11           **Abstract**

12           The duration of dry or wet hydrological epochs (run lengths) associated with positive or  
13 negative Inter-decadal Pacific Oscillation (IPO) or Pacific Decadal Oscillation (PDO) phases, termed  
14 Pacific Decadal Variability (PDV), is an essential statistical property for understanding, assessing and  
15 managing hydroclimatic risk. Numerous IPO and PDO paleoclimate reconstructions provide a  
16 valuable opportunity to study the statistical signatures of PDV, including run lengths. However,  
17 disparities exist between these reconstructions making it problematic to determine which  
18 reconstruction(s) to use to investigate pre-instrumental PDV and run length. Variability and  
19 persistence on centennial scales are also present in some millennium long reconstructions, making  
20 consistent run length extraction difficult. Thus, a robust method to extract meaningful and consistent

1 run lengths from multiple reconstructions is required. In this study, a dynamic threshold framework to  
2 account for centennial trends in PDV reconstructions is proposed. The dynamic threshold framework  
3 is shown to extract meaningful run length information from multiple reconstructions. Two  
4 hydrologically important aspects of the statistical signatures associated with the PDV are explored: (i)  
5 whether persistence (i.e. run lengths) during positive epochs is different to persistence during negative  
6 epochs and (ii) whether the reconstructed run lengths are stationary during the past millennium.  
7 Results suggest that there is no significant difference between run lengths in positive and negative  
8 phases of PDV and that it is more likely than not that the PDV run length has been non-stationary in  
9 the past millennium. This raises concerns about whether variability seen in the instrumental record  
10 (the last ~100 years), or even in the shorter 300-400 year paleoclimate reconstructions, is  
11 representative of the full range of variability.

12 Key words: PDV; run length; multiple reconstructions; stationarity

## 13 **1. Introduction**

14 A pattern of Pacific ocean-atmosphere climate variability at decadal time scales has been  
15 identified and explored at various locations around the world including Africa (Reason and Rouault,  
16 2002;Hoell and Funk, 2014), Eastern and Southern Asia (Krishnan and Sugi, 2003;Ma, 2007),  
17 America (Mantua and Hare, 2002;Andreoli and Kayano, 2005) and Australia (Kiem et al.,  
18 2003;Verdon et al., 2004;Verdon and Franks, 2006;Henley et al., 2011). This pattern, referred to in  
19 this paper as Pacific Decadal Variability (PDV), is associated with sea surface temperature  
20 fluctuations and sea level pressure changes in the north and south Pacific Ocean.

21 PDV is usually described by the Inter-decadal Pacific Oscillation (IPO) or Pacific Decadal  
22 Oscillation (PDO) indices (Mantua et al., 1997;Power et al., 1999). Of particular hydrological  
23 relevance are the statistical characteristics of PDV phases where a phase refers to a period during  
24 which the PDV index lies above (or below) some thresholds (Dong and Dai, 2015;Verdon et al.,  
25 2004;Henley et al., 2011;Vance et al., 2015). The duration of a PDV phase (termed run length) is

1 defined as the time between consecutive crossings of the threshold. The phase may be described as  
2 positive (negative) if the PDV index is above (below) the threshold, or dry (wet) if the PDV phases  
3 are associated with predominantly dry (wet) hydrological conditions.

4 Of particular relevance to the hydrology and water resources community is the evidence that  
5 the PDV phases can be associated with multi-decadal periods of persistently wetter or drier conditions  
6 and corresponding increases in flood or drought risk in affected regions, particularly those on the  
7 Pacific rim. PDV has been found to be related to a number of hydrological variables including  
8 precipitation, streamflow, flood/drought risk (Cook et al., 2013;Kiem et al., 2003;Verdon et al.,  
9 2004;Dai, 2013;Goodrich and Walker, 2011;Hu and Huang, 2009;Li et al., 2012;McCabe et al.,  
10 2012;Mehta et al., 2011;Wang et al., 2014;Henley et al., 2013). For example, Kiem and Franks (2004)  
11 showed in a case study for eastern Australia that the probability of reservoir storages falling below a  
12 critical level differs significantly depending on the PDV phases (see Figure 6 in Kiem and Franks  
13 (2004)). Kiem and Franks (2003) and Micevski et al. (2006) demonstrated that flood risk in eastern  
14 Australia is strongly dependent on PDV phase. Henley et al. (2013) extended this work to show that  
15 short-term drought risk is strongly dependent not only on the PDV phase but also on the time spent in  
16 a particular phase.

17 Despite the clear relevance of PDV phases to hydrological risk assessment and water resource  
18 management, there remain considerable knowledge gaps about the statistical characteristics of PDV,  
19 including run lengths. The instrumental record shows that PDV phases have varied irregularly with  
20 runs ranging from less than a decade to several decades during the past century. However, the  
21 instrumental record is insufficient to characterize the statistical characteristics of PDV run lengths. In  
22 response to this, significant advances have been made in reconstructing pre-instrumental PDV  
23 behaviour to extend data length. For example, at least 12 IPO or PDO reconstructions have been  
24 published (Biondi et al., 2001;Gedalof and Smith, 2001;D'Arrigo et al., 2001;MacDonald and Case,  
25 2005;D'Arrigo and Wilson, 2006;Shen et al., 2006;Verdon and Franks, 2006;Linsley et al.,  
26 2008;Mann et al., 2009;McGregor et al., 2010;Henley et al., 2011;Vance et al., 2015).

1 In view of these published PDV reconstructions, the fundamental question is whether useful  
2 information can be extracted about the statistical characteristics of PDV persistence. In dissecting this  
3 question, several unresolved issues are identified:

4 1) Static threshold methods have been used to estimate run lengths of PDV phases. This  
5 raises the concern that biased conclusions about the statistical characteristics of decadal climate  
6 variability may be drawn when reconstructions exhibit centennial or longer trends. The non-  
7 parametric Mann-Whitney test method was used in Verdon and Franks (2006) whereby a crossing  
8 was defined when the test detected a statistically significant difference between two halves of data in  
9 a 30-year moving window, with zero used as a static threshold to define the sign of PDV phases  
10 (Verdon-Kidd, personal communication, 24 April, 2017). Henley et al. (2011) used the instrumental  
11 mean of the composite IPO/PDO index. After standardizing the indices, Vance et al. (2015) used  $\pm 0.5$   
12 as thresholds to determine crossings and the sign of PDV phases, and Henley et al. (2017) used the  
13 long-term modelled IPO Tripole Index (TPI) mean as the static threshold with run lengths less than 5  
14 years omitted. However, when static threshold methods are used, extraordinary long centennial run  
15 lengths may be identified in the reconstructions that exhibit centennial or longer trends (MacDonald  
16 and Case, 2005; Mann et al., 2009). Analysis based on data with long-term trends can lead to results  
17 that are overwhelmed by such trends and hence efforts have been made to detrend data without losing  
18 useful signals (Wahl et al., 2006; von Storch et al., 2006; Wu et al., 2007). As stated by von Storch et al.  
19 (2006), “it is commonly accepted that proxy indicators may contain nonclimatic trends”. Moreover,  
20 the calibration and validation of any statistical method using nondetrended data may be compromised  
21 because the nonclimatic trends may be interpreted as a climate signal. The centennial trends in PDV  
22 reconstructions may be either nonclimatic trends or non-decadal climate trends. Whichever the case, it  
23 is necessary to filter such centennial trends before interpreting decadal climate variability. Given that  
24 static threshold methods cannot remove trends, how should the run length extraction method be  
25 designed to extract useful and consistent information from all reconstructions, including  
26 reconstructions exhibiting centennial trends? To what extent are run length distributions sensitive to  
27 the choice of extraction parameters (e.g. threshold, window width etc.)?

1           2)       The durations of positive and negative PDV phases have not been treated separately  
2 in most previous research (e.g. Verdon and Franks, 2006; Linsley et al., 2008; Henley et al., 2011a )  
3 Using a high-resolution millennial-length IPO reconstruction, Vance et al. (2015) observed that  
4 positive phases dominate and last longer than negative phases. Owing to nonlinear hydrologic  
5 feedback mechanisms, such as elasticity of streamflow to runoff (Chiew, 2006) and shifted rainfall-  
6 runoff relationships (Saft et al., 2015), the duration of increased (decreased) precipitation during a wet  
7 (or dry) PDV phase may impact on streamflow in a highly nonlinear manner. Therefore, assuming wet  
8 and dry runs follow the same distribution may misrepresent the intensity of impacts. Is there sufficient  
9 evidence about the dissymmetry between positive and negative phase run lengths from the multiple  
10 reconstructions? Will run length samples from each phase lead to significantly different run length  
11 simulations?

12           3)       Stationarity of climate signatures is a necessary, yet implicit, assumption underlying  
13 many analyses based on paleoclimate reconstructions – and hydroclimate stochastic modelling used in  
14 water resource assessment (e.g. Henley et al., 2013). However, a number of studies have suggested  
15 the possibility of climatic non-stationarity over the past millennium. Phipps et al. (2013) found that  
16 the relationships between paleoclimate proxies and climatic variables have been changing at least the  
17 last millennium. Razavi et al. (2015) explored the stationarity of the mean, variance and  
18 autocorrelation structures of paleo tree-ring proxy data and concluded that the key statistical  
19 characteristics of climate had undergone significant change over time. The existence of extraordinary  
20 warm and cold periods, known as Medieval Climate Anomaly (~950-1250CE) and Little Ice Age  
21 (~1400-1700CE) (Mann et al., 2009;Phipps et al., 2013;Atwood et al., 2015), also challenges the  
22 assumption of climatic stationarity. Furthermore, externally forced anthropogenic climate change,  
23 arising from elevated atmospheric concentrations of greenhouse gases, may also make recent and  
24 future climate different from the long past (Kirtman et al., 2013). Therefore, care should be taken  
25 when positing that PDV characteristics are stationary. Statistical signatures of past reconstructed PDV  
26 runs should be tested for non-stationarity (and where possible non-stationarity should be attributed to  
27 causal mechanisms) to ensure robust and representative estimation of the full range of variability.

1 In view of the above mentioned issues, this study has the following objectives:

2 1) To develop a more robust run length extraction method that is applicable to all  
3 reconstructions, including those with centennial trends. Of particular importance is the sensitivity of  
4 the inferred run length distributions to the choice of the extraction method parameters.

5 2) To identify hydrologically important statistical properties of PDV that are common to  
6 different reconstructions. In particular two fundamental questions are explored: (i) whether  
7 persistence (i.e. run lengths) during positive epochs is different to persistence during negative epochs  
8 and (ii) whether the reconstructed run lengths are stationary during the past millennium. Both  
9 questions address fundamental concerns about using PDV and run length information in stochastic  
10 hydroclimatic models used to assess drought and flood risk.

11 The rest of the paper is organized as follows. Section 2 briefly introduces the instrumental and  
12 reconstructed PDV records used in this research. The dynamic threshold run length extraction method  
13 is introduced in Section 3, along with its comparison with the static threshold method and  
14 determination of its parameters. The hydrologically important statistical signatures of PDV are  
15 analysed and discussed in Section 4, with conclusions presented in Section 5.

## 16 **2. Data**

### 17 **2.1 Instrumental PDV records**

18 A number of instrumental IPO and PDO indices have been published to characterize PDV  
19 since ~1900. There is a strong correlation between IPO and PDO indices, suggesting that both indices  
20 represent a similar broad pattern of climate variability. The primary difference between the IPO and  
21 PDO indices is that the IPO index is based on a broader spatial scale than the PDO index (Folland et  
22 al., 2002; Verdon and Franks, 2006; Henley et al., 2011).

1 Three PDV indices are used in this study: (1) The unfiltered instrumental PDO index  
2 (<http://research.jisao.washington.edu/pdo/PDO.latest.txt>), denoted as PDO\_Mantua, is the monthly  
3 standardized value of the leading principal component of monthly Sea Surface Temperature (SST)  
4 anomalies in the North Pacific Ocean, poleward of 20N (Mantua et al., 1997;Zhang et al., 1997); (2)  
5 The unfiltered monthly IPO index from Parker et al. (2007), denoted as IPO\_Parker, is the second  
6 covariance empirical orthogonal function of low-pass-filtered SST; (3) The unfiltered monthly Tripole  
7 Index (TPI) for the IPO (Henley et al., 2015), denoted as IPO\_Henley, is based on the SST anomalies  
8 in three large geographic regions of the Pacific. Annual (calendar year) values of these three indices  
9 are taken as the average of monthly values.

10 Figure 1 shows time series of the three indices along with probability density plot, quantile-  
11 quantile (QQ) plot and autocorrelation plots. The distribution density plot and QQ plot of the annual  
12 PDV indices suggest that the instrumental PDV indices are approximately normally distributed with  
13 zero mean and unit standard deviation (except for IPO\_Parker). The lag-one autocorrelation lies  
14 between about 0.3 and 0.5. By lag three, the autocorrelations lie within the 95% confidence bands for  
15 zero autocorrelation.

16 The instrumental PDV indices are used for two purposes in this study:

17 (a) to assess the similarity between IPO and PDO indices. If instrumental IPO and PDO  
18 indices can be used to represent the same broad pattern of climate variability - and noting that  
19 different reconstructions are calibrated against different instrumental indices - there is no need to  
20 recalibrate all reconstructions against the same instrumental data.

21 (b) to guide the selection of the parameters of the run length extraction method. If selected  
22 parameters can identify credible run lengths in the instrumental PDV record, it is assumed that they  
23 can also produce credible run lengths in the reconstructed record.

## 2.2 PDV reconstructions

Twelve published annual PDV reconstructions from different sites with different proxies are used in this study. Of these, nine reconstructed the last 300-400 years and three reconstructed the last ~1000 years. The reconstructions are based on paleo proxies (i.e. preserved physical characteristics of the environment that can be directly measured) from the northern and southern, and western and eastern regions of the Pacific Ocean. A summary of these reconstructions is presented in Table 1, while Figure 7 in Section 3.2.3 presents time series plots of the 12 reconstructed indices, and they are denoted throughout by the four-character author name and two-character publishing year. It is worth noting that Mann09 was not directly calibrated to an instrumental PDV index, and also has a negative correlation with other reconstructions. However, because the correlation of this reconstruction with the other ones is relatively high (Henley, 2017), the Mann09 reconstruction is retained with the sign reversed.

## 3. Run length extraction

### 3.1 Static and dynamic threshold run length extraction methods

However, for reconstructions Macd05, Mann09 and Vanc15 which exhibit centennial trends (see Table 1 and Figure 2), the above mentioned static threshold methods used in Verdon and Franks (2006), Henley et al. (2011), Vance et al. (2015) and Henley et al. (2017) may not identify meaningful decadal phases. Extraordinary long run lengths are identified if the overall mean is used as a threshold with some runs lasting several centuries (see Figure 2). It is not clear whether these centennial trends are due to low frequency climate variability or due to unknown local factors affecting the proxy. With such reconstructions, one can either exclude them from analysis or filter out the centennial trends.

1 Exclusion forgoes any useful information from the reconstructions. On the other hand, filtering out  
2 the centennial trends offers the prospect of extracting possibly useful information about run lengths.

3 We adopt the latter approach proposing a dynamic threshold framework to filter out  
4 centennial trends. In this framework, potential crossings are taken to be the change points detected by  
5 the Mann-Whitney test, and the sign of PDV phases is determined by a dynamic threshold that takes  
6 centennial trends into consideration - this relaxes the restriction of a static threshold defining a phase  
7 crossing. Figure 2 provides insight about the mechanics of dynamic threshold method showing the  
8 PDV time series and the resulting block phase waveform. The key steps of this framework are:

9 1. Detect step-change points. For a given reconstruction, apply a change point detection  
10 method. A number of methods can be used. In this study we used the non-parametric Mann-Whitney  
11 test method (Mauget, 2003) with a given window width  $w$  and confidence level  $\alpha$  to identify the step-  
12 change points. The method involves centring a window of width  $w$  at a particular year  $t$  and then  
13 applying the Mann-Whitney test to the samples of width  $w/2$  at or before and after year  $t$ . A step  
14 change is deemed to occur if the Mann-Whitney test statistic lies outside the  $\alpha$  confidence limits  
15 (under the null hypothesis).

16 2. Merge consecutive step-change points. When two or more step change points occur in  
17 consecutive years, replace them with a single change point. That is, if there are either  $2n-1$  or  $2n$  years  
18 that are determined as consecutive change points ( $n=1, 2, \dots$ ), replace them with one change point at  
19 year  $n$ . This guarantees that the new change point is always closest to the middle of the run of  
20 consecutive step-change points.

21 3. Assign a phase to each run defined by the interval bounded by two step-change points. Let  $i(t)$   
22 denote the PDV index in year  $t$ ,  $i_f(t)$  the filtered PDV index using a first-order Butterworth filter  
23 (which was used by Henley et al. (2011) to filter paleo PDV indices) with cut-off frequency  $1/y$   
24 year<sup>-1</sup>,  $t_{cp}^k$  the year that the  $k^{\text{th}}$  change point occurs (from steps 1 and 2) and  $s(t)$  the phase state of  
25 year  $t$ . The mean PDV index for the  $k^{\text{th}}$  run is

1 
$$\bar{i}^k = \frac{1}{(t_{cp}^k - t_{cp}^{k-1} + 1)} \sum_{t_{cp}^{k-1}}^{t_{cp}^k} i(t) \quad (1)$$

2 while the corresponding mean of the filtered index is

3 
$$\bar{i}_f^k = \frac{1}{(t_{cp}^k - t_{cp}^{k-1} + 1)} \sum_{t_{cp}^{k-1}}^{t_{cp}^k} i_f(t) \quad (2)$$

4 The phase of the  $k^{th}$  run length is then defined by

5 
$$s(t) = \begin{cases} 1 & \text{if } \bar{i}^k \geq \bar{i}_f^k \\ 0 & \text{if } \bar{i}^k < \bar{i}_f^k \end{cases}, t \in (t_{cp}^{k-1}, t_{cp}^k - 1) \quad (3)$$

6 4. Determine run lengths using the time series  $s(t)$ . The run length of the  $k^{th}$  run will be  
7  $t_{cp}^k - t_{cp}^{k-1}$ .

8 This dynamic threshold method can be seen as a generalization of previous run length  
9 extraction methods. If parameter  $y$  is set to the total number of years in a given reconstruction, the  
10 dynamic threshold method reduces to the method used in Verdon and Franks (2006). If change points  
11 are defined by the PDV index crossing the threshold and the cut-off frequency parameter  $y$  of the first-  
12 order Butterworth filter is set to the total number of years in the reconstruction, the dynamic threshold  
13 reduces to the method used in Henley et al. (2011) and Henley et al. (2017).

14 Three parameters need to be specified in the dynamic threshold method: window width  $w$  and  
15 confidence level  $\alpha$  in the Mann-Whitney test, and cut-off frequency  $y$  of the Butterworth filter. The  
16 standard cut-off frequency parameter in the dynamic threshold method is used to filter out centennial  
17 trends that may be mixed with decadal variability and should have little influence on the statistical  
18 characteristics of the inferred runs. A cut-off frequency of 1/100 years is considered to adequately  
19 meet these requirements. Hence,  $y=100$  is used in this study. In this study, we set the confidence level  
20 to be 90%, a value that is consistent with other reconstruction studies (eg Gedalof and Smith, 2001;

1 Shen et al., 2006; McGregor et al., 2010; Pent et al., 2015). It has been shown that reconstructions are  
2 sensitive to the choice of the window used in the Mann-Whitney test as well as the choice of threshold  
3 (Henley et al., 2017; Henley, 2013). Accordingly, this study investigates the sensitivity of dynamic  
4 threshold method results to the choice of window width  $w$  in the Mann-Whitney test. This sensitivity  
5 analysis is used to guide the selection of parameters to be used in the analysis of all 12 PDV  
6 reconstructions.

## 7 **3.2 Results from different run length extraction**

### 8 **methods**

#### 9 **3.2.1 Comparison of static and dynamic threshold**

10 To further demonstrate the shortcomings of the static threshold method and the need for a  
11 dynamic threshold method, run length samples are extracted using the dynamic threshold method  
12 proposed in this study (denoted as “Dynamic” in the figures) and the static threshold method used in  
13 Verdon and Franks (2006) (denoted as “Static” in the figures). These two methods only differ in step  
14 3 of Section 3.1. In the static method, the overall mean defined as  $\bar{i}_f = \frac{1}{n} \sum_1^n i_f(t)$  (in which  $n$  is  
15 number of years in corresponding reconstruction) is used as the threshold instead of the dynamic  
16 threshold defined in equation (2). Extracted run length samples using the dynamic and static threshold  
17 methods from 3 millennium long reconstructions with centennial trends are plotted in Figure 2. Black  
18 lines are filtered standardized PDV indices; green lines represent the Butterworth (1/100) filtered data  
19 in the dynamic plots and the overall mean in the static plots; red lines represent the run extracted  
20 using either the dynamic or static thresholds method. The run length distributions are plotted in Figure  
21 3.

22 It is shown in Figure 2 that extraordinarily long runs are identified when the static threshold  
23 method is used - the stronger the centennial trends, the longer the runs. On the other hand, use of the

1 dynamic threshold framework appears to filter centennial trends and produce more meaningful run  
2 lengths. The run length density plots show that the dynamic threshold method for the Macd05 and  
3 Mann09 reconstructions removes centennial-scale runs. In the case of Vanc15 the centennial trends  
4 are muted, possibly because Vanc15 is annually resolved and very accurately dated (Vance et al.,  
5 2015) and as such is more likely to exhibit more realistic annual to decadal variability than Macd05  
6 and Mann09 (see also Figure 2). Individual reconstructions are subject to different error structures and  
7 magnitudes. Use of multiple reconstructions can help reduce the impact of errors, and thus provide  
8 more insight into the statistical characteristics of PDV run lengths. Nonetheless, errors still need to be  
9 carefully considered. This is illustrated by Henley et al. (2011) who combines individual  
10 reconstructions according to their accuracy. However, the accuracies of the individual reconstructions  
11 are not high (Nash-Sutcliffe indices  $<0.48$ ) suggesting that even favouring the more accurate  
12 individual reconstructions will still result in a combined/overall reconstruction with large errors.  
13 Therefore, the focus of our research is to identify a signal (or signals) that is (are) common to all  
14 individual reconstructions.

### 15 **3.2.2 Window width sensitivity analysis**

16 Henley (2013) demonstrated that the mean run length is strongly dependent on the choice of  
17 window width in Mann-Whitney method and concluded that a subjective choice of window width is  
18 likely to bias the resulting run length distributions. To explore the sensitivity of window width on run  
19 length distributions, run length boxplots for all reconstructions are plotted in Figure 4 for window  
20 widths from 10 to 60 years with step of 2, with positive and negative samples plotted together and  
21 separately.

22 Figure 4 shows that the run length distributions clearly depend on the choice of window width  
23 with longer window widths leading to longer run length samples. However, the change is gradual  
24 particularly for shorter window widths. As a result, run length distributions are not particularly  
25 sensitive to small variations in window width of the order of 10 years.

### 3.2.3 Determination of parameters and application of dynamic threshold

#### method

To guide the selection of an operationally useful window width, several window widths are applied to the three instrumental PDV time series to identify which produces results that match existing knowledge about run length in instrumental periods. Four window widths, 10, 20, 30 and 40 years, are applied to the instrumental time series with the extracted runs plotted in Figure 5.

Interpretation of Figure 5 is illustrated for Figure 5d. The green line represents the IPO\_Henley index, from which three runs, denoted by green circles, are extracted: ~1900-1938 (positive), ~1938-1976 (negative), ~1976-2004 (positive). These are very similar (in number, sign and duration) to the black (PDO\_Mantua) and red run lengths (IPO\_Parker). It can be seen that a window width of 10 years identifies very short runs which are more likely to represent random fluctuations rather than different PDV phases - we note that Henley et al. (2017) discarded runs with lengths less than 5 years. However, for the longer window widths of 20, 30 and 40 years, the differences become more muted.

To better understand these differences, consider window widths of 20 and 40 years. When the 40-year window is used, the first 20 years of the window are compared to the last 20 years. As a result, runs of less than 20 years may be overlooked. To demonstrate this, different window widths are applied to all reconstructions to extract run lengths, from which conditional run length distributions are determined. Figure 6 presents run length distributions in six panels. Panels (a1) to (a3) compare distributions for 20 and 40-year windows. Panel (a1) shows the empirical density of run lengths, while panels (a2) and (a3) show the empirical densities conditioned on run lengths less than 20 years and greater than 20 years respectively. Likewise Panels (b1) to (b3) repeat this sequence for 20 and 60-year windows with the conditioning threshold of 30 years.

Panels (a1) and (b1) show that the unconditional run length distributions are different using different window widths with the difference greater for a greater difference in window width. However, panels (a3) and (b3) show that the conditional distributions for the longer runs are very similar. This shows that both the short and long window widths extract the longer runs in a largely

1 consistent manner. However, the choice of window width strongly affects the distribution of shorter  
2 runs as shown in panels (a2) and (b2). Overall, this demonstrates that shorter window widths can “see”  
3 higher frequency runs better than longer window widths but both “see” the same distribution of lower  
4 frequency runs.

5         These considerations suggest that the window width should be as small as possible, yet  
6 sufficiently big to filter out runs that are considered more likely to be random fluctuations rather than  
7 PDV phases. Therefore, in this study, a 20-year window is used to ensure decadal or longer runs are  
8 identified. Figure 7 plots the extracted runs for the 12 reconstructions using the dynamic threshold  
9 method with 90% confidence limits and 20-year window in the Mann-Whitney test. The PDV indices  
10 plotted in Figure 7 were filtered using a Butterworth filter with a cut-off frequency of  $1/11 \text{ years}^{-1}$  to  
11 more clearly present the decadal variability in each reconstruction. In the case of Verd06, no PDV  
12 indices are available, so the original runs are plotted. Visual inspection of Figure 7 suggests that the  
13 identified runs in all reconstructions seem largely consistent with the multi-decadal fluctuations in the  
14 filtered PDV indices. In the case of reconstructions with pronounced centennial trends (such as  
15 Macd05 and Mann09), positive and negative runs tend to match multi-decadal fluctuations in the  
16 filtered indices even when the indices persist above or below the long-term average over centennial  
17 scales.

## 18         **4. Statistical signatures of PDV run lengths**

19         The dynamic threshold method allows run lengths to be extracted from all the PDV  
20 reconstructions, even from those with centennial trends. If we had a perfect reconstruction there  
21 would be no need for any further reconstructions. However, the fact is that each paleoclimate  
22 reconstruction is subject to errors, both random and systematic, that are not fully understood.  
23 Therefore, it is pertinent to identify statistical features that are common to the reconstructions and also  
24 important to hydroclimatic risk assessments. This addresses the second objective of this study. In  
25 particular, the analysis seeks to answer the following questions: Are the distributions of positive and

1 negative PDV run lengths statistically different, and is the variability seen in the instrumental record  
2 (the last ~100 years), or the shorter 300-400 year paleoclimate reconstructions, representative of the  
3 full range of variability that has occurred in the past or of what is plausible in the future? These  
4 questions are of particular importance for predicting near-term PDV phase behaviour and assessing  
5 near-term flood and drought risk and therefore are the primary focus of this section.

## 6 **4.1 Are run lengths different during positive and** 7 **negative PDV phases?**

8 Vance et al. (2015) analysed an IPO reconstruction from AD 1000 to 2003 and concluded that  
9 the positive IPO phase ( $IPO > 0.5$ ) has an average duration of 14 years and the negative IPO phase  
10 ( $IPO < -0.5$ ) has an average duration of 9 years. This is the first known analysis that considered  
11 positive and negative PDV phases separately.

12 To explore the hypothesis that run lengths have different distributions during positive and  
13 negative PDV phases, boxplots of run lengths for each reconstruction are shown in Figure 8. Panel (a)  
14 shows boxplots for all run lengths for each reconstruction, Panel (b) shows boxplots of pooled  
15 positive and negative run lengths, while Panel (c) shows boxplots of positive and negative run lengths  
16 for each reconstruction. Panel (b) suggests that the pooled median positive and negative run lengths  
17 are similar, but that positive run lengths are more variable. However, Panel (c) shows that there is  
18 considerable variability between reconstructions. The absence of a consistent difference between  
19 positive and negative run distributions may be a consequence of sampling variability masking any  
20 underlying difference. Sampling variability refers to the variability in the target statistics that arises  
21 when random sampling is repeated. Therefore, it is important to recognize that differences in run  
22 statistics may be due to sampling variability. It is only when differences are bigger than what would  
23 be expected due to sampling variability that we would conclude there is a significant difference. This  
24 seems reasonable given that the average number of phases (either positive or negative) per

1 reconstruction is only 13. A more formal statistical analysis is required to explicitly deal with  
2 sampling variability arising from the small samples.

3 Henley et al. (2011) adopted the Gamma distribution as the probability model of PDV run  
4 lengths. The Gamma distribution has two parameters which are related to the mean  $\mu$  and standard  
5 deviation  $\sigma$  of the run lengths. For each reconstruction, the positive and negative runs are extracted  
6 and the posterior distribution of the mean and standard deviation is inferred using MCMC (Gelman  
7 and Rubin, 1992). Figure 9 presents the joint posterior distribution of the differences in  
8 mean( $\mu^+ - \mu^-$ ) and standard deviation ( $\sigma^+ - \sigma^-$ ) for each reconstruction. If the difference between  
9 positive and negative runs is statistically significant, one would expect the posterior distribution to be  
10 well removed from the zero-difference origin.

11 Inspection of Figure 9 suggests there is no strong and consistent evidence to reject the  
12 assumption that positive and negative phase run length distributions are the same. Although the mean  
13 of positive phase run lengths tends to be longer than negative phase run lengths in several  
14 reconstructions (e.g. Vanc15, Hen11, Lins08, Darr01), the statistical significance of this difference is  
15 weak and the phenomenon is not consistent across all reconstructions. A similar conclusion applies to  
16 the standard deviation of positive and negative phase run lengths. This highlights the fundamental  
17 limitation of the small PDV run samples derived from the reconstructions.

## 18 **4.2 Are run lengths stationary over the last millennium?**

19 With paleoclimate reconstructions becoming longer, questions arise whether the PDV run  
20 length has been stationary in the past millennium and whether a shorter paleoclimate reconstruction is  
21 representative of the full range of variability that has occurred in the past or of what is plausible in the  
22 future. The stationarity issue has been explored most PDV reconstructions used in this study. Biondi  
23 et al. (2001) identified weakened amplitude of bi-decadal oscillations in the late 1700s to mid-1800s.  
24 Based on reconstruction over 1700-1979, D'Arrigo et al. (2001) declared that variations at around 12-  
25 17 years are considerably more pronounced from 1700-1849 relative to 1850-1979 with a shift

1 towards decreased amplitude since about 1850. Using visual inspection, Gedalof and Smith (2001)  
2 stated that the 30-70 year PDV frequency is confined to the pre-1840 portion of the series over the  
3 period of 1599-1983. D'Arrigo and Wilson (2006) reported a broad range of lower (multi-decadal to  
4 centennial) frequencies over the 1565-1988 period. Shen et al. (2006) pointed out that the major PDO  
5 regime timescale modes of oscillation have not been persistent over 1470-1998 and that 75-115 year  
6 and 50 –70 year oscillations dominated the periods before and after 1850, respectively. Linsley et al.  
7 (2008) argued that decadal to inter-decadal variability in the south Pacific convergence zone region  
8 has been relatively constant over 1650-2004. MacDonald and Case (2005) presented evidence for a  
9 strong and persistent negative PDO state during the medieval period (AD 900 to 1300), suggesting a  
10 cool north eastern Pacific at that time. Mann et al. (2009) observed that the Little Ice Age (LIA, 1400  
11 to 1700) and the Medieval Climate Anomaly (MCA, 950 to 1250) showed extra variability and  
12 persistence, challenging the assumption of a stationary climate in the past millennium. The  
13 mechanism responsible for the extra variability and persistence in studies done by MacDonald and  
14 Case (2005) and Mann et al. (2009) is unclear and may be explained by centennial climate variability.  
15 It is unknown whether the PDV structure in the past millennium has remained stationary during  
16 periods that display extra variability and persistence. This issue can be investigated by filtering out the  
17 centennial trends.

18 All the above stationarity studies are based on single reconstructions. A further complication  
19 arises for reconstructions that only cover the last ~300-400 years where the underlying non-  
20 stationarity may be masked as a consequence of sampling variability or the sampling variability is  
21 misinterpreted as non-stationarity. To mitigate this, here we use only millennium-length records,  
22 Macd05 (993-1996), Mann09 (500-2006) and Vanc15 (1000-2003), in an attempt to obtain  
23 statistically meaningful conclusions on PDV stationarity. The millennium-length records are split into  
24 pre-1600 and post-1600 samples to explore whether run length characteristics are statistically similar  
25 in these two periods and to shed light on whether shorter records (either the ~100 year instrumental  
26 record or the 300-400 year paleoclimate reconstructions) are able to represent the full range of

1 variability. The year 1600 is selected as the change point because most of the shorter PDV  
2 reconstructions date back to ~1600 (refer to Table 1 and Figure 2 for details).

3 Figure 10 presents boxplots of pre-1600 and post-1600 run lengths: panel (a) presents  
4 boxplots of pooled pre-1600 and post-1600 run lengths, while panel (b) shows boxplots of pre-1600  
5 and post-1600 runs for each of the three millennium-length reconstructions. A consistent pattern  
6 emerges in which the median run length and interquartile range are greater in the pre-1600 period for  
7 both pooled samples (Figure 10a) and each individual reconstruction (Figure 10b).

8 Bearing in mind that the samples are small, a Gamma distribution was inferred for the pre-  
9 and post-1600 samples. Figure 11 presents the joint posterior distribution of the differences in the pre-  
10 and post-1600 means and standard deviations for each reconstruction using all run lengths. A  
11 consistent pattern once again emerges. For all three reconstructions the posteriors of the pre- and post-  
12 1600 differences lie in the lower left quadrant with the origin minimally intersecting with the posterior.  
13 Therefore, the evidence that there is a difference is visually strong.

## 14 **4.3 Discussion**

15 All of the reconstructions reported in Table 1 did not distinguish between positive and  
16 negative PDV runs in their analysis, except for Vance et al. (2015). Based on a millennium IPO  
17 reconstruction, Vance et al. (2015) found that IPO has an average positive phase ( $IPO > 0.5$ ) duration  
18 of 14 years and a negative phase ( $IPO < -0.5$ ) duration of 9 years over A.D.1000-2003, and concluded  
19 that positive and negative phases durations and frequencies were different in the last millennium. This  
20 is the first study that addresses positive and negative PDV runs separately. However, based on  
21 comparisons with other reconstructions our results show that there remains uncertainty as to whether  
22 or not the run lengths of positive epochs are statistically different to the run length of negative epochs.  
23 It is important to keep in mind that the analysis here is fundamentally limited by small PDV run  
24 length sample sizes from most of the reconstructions. Two theories may explain the absence of a  
25 consistent difference between positive and negative run distributions. One is that no statistically

1 meaningful differences exist and the other is that differences do exist but are masked by sampling  
2 variability. The latter seems plausible given the average number of phases (either positive or negative)  
3 per reconstruction are only 13.

4 All three millennium-length records lead to higher inferred run length mean and standard  
5 deviation in the pre-1600 samples, suggesting longer and more varied PDV runs during the period  
6 before 1600 AD. The fact that the differences in the mean and standard deviation of run lengths pre-  
7 and post-1600 appear to be statistically significant raises an important question, should the  
8 information from pre-1600 reconstructions be used to infer PDV behaviour in the near climate. If one  
9 adopts a gradualist view of climate non-stationarity, the immediate past would be considered more  
10 representative of the present than the more distant past. Setting aside for the moment the possibility  
11 that the climate-proxy relationship may be not be stationary, the gradualist perspective would support  
12 discarding the information from the pre-1600 reconstruction on the grounds that it introduces bias  
13 when inferring a statistical model of near climate PDV runs. We offer two reasons opposing this  
14 perspective.

15 First, there is no assurance that climate non-stationarity evolves in a gradual manner so that  
16 PDV behaviour in the near climate is better represented by the post-1600 climate than the pre-1600  
17 climate. Indeed there is evidence to the contrary, namely that non-stationarity may be characterized by  
18 seemingly shorter-term shifts. Ho et al. (2017) found that American streamflow in the twentieth  
19 century featured longer wet and dry spells compared to the preceding 450 years, suggesting the  
20 possibility of occurrence of extended dry or wet periods in the future that exceeds variability  
21 presented in instrumental and short (i.e. < 500 years) paleoclimate reconstructions. Similar  
22 conclusions are also drawn in other studies (Vance et al., 2015;Tozer et al., 2016;Ho et al., 2015b, a).

23 Second, the inclusion of pre-1600 records offers a significantly larger sample of run lengths  
24 and therefore is more likely to capture the full range of what is plausible. Extended wet/dry periods  
25 considered as rare and extreme (or even impossible) based on recent (i.e. instrumental) history might  
26 actually be more likely than thought (or even common) when put into context of climate conditions

1 seen over the last 1000-2000 years. Even if one accepts the gradualist view of non-stationarity, the  
2 increased information about PDV more than outweighs the potential bias arising from the use of an  
3 apparently statistically inconsistent record. At least until such time as it is proven that the climate has  
4 totally shifted and that what occurred in the past is no longer possible – also required is identification  
5 of when that shift occurred.

6         It is therefore clear that in addition to short instrumental records inadequately sampling the  
7 length and severity of dry/wet epochs, the shorter paleoclimate reconstructions may similarly  
8 misrepresent hydroclimatic variability and persistence. For instance, from Ho et al. (2015a), when  
9 using the period 1684–1980, both the driest and wettest instrumental decadal rainfall lies closer to the  
10 middle of the minimum and maximum decadal reconstructed rainfall range. However, using the same  
11 method, Ho et al. (2015a) found that when 2751 years of reconstructions were examined, the wettest  
12 instrumental decadal rainfall is near the bottom of the maximum decadal reconstructed rainfall range,  
13 while the driest instrumental decadal rainfall is near the top of the minimum decadal reconstructed  
14 rainfall range. This suggests that statistics inferred from either instrumental data or short paleoclimate  
15 reconstructions will underestimate the variability contained in the longer palaeoclimate  
16 reconstructions. Therefore, research focused on developing and analysing information about  
17 hydroclimatic conditions over the last 1000 years or more (e.g. multi-millennium paleoclimate  
18 reconstructions) is critical if we are to better understand, quantify and manage the full range of  
19 hydroclimatic variability, and associated risks, that are possible in the future.

20         This study is affected by two fundamental limitations. One is the small PDV run sample size  
21 from the reconstructions. For instance, the average number of phases (either positive or negative) per  
22 reconstruction are only 13. Another limitation is that all statistical signatures are based on  
23 paleoclimate reconstructions. Although multiple reconstructions are used, this study is constrained by  
24 the intrinsic limitations of paleoclimate reconstruction based interpretations, such as assumptions of  
25 stationarity of the proxy-climate relationship (Phipps et al., 2013). The possibility that all these

1 reconstructions are biased in the same direction cannot be ruled out and as such conclusions based on  
2 multiple reconstructions may also be biased.

## 3 **5. Conclusions**

4 PDV, and associated run lengths of predominantly dry or wet conditions, has profound  
5 implications for precipitation/streamflow prediction, flood/drought risk assessment and water resource  
6 management. Therefore, a better understanding of the statistical characteristics of PDV is needed.  
7 However, because instrumental records are short (~100 years at best in Australia), there is  
8 considerable uncertainty about the key statistical signatures of PDV, including run lengths.  
9 Paleoclimate reconstructions, serving as a vehicle to provide longer realizations of PDV, have been  
10 widely studied and used. However, for various reasons (e.g. proxy sources, site locations, proxy  
11 resolutions, reconstruction methods and local non-PDV effects) temporal coherence between different  
12 reconstructions varies significantly (Kipfmüller et al., 2012). Hence, one PDV reconstruction may  
13 lead to significantly different conclusions from another reconstruction.

14 The aim of this paper was to explore the characteristics of key statistical signatures of PDV  
15 based on multiple PDV reconstructions. We focused on the duration of dry or wet hydrological  
16 epochs (i.e. run lengths) as the key statistical signature and developed a robust method for extracting  
17 run lengths from multiple reconstructions. Extracting run lengths objectively is challenging, given  
18 interactions with sources of variability on a variety of temporal and spatial scales. For instance, when  
19 millennium-length reconstructions are used, variability and persistence at the centennial scale can lead  
20 to biased characterisation of decadal climate variability. The dynamic threshold framework introduced  
21 in this study, which takes centennial trends into consideration, was shown to extract meaningful run  
22 length information from multiple reconstructions.

23 No strong evidence was found to support the assumption that run lengths have statistically  
24 different distributions during positive and negative PDV phases. Analysis based on three millennium  
25 long reconstructions suggests that it is more likely than not that PDV run length has been non-

1 stationarity in the past millennium. This again highlights that the instrumental record (~100 years at  
2 best), and even short paleoclimate reconstructions (i.e. less than 400 years into the past), should not be  
3 assumed to represent the full range of variability that has occurred in the past or what may occur in  
4 the future. Caution should be exercised regarding assumptions that the climate is stationary and the  
5 implications of a non-stationary climate should at least be tested. Longer climate reconstructions (i.e.  
6 1000 years or more) appear to give more useful information and insights into what has occurred in the  
7 past and also tell us more about what is plausible and what needs to be planned for in the future.

8 All of the reconstructions explored in this study have focused on the run length of PDV, yet  
9 they have provided quite different run length characterizations. This again highlights that each  
10 reconstruction is subject to errors, both random and systematic, that are not fully understood.  
11 Therefore, a challenging and important research direction is the analysis of run length characteristics  
12 with explicit consideration of the errors. Another important research direction is the continued  
13 refinement of methods that utilize PDV information in water resource management as we work  
14 toward improving how we assess and manage hydrological risks in a variable and changing climate.

# 1 Tables

2 **Table 1 Available PDV paleoclimate reconstructions and their descriptions**

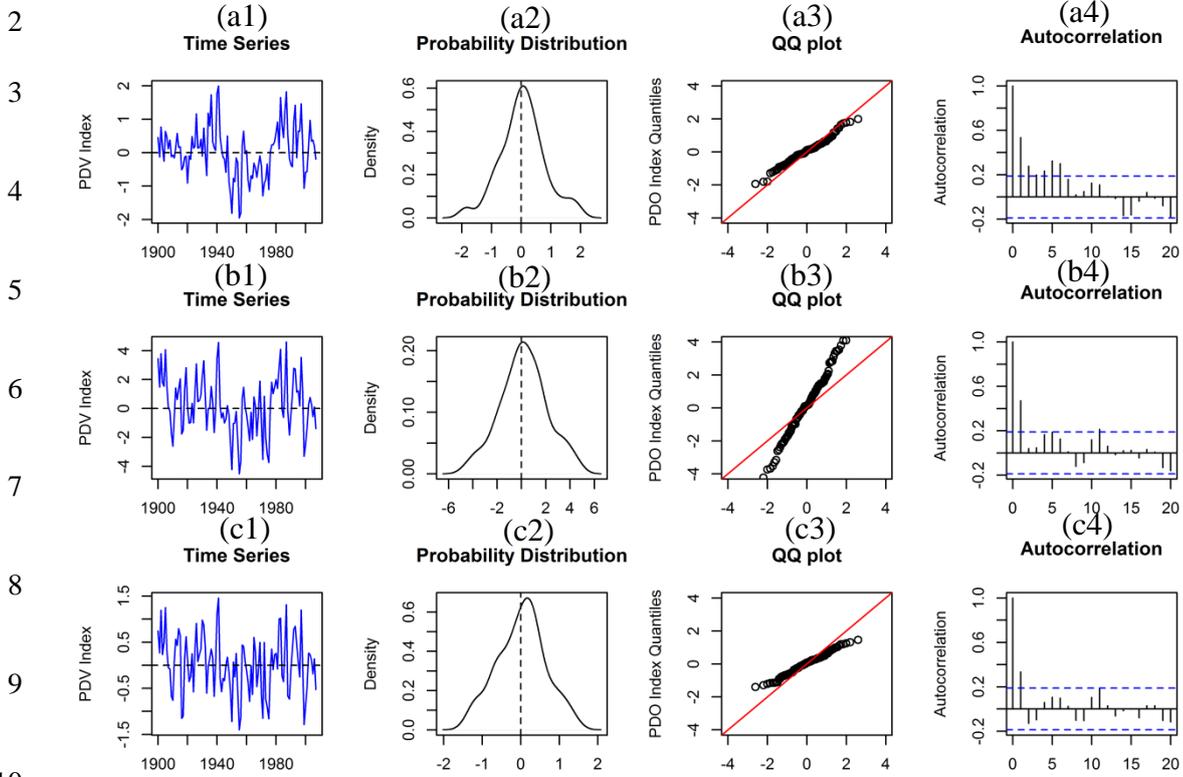

Reconstruction	Abbreviation	Period	Location	Proxy
Biondi et al. (2001)	Bion01	1661-1991	North Pacific (North America)	Tree ring based PDO
D'Arrigo et al. (2001)	Darr01	1700-1979	Northeast Pacific (Western North America)	Tree ring based PDO
Gedalof and Smith (2001)	Geda01	1599-1983	North Pacific (Coastal western North America)	Tree ring based PDO
MacDonald and Case (2005)	Macd05	993-1996	North Pacific (South California and Canada)	Tree ring based PDO
D'Arrigo and Wilson (2006)	Darr06	1565-1988	North Pacific (Eastern Asian)	Tree ring based PDO
Shen et al. (2006)	Shen06	1470-1998	Western North Pacific (Eastern China)	Proxy data of Summer Rainfall
Verdon and Franks (2006)	Verd06	1662-1998	Both North and South Pacific	Other reconstructions based PDO
Linsley et al. (2008)	Lins08	1650-2004	South Pacific (Fiji and Tonga)	Oxygen isotope from coral cores based IPO
Mann et al. (2009)	Mann09	500-2006	Global	Global tree ring, ice core, coral, sediment, and other assorted proxy records
McGregor et al. (2010)	Magr10	1650-1977	Global	low frequency variability of the proxies of ENSO
Henley et al. (2011)	Hen11	1471-2000 (filtered)	Both North and South Pacific	Other reconstructions
(Vance et al. (2015))	Vanc15	1000-2003 (filtered)	East Antarctica	Law Dome ice core based IPO

# 1 A list of figure captions

- 2 Figure 1 Annual instrumental time series, probability density plot, QQ plot and autocorrelation plot:  
3 (a): PDO from Mantua (1900-2015); (b): IPO from Parker (1871-2007); (c): IPO from Henley (1870-  
4 2007)
- 5 Figure 2 Run length time series extracted using the dynamic and static threshold methods for  
6 reconstructions with centennial trends
- 7 Figure 3 Comparison of run length distributions extracted using the dynamic and static threshold  
8 methods in reconstructions with centennial trends
- 9 Figure 4 Boxplot of run lengths samples from all reconstructions with different window width in  
10 Mann-Whitney method
- 11 Figure 5 Time series plots of different instrumental PDV indices and corresponding run lengths  
12 (represented by dots in corresponding colour) extracted using different window: (a) 10; (b) 20; (c) 30;  
13 (d) 40 years
- 14 Figure 6 Density plot of run length samples by applying different window widths to all  
15 reconstructions, (a1-a3): comparison between window width 20 and 40, in which (a1) is unconditional  
16 run length distribution, panel (a2) is the distribution conditioned on run lengths less than 20 years and  
17 panel (a3) is the distribution conditioned on run lengths greater than 20 years; (b1-b3): comparison  
18 between window width 20 and 60, in which (b1) is unconditional run length distribution, panel (b2) is  
19 the distribution conditioned on run lengths less than 30 years and panel (b3) is the distribution  
20 conditioned on run lengths greater than 30 years
- 21 Figure 7 Filtered PDV reconstruction time series (black line) with extracted run length (red line)
- 22 Figure 8 Boxplot of run lengths samples from different reconstructions: (a) all run lengths for each  
23 reconstruction; (b) pooled positive (grey) and negative (white) run lengths; (c) positive (grey) and  
24 negative (white) run lengths for each reconstruction
- 25 Figure 9 Density and scatter plots of the differences between mean and standard deviation of positive  
26 and negative run length simulations (positive minus negative)
- 27 Figure 10 Boxplot of run lengths samples from different reconstructions (white box indicates pre-  
28 1600 and grey box indicates post-1600): (a) pooled run lengths from all three reconstructions; (b) run  
29 lengths for each reconstruction
- 30 Figure 11 Density and scatter plots of the differences between mean and standard deviation of pre-  
31 1600 and post-1600 run length simulations (post-1600 minus pre-1600): (a) Macd05; (b) Mann09; (c)  
32 Vanc15
