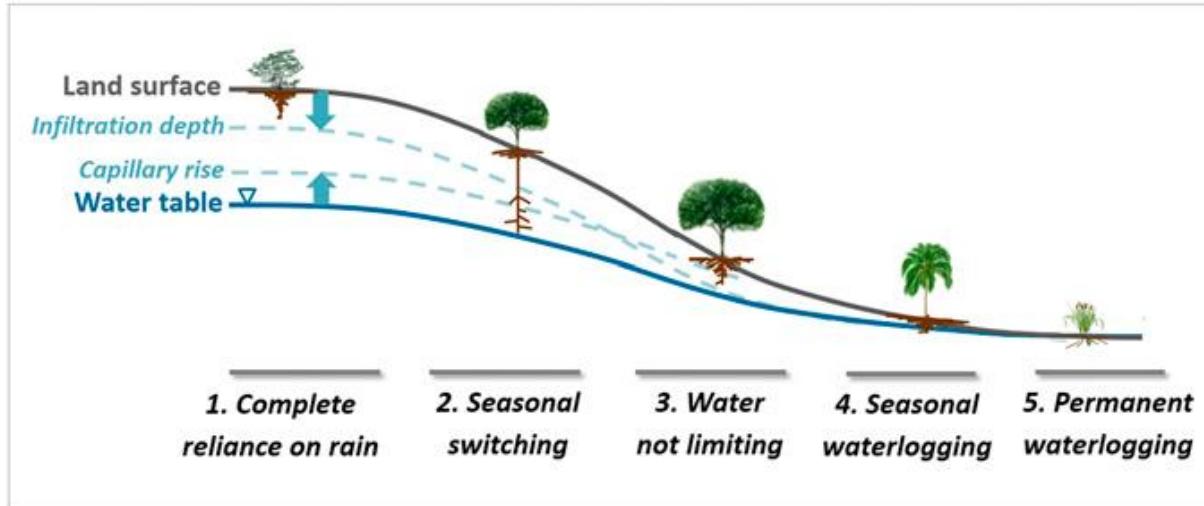

1006

1007 Table 4. Impacts of MOPEX catchment characteristics on model performance (HSC, HBV, and TOPMODEL)

Catchment characteristics	HSC > HBV	HSC ≈ HBV	HSC < HBV	HSC >	HSC ≈	HSC <
Averaged						
HAND (m)	37	71	-	27	69	193
Averaged slope						
(degree)	4.0	5.7	-	3.6	5.6	13.5
Averaged						
elevation (m)	454	395	-	469	393	740
Averaged K-factor (-)						
	0.28	0.29	-	0.29	0.29	0.25
Forest						
proportion (%)	22	43	-	14	43	68
Aridity index (-)	1.1	0.9	-	1.3	0.9	0.8
Stream density						
(-)	0.72	0.81	-	0.77	0.80	0.83

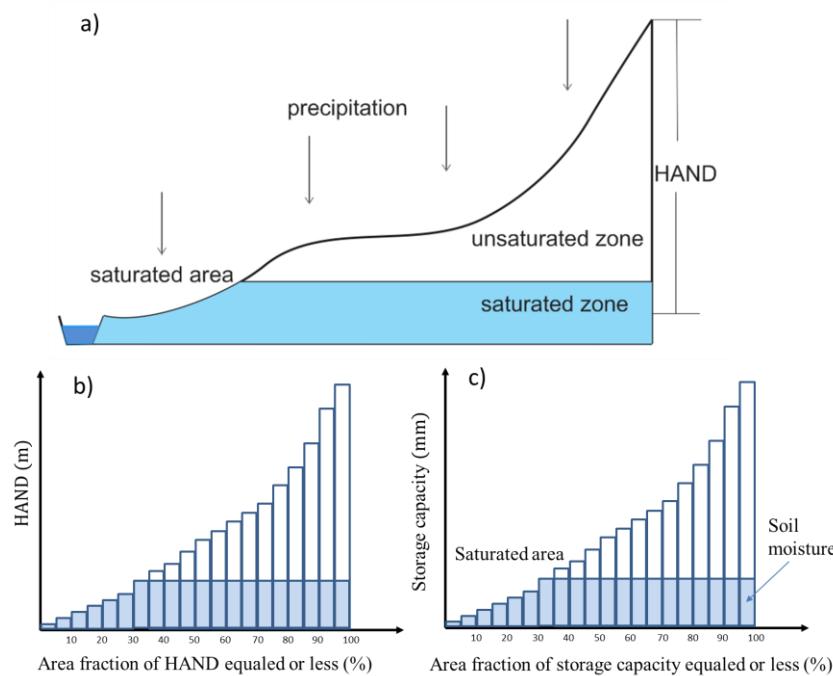

Averaged depth to rock (cm)	192	219	-	210	215	333
-----------------------------------	-----	-----	---	-----	-----	-----

1008

1009

1010 Figure 1. The variation of plant rooting depths along a hillslope profile, showing the impact of HAND
1011 (Height Above the Nearest Drainage) on rooting depth. (Taken from Fan et al., 2017 by permission of PNAS)

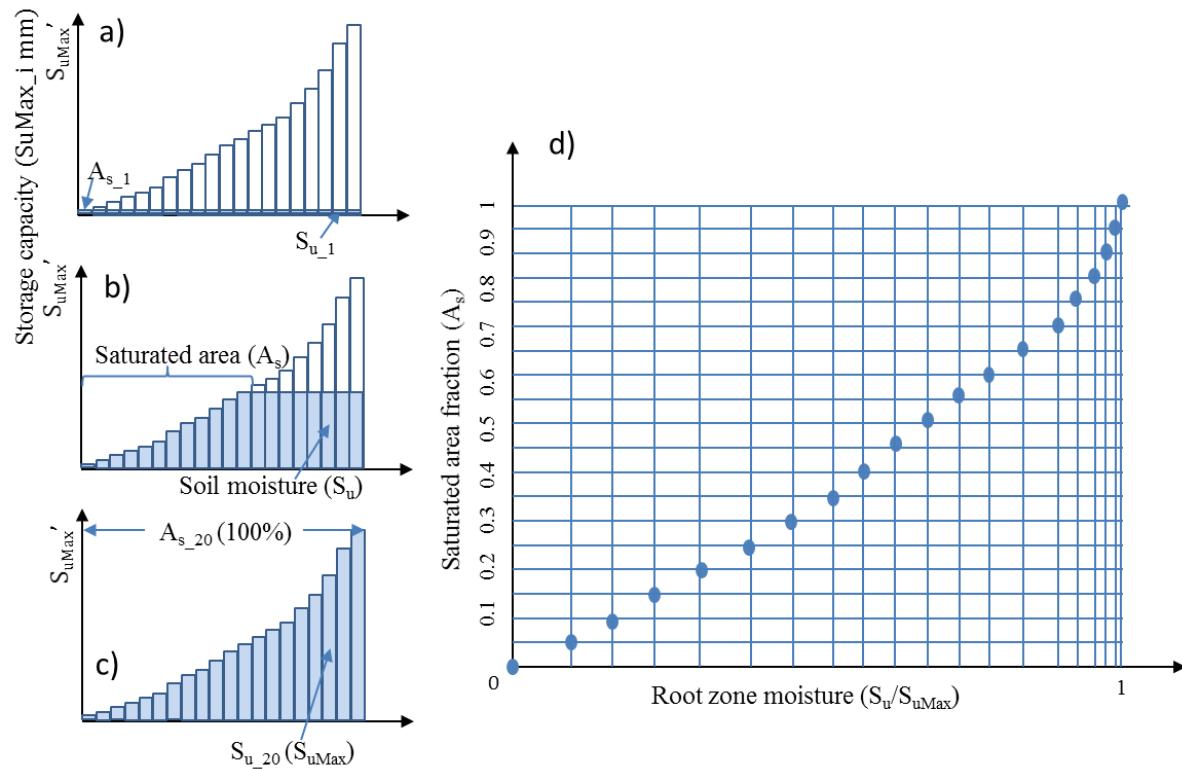

1012

1013 Figure 2. The perceptual model of the HAND-based Storage Capacity curve (HSC) model. a) shows the representative
1014 hillslope profile in nature, and the saturated area, unsaturated zone and saturated zone; b) shows the relationship

1015 between HAND bands and their corresponded area fraction; c) shows the relationship between storage capacity-
 1016 area fraction-soil moisture-saturated area, based on the assumption that storage capacity linearly increases with
 1017 HAND values.

1018

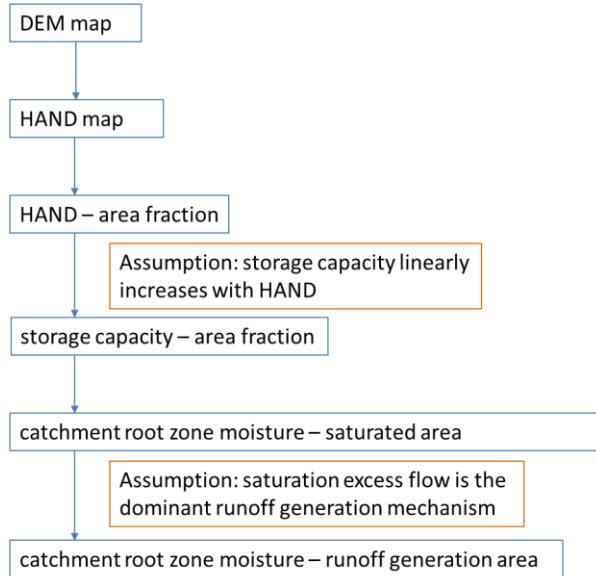

1019

1020

1021 Figure 3. The conceptual model of the HSC model. a), b) and c) illustrate the relationship between soil moisture (S_u)
 1022 and saturated area (A_s) in different soil moisture conditions. In d), 20 different S_u - A_s conditions are plotted, which
 1023 allow us to estimate A_s from S_u .

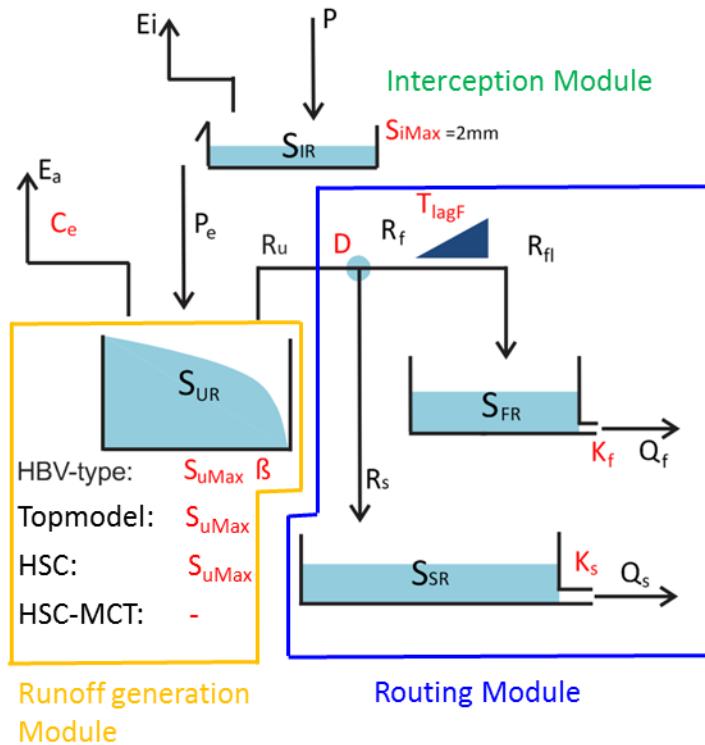

1024

1025

1026 Figure 4. The procedures estimating runoff generation by the HSC model and its two hypotheses.

1027

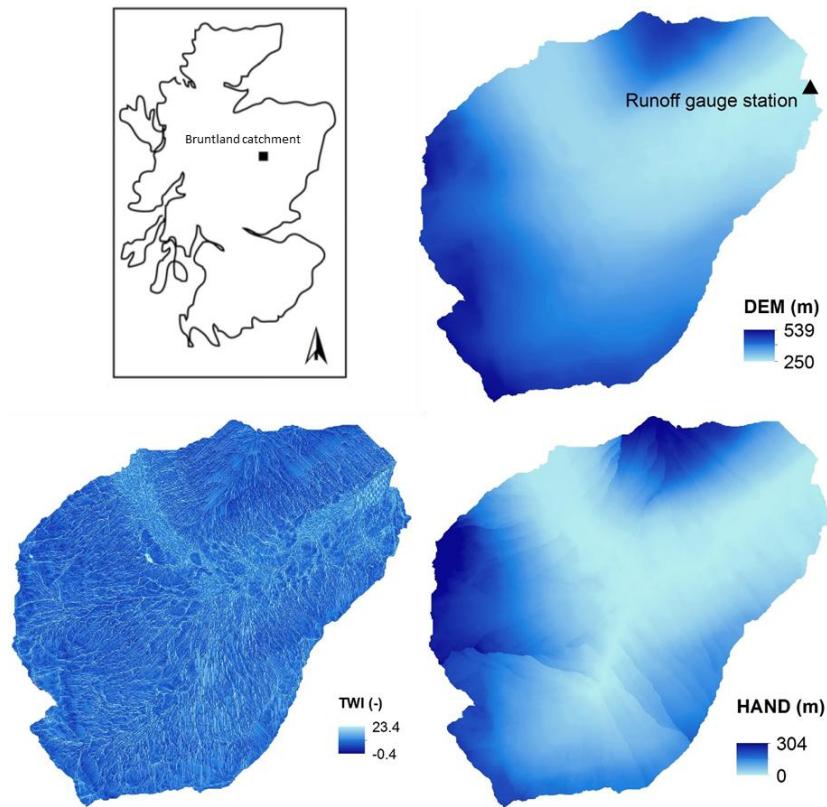

1028

1029 Figure 5. Model structure and free parameters, involving four runoff generation models (HBV-type, TOPMODEL, HSC,
1030 and HSC -MCT). HBV-type has S_{uMax} and beta two free parameters; TOPMODEL and HSC models have S_{uMax} as one

1031 free parameter; and HSC-MCT model does not have free parameter. In order to simplify calibration process and
1032 make fair comparison, the interception storage capacity ($S_{i\text{Max}}$) was fixed as 2mm.

1033
