Thank you for all the comments and questions regarding to our submission to HESS: Hydrological functioning of West-African inland valleys explored with a critical zone model". Many thanks to the four reviewers who raised relevant questions that we hope to address in this final response. We will mainly gather previous replies written in the debate phase and add our suggestions for changes in the manuscript.

5 Specific changes made in response to reviewers comments are noted in the following. We also corrected as much as possible grammar and typos issues, and we made some minor changes to help reading the manuscript.

RV#1
1. The experiments with low-K layers were interesting and provided some counter-intuitive findings. Did the authors
10 **conduct any experiments where the layers were discontinuous? If not, can they comment about how this might impact results?**

=> Concerning the potential impact of discontinuous layers, this would indeed be an interesting study in itself. There is an extensive literature on the topic, including with the same model (Atchley & Maxwell, 2011, Meyerhoff & Maxwell, 2011,
15 Meyerhoff et al., 2014, Gilbert et al., 2016, among others). The target of the study was essentially to not focus on local heterogeneity to extract the main features and main behaviors of inland valleys.

However, there are still some discussion points that we should include in the paper:
- We have noted the presence of dual-porosity soils, which we do not take into account in this study. It is likely that the
20 dampening effect of the unsaturated clays contribute to play this role.
- The valley thalweg is oversimplified, and the lack of recharge of the permanent water table by direct infiltration (see Fig. 4.a), is probably due to the homogeneity of the valley thalweg material, while in the real world, heterogeneity and clay lens topography certainly impact the spatial distribution of recharge, as explained p.12 l.19-22.
- Figure 4.a and 4.b belong to different simulations, although both associated data are real world data of the same catchment.
25 This means that we actually still miss some features: if we set a 'higher' permeability to the valley banks, it will result in the filling of the permanent water table in the valley thalweg, which is not observed. To successfully match the observations, we would definitely have to include lateral variations in permeability. But again, this was not the target of this study.

Modifications in the manuscript:
30
P. 5 L 7.: 'There is an extensive literature, using the same critical zone modeling framework that provides insights on the effect of lateral variability of soil properties through dedicated sensitivity studies (Atchley & Maxwell, 2011, Meyerhoff & Maxwell, 2011, Meyerhoff et al., 2014, Gilbert et al., 2016).'

35 P19 L 21:
Furthermore, one should note that Fig. 4.a and 4.b show results from different simulations (reference and saprolite, respectively), although both associated water table levels are real world data of the same catchment. This means that some features are still missing in order to comprehensively reproduce the behaviors of this specific catchment. If a high permeability is set to the valley banks (as in the saprolite simulation), it will result in the filling of most of the valley thalweg
40 by the permanent water table and the absence of the perched water table, which is not observed. On the opposite, in the low permeability scenario (reference simulation), the simulated water table on the valley banks mismatches the observed data. To successfully match all the observations, lateral variations in the permeability are needed, but this was not the target of this study, which was instead the extraction of main features and behaviors of inland valleys.

2. Domain geometry. Did the authors experiment with other domain configurations? It would be interesting to see how changes in slope for the v-catchment "banks" changed response. Do the choices in slope represent something in the real catchment?

15

=> As stated P.9 L14-15, 'topographic slopes are gentle (mean N-S and E-W slopes correspond to those imposed on the virtual V-shaped catchment).'. This comment is shared with RV2, and we will provide more response below (in final response to RV2), together with manuscript changes suggestions.

20   **3. Boundary conditions. Perhaps I missed it, but how were the boundaries set for the tilted-V catchment? Did this have an impact on e.g. water table dynamics and fluxes?**

=> No-flow boundary conditions where applied over the catchment sides (as stated P. 7 L. 22), but we did not precise that a no-flow boundary condition is also applied to the bottom of the catchment. We could add this precision. This choice is
25   backed-up by the limited regional gradient as explained by 1) the low fracture connectivity within the bedrock (El Fahem et al., 2008) and 2) the low transverse hydraulic gradient at the larger scale (gradient of 0.01 m/m over about 3km) showing very little variations between the dry and the wet season, and suggesting limited larger-scale transverse flow which would affect the boundary conditions. These numbers are based on Hama Garba's Msc thesis (Hama Garba, 2016), available upon request.

30

Modifications in the manuscript:
- P7. L-22: 'No-flow boundary conditions are applied on the catchment edges (symmetric assumption) and bottom.

RV#2
35   **It is not clear from the manuscript how the slopes of the tilted-v catchment (4% and 2% in Y- and X-directions, respectively) are representative of the real topography? This is important because the authors are using ParFlow, which is a 3D variably saturated surface water/groundwater flow model. The water flow in this model is dominated by topography. The authors presented the comparisons between observations and simulation results. How much does the representation of the topographic slopes contribute to the differences between the observed and simulated fluxes?**
40   **Moreover, without a comprehensive representation of the real topography or justification of the considered topographic slopes, how can this be assured that the hydrological processes of the simulated tilted-v are representative of those of the actual catchment? Reasonable agreements between the observations and simulation results do not answer all these questions. Is it worthwhile to consider the real topography (which is very possible as ParFlow-CLM is a distributed model) of the area rather than a tilted-v catchment with arbitrary slopes? These issues**
45   **should be clarified in the manuscript before publication.**

=> Both two reviewers (#1 & #2) had relevant interrogations about the impact of topography on the generalization of the results presented in this study.

Although we specified that the V-shaped (virtual) catchment slopes correspond to the actual slopes of the reference inland valley of Nalohou (P.9 L. 14: "(mean N-S and E-W slopes correspond to those imposed on the virtual V-shaped catchment)"), it is clear that more details should be provided.

5 Nalohou catchment has been surveyed with double-difference GPS campaigns to provide accurate topography at 5m resolution. Local mean N-S & E-W slopes come from such dataset.

At the Upper Oueme catchment scale (14 000 km2), comprising many more inland valleys (Giertz et al., 2012), a quick slope analysis from 3" (about 90m) Hydrosheds DEM provided an average slope of 2.6 %. On nearby Togo in similar
10 geomorpholigical context (Région centrale, 13000 km2), Runge (1991), noted that 80% of surface have slopes comprised in the range 1.7 – 5.2 %. They further identified inland valley to develop preferentially in the range 3.0 – 4.4 % along the steepest axis.
The transverse axis (X in our case) ranges from 1.7 to 3.5% and the longitudinal axis (Y) from 3.5 to 5.2%. These numbers are very close to our virtual catchment (X: 2% Y: 4%).
15
Despite this relevance with respect to other (including larger scales) inland valleys, we wanted to check the impact of slopes on simulation results (budgets, and agreement to observations, as suggested by reviewers. We have not had the time to conduct the virtual experiments so far but could do so if needed.

20 going further than our previous reply, we ran two more simulations using the reference case, and multiplying the slopes by a factor 2 and a factor 0.5. The results are given below in terms of mean + standard deviations over the 6 years period for the different budget components. Other test cases are presented for comparison.

	ET (mm)	Q (mm)	S (mm)
reference	839 ± 64	454 ± 151	8 ± 26
No Inland valley	830 ± 64	463 ± 153	8 ± 24
trees	944 ± 53	361 ± 144	-5 ± 54
herb	791 ± 72	500 ± 151	10 ± 17
saprolite	793 ± 60	495 ± 153	13 ± 36
mixed	816 ± 62	475 ± 154	10 ± 28
Slope ref x 0.5	**933 ± 62**	**354 ± 154**	**14 ± 28**
Slope ref x 2	**773 ± 64**	**526 ± 157**	**1 ± 21**

25 Table 1: summary of the annual average and standard deviation for the 6 simulated years and for each budget component. Reference case with slopes multiplied by 0.5 and 2 are also shown.

There is an insignificant impact on the interannual variability (standard deviation), but a significant impact on yearly averages. The slope values taken in this short experiment are extreme cases as compared to the regional topography where inland-valleys are found (see previous comment). Yet their impact is comparable to the impact of vegetation distribution
30 (trees case ~ slope ref x0.5 ; herb case ~ slope ref x2). Lower slopes (resp. higher) decrease (resp. increase) lateral transfers to the benefit (resp. cost) of evapotranspiration. This short analysis can be added to the paper, together with the references

given in our previous reply to comments. We also ran a simulation with the real topography which show water budgets within those ranges, but we do not wish to include it directly to the paper as this is too specific to this catchment.

The goal of the paper is not to reproduce absolutely the behavior of our benchmark catchment say, by using the real topography, as we want to derive the controlling factors of inland valley critical zone systems -through virtual experiments- among factors that are either susceptible to evolve (land cover), that characterize inland valleys (thalweg clay lens) or are still largely unknown (subsurface lithology). To this respect, slopes are not unknowns nor susceptible to evolve much (as land cover which have been observed to change significantly, and are also projected to do so) and are not targets of this study. However, catchment slopes may significantly impact the water budgets as shown by these two experiments, and impact our ability to generalize the inland valley functioning based on this study only.

Modifications in the manuscript:

P6. L.6. add a section: 2.1.2: Topography:
At the Upper Oueme catchment scale (14 300 km², which includes the Nalohou area), comprising many inland valleys (Giertz et al., 2012), a slope analysis from the 3" (about 90m) Hydrosheds DEM (www.hydrosheds.org) provided an average slope of 2.6 %. On nearby Togo in similar geomorphological context (Région centrale, 13000 km²), Runge (1991), noted that 80% of the surface have slopes comprised in the range 1.7 – 5.2 %. The slope along the transverse axis ranges from 1.7 to 3.5% and from 3.5 to 5.2% along the longitudinal axis. They further identified inland valleys to develop preferentially in the range 3.0 – 4.4 % along the steepest axis. For the specific Nalohou catchment, mean longitudinal slope (N-S) is 4% and mean transverse (E-W) slope is 2%, according to a 5m lateral resolution DEM derived from DGPS survey, as described in Hector et al., (2013).

P19. L.22. add a section: 4.4: Discussion on topographic impacts on water budgets

The goal of the paper is to derive the controlling factors of inland valley critical zone systems -through virtual experiments- among factors that are either susceptible to evolve (land cover), that characterize inland valleys (thalweg clay lens) or are still largely unknown (subsurface lithology). To this respect, slopes and topographic effects are not unknowns nor susceptible to evolve much (as land cover which have been observed to change significantly, and are also projected to do so) and are not targets of this study. However, as topography drives lateral flow, catchment slopes may significantly impact the water budgets. We ran two experiments, using the reference case, and multiplying the slopes by a factor 2 and a factor 0.5 to extract the effect of extreme topography ranges found in this environment (Runge, 1991). Table 7 compares the results from these experiments to the reference case and show that there is weak impact on the interannual variability (standard deviation), but a marked impact on yearly averages. The impact of slopes is comparable to the impact of vegetation distribution (in Table 6: Trees case ~ slope ref x0.5 ; Herbaceous case ~ slope ref x2). Lower slopes (resp. higher) decrease (resp. increase) lateral transfers to the benefit (resp. cost) of evapotranspiration.

reference	839 ± 64	454 ± 151	8 ± 26
Slope ref x 0.5	933 ± 62	354 ± 154	14 ± 28
Slope ref x 2	773 ± 64	526 ± 157	1 ± 21

Table 7: Interannual mean and standard deviation of simulated evapotranspiration (ET), streamflow (Q) and storage (S) for the period 2007-2012 for the reference case and two extreme slope cases

RV #3
1. The authors state that this is a synthetic study of an elementary catchment, however, which is based on their best knowledge and a plethora of data of the real system. In addition, the model is validated quite comprehensively. This is not consistent. In my opinion, the authors present a well-informed case study and not a synthetic study, which needs to be made clear in the text. If [the authors] seek generalization of their results beyond their test site (and I feel that is what they suggest with the term elementary catchment) they need to find a way to make the results transferable and show this by applying their findings to inland valley across the region.

=> In the text, the two occurrences of 'synthetic' refer to a generic virtual elementary catchment comprising an inland valley (as in P3. L18: 'idealized elementary V-shaped catchment'), designed for generalization, and regardless of the "well-informed case study", which we use to draw schematic configurations to build virtual experiments, also based on our knowledge and literature review of other inland valleys configurations. From these results we draw conclusions on the sensitivity of such critical zone system to its unknown and likely-to-evolve components (vegetation, clay lens, lithology). We will remove occurrences of 'synthetic', which are misleading.

'Elementary' refers to the usual term : the smallest catchment (two hillslopes) draining into first order streams. The modeled synthetic case is built based on our knowledge of inland valleys. The model is not intended to reproduce every single inland valley behavior, but instead draw the first order lines of the impact of main inland valleys characteristics (clay lens), of their sensitivity to changes (in land cover) and to largely unknowns parameters (susbsurface lithology). We reckon that further explanations should be added to the abstract, introduction, and conclusion. We also hope that the references added on topography (see reply to reviewer #1 & #2 above), and on similar hydrological behavior from the inputs of reviewer #4 (see below) further help the understanding of the framework.

Modifications in the manuscript:
Abstract. L17: replace 'synthetic' by 'virtual generic'
Abstract. L.17: Model forcings are based on 20 years data from the AMMA-CATCH observation service and parameters are evaluated against multiple field data (Q, evapotranspiration –ET-, soil moisture, water table levels, and water storage) acquired on a pilot elementary catchment. The hydrological model applied to the conceptual lithological/pedological model proposed in this study reproduces the main behaviors observed, which allowed conducting those virtual experiments ~~on a highly instrumented elementary catchment., allowing to further conduct virtual experiments~~:

P3. L19: replace:
'This deterministic modeling approach largely builds on the large panel of observations available within the AMMA-CATCH observation service (www.amma-catch.org (Galle et al., Submitted; Lebel et al., 2009) and several campaigns, as well as on a highly instrumented elementary catchment for which we previously built a conceptual lithological/pedological model (Hector et al., 2015).'
In the first section, we briefly discuss the physical environment and how we model it using a physically-based CZ model. Then, we present the results of a reference case, which are compared to observations from an elementary headwater catchment in the hard-rock area of the Sudanian region, to show that the model is able to reproduce to a large extent the complex critical zone behavior. We finally use the results of a set a virtual experiments to infer the model sensitivity to the main inland valley features (presence of a clay layer, hydrodynamic properties of the contributive areas, vegetation distribution), and discuss these results.

by

' This idealized elementary V-shaped catchment is built based on the main features of elementary catchments comprising an inland valley in the region (topography, clay lens, vegetation distribution), but also following a highly instrumented elementary catchment for which we previously built a conceptual lithological/pedological model (Hector et al., 2015).

5   In the first section, we briefly discuss the physical environment and how we model it over a 7-years period using a physically based CZ model. Then, we present the results of a single simulation, which are compared to observations from the elementary headwater catchment, available within the AMMA-CATCH observation service (www.amma-catch.org, Galle et al., 2018; Lebel et al., 2009) and several campaigns, to show that the model is able to reproduce to a large extent the complex critical zone behavior. We finally use the results of a set of virtual experiments to infer the model sensitivity to the main inland valley

10 features (presence of a clay layer in the valley thalweg and hydrodynamic properties of the contributive areas) and the vegetation distribution, likely to evolve, and discuss these results.'

15 P7. L13:Y-direction slope is 4 % and X-direction slope is 2 %, **following Runge (1991) and specific values for the Nalohou catchment.**

P19. L23: replace:
'In this paper, we studied the hydrological functioning of Sudanian inland valleys and their sensitivity to land cover and
20 contributive areas through deterministic sensitivity experiments using a physically-based critical zone (CZ) model applied on a synthetic catchment which comprises an inland valley. This is a first approach to try to investigate what can control and explain the behavior of an inland valley.'

By:
25 'In this paper, we studied the hydrological functioning of Sudanian inland valleys and their sensitivity to land cover and their main features (pedology of contributive areas, clay lens), through deterministic sensitivity experiments using a physically-based critical zone (CZ) model applied on a virtual generic catchment which comprises an inland valley. This is a first approach to try to understand what controls and explains the behavior of an inland valley.'

30
3.**Define the length of the time series earlier in the text.**
=> Done in the introduction: see modification P3. L19

35 **4. The forcing is homogeneous over the model domain?**
=> The meteorological forcing is indeed homogeneous over the domain. The domain extent is small enough to justify this. We will mention this precision in the text, thank you!

Modifications in the manuscript:
P8. L15: PFCLM is being forced at a 30 mn time step, over the 7-years period 2006-2012, **with spatially homogeneous**
40 **forcings.**

5. Is it evaluation or validation data; please check section title

=> The data is evaluation data (as in section 2.5 title): we will replace the single occurrence of 'validation' by evaluation because this is indeed evaluation of a synthetic case. Thanks much for pointing that out.

7. I would prefer Sudanian Savanna instead of Sudanian area.

=> We will replace Sudanian area by Sudanian Savanna.

8. In the EOF analyses, I assume that additional modes do not show any useful information, which I find disappointing, because I would have expected perhaps also some variance over longer time scales in storages in the 7 year time series. The annual signal is clear, which is not surprising.

=> Mode 2 accounts for about 8% of the total variance, and this is why we did not discuss it. However, you are right, the interanual storage variations are present in this mode, but together with some residuals at the seasonal level. As our hybrid gravity data only covers 2 years, which is limited for interanual terms comparison, and because of the low level of variance explained (there is much more signal at the seasonal level than the interanual one), we did not choose to show other modes than mode 1. We will add a line to mention the content of mode 2, as explained above.

Modifications in the manuscript:

P12. L4. Mode 2 accounts for about 8% of the total variance, and although we do not discuss it in the current study, one should note that interannual storage variations together with some residuals at the seasonal level are present in this mode.

RV #4

1. With the information provided, it is basically impossible to reproduce any results. There are some tables with parameters but it would be so much easier if the complete code and data were made available, preferably as a Docker container. Where are the the topographic data? Where are the measurement values? Which version of ParFlow was used (why not link to the code?)? See, for example, the article "Most computational hydrology is not reproducible, so is it really science?" (https://doi.org/10.1002/2016WR019285). This is a serious issue within hydrology and I would urge the authors to spend some time carefully curating their code and data. This would greatly improve usability and uptake of their approach.

=>Thank you for pointing that out. We tagged the version of ParFlow-CLM we used to run the simulations (on Github) and will provide the link (https://github.com/basileh/parflow/releases/tag/v3.3.1-IGE) in the article. Input data and ParFlow configuration script will be made available upon request, together with a Docker image (too large to provide with the paper anyway) that allows to run the model in the same configuration as for the paper.

Modification in the manuscript:

P.7 L.9. We used the tagged version v3.3.1-IGE (https://github.com/basileh/parflow/releases/tag/v3.3.1-IGE).

P.7 L26. Forcing data is obtained from the Benin site of the AMMA-CATCH observatory, and is available on the data portal (http://db.amma-catch.org).

2. It is stated that a complete study would be needed to describe the effects of H2. I agree but perhaps tell the reader a bit more about the geology. Is the geology metamorphic or granitic? The work by Bertrand may be useful here with a nice overview presented in Sitapha Diatta's work on impermeable layers in inland valleys (http://docnum.univ-lorraine.fr/public/SCD_T_1996_0043_DIATTA.pdf). Being familiar with their work, I can still not determine if the Nalohou is similar or completely different. So please add some morphological/geological information.

=>The Geology is metamorphic, thank you for pointing out this omission.

Many thanks also for the reference given, which we did not know, but significantly strengthen the current study. This inland valley study describes the same hydrological behavior between the perched water table and the permanent water table : a disconnexion in the valley thalweg and some lateral connexion upstream, as described in Figure 13 in Hector, B., Séguis, L., Hinderer, J., Cohard, J.-M., Wubda, M., Descloitres, M., Benarrosh, N. and Boy, J.-P.: Water storage changes as a marker for base flow generation processes in a tropical humid basement catchment (Benin): Insights from hybrid gravimetry, Water Resour. Res., doi:10.1002/2014WR015773, 2015.

We will discuss our settings and results with respect to their study.

Modifications in the manuscript:

P4. L3: In this section, we briefly describe our conceptual representation of the main soil and vegetation characteristics found in the hard-rock basement areas of the Sudanian climatic region (yearly precipitation amount between 700 and 1400 mm), **dominated by metamorphic settings.**

P4. L11: this specific behavior is representative of inland valley functioning in similar geological/climatic context (see e.g. Brabant, 1991 in Cameroun or Diatta, 1996 in Ivory Coast)

Hydrological functioning of West-African inland valleys explored with a critical zone model

Correspondence to: Basile Hector (basile.hector@ird.fr)

Abstract. Inland valleys are seasonally waterlogged headwater wetlands, widespread across West-Africa. Their role in the
10 hydrological cycle in the humid, hard rock-dominated Sudanian ~~area~~ Savanna is not yet well understood. Thus, while in the region recurrent floods are a major issue, and hydropower has been recognized as an important development pathway, the scientific community lacks a precise knowledge of streamflow (Q) generation processes and how they could be affected by the presence of inland valleys. Furthermore, inland valleys carry an important agronomic potential, and with the strong demographic rates of the region, they are highly subjected to undergo land cover changes. We address both the questions of
15 the hydrological functioning of inland valleys in the Sudanian ~~area~~ Savanna of West-Africa and the impact of land cover changes on these systems through deterministic sensitivity experiments using a physically-based critical zone model (ParFlow-CLM) applied on a ~~synthetic~~ virtual generic catchment which comprises an inland valley. Model forcings are based on 20 years data from the AMMA-CATCH observation service and parameters are evaluated against multiple field data (Q, evapotranspiration –ET-, soil moisture, water table levels, and water storage) acquired on a pilot elementary catchment. The
20 hydrological model applied to the conceptual lithological/pedological model proposed in this study reproduces the main behaviors observed, which allowed conducting those virtual experiments. ~~on a highly instrumented elementary catchment.~~ We found that yearly water budgets were highly sensitive to the vegetation distribution: average yearly ET for a tree-covered catchment (944 mm) exceeds that of herbaceous-cover (791 mm). ET differences between the two covers vary between 12 and 24 % of the precipitation of the year for the wettest and driest year, respectively. ~~As a consequence~~Consequently, the tree-
25 covered catchment produces a yearly Q amount~~budget~~ 28 % lower on average as compared to ~~a~~an herbaceous-covered catchment, ranging from 20 % for the wettest year to 47 % for a dry year. Trees also buffer interannual variability in ET by 26 % (with respect to herbaceous). On the other hand, pedological features (presence -or absence- of the low permeability layer commonly found below inland valleys, upstream and lateral contributive areas) had limited impact on yearly water budgets but marked consequences on intraseasonal hydrological processes (sustained/non-~~un~~sustained baseflow in the dry season,
30 catchment water storage redistribution…). Therefore, subsurface features and vegetation cover of inland valleys have potentially significant impacts on downstream water-dependent ecosystems and water uses as hydropower generation, and should focus our attention.

1 Introduction

It is widely recognized that wetlands exert a strong influence on the hydrological cycle. However, they hardly support generalization in their functioning, according to their different types and settings, and the limited available hydrological observations (Bullock and Acreman, 2003). In Sub-Saharan West-Africa, "Bas-fonds", or inland valleys, are seasonally waterlogged wetlands located at the headwater of streams and cover 22-52 Mha (Andriesse et al., 1994). They can be found in the whole continent, although they hold different names, such as dambos, mbuga, inland valleys, or valley bottoms. Their role in the hydrological cycle is still unclear and lacks significant attention. This is particularly true for the humid Sudanian zone, mostly located on hard-rock lithology with rather shallow water tables and low-capacity aquifers (MacDonald et al., 2012) where all components of the critical zone are tightly linked (e.g. trees roots systems are likely to be connected to the water tables (Mamadou et al., 2016; Richard et al., 2013)). There, for instance, the role of inland valleys in streamflow generation is still poorly understood, while they are suspected to provide most of the observed streamflow as baseflow through exfiltration of perched seasonal water tables (Séguis et al., 2011).

Streamflow generation mechanisms deserve more attention, as (1) the region suffers severe floods, which affect an increasing number of people (Di Baldassarre et al., 2010) and (2) hydropower development is also undergoing (Cervigni et al., 2015) and is recognized to be a fundamental large scale source of energy for the development of Sub-Saharan Africa (http://www.worldbank.org/en/topic/hydropower/overview, April 2018) (World Bank, 2009).

Moreover, the strong West-African demographic rates (2.6 % on average in the period 2000-2010) imply rapid changes in land use and land cover (LULC) (FAO, 2012). For instance, about 42 % (respectively 8 %) of forested land (respectively non-forested vegetation) have been converted into agricultural land (which amount to an increase of more than 11 %) in the Sudanian area Savanna between 1975 and 2000 (Eva et al., 2006). This is also likely to affect the functioning of inland valleys, although it is yet unknown to what extent.

Despite the possible role of inland valleys in the hydrological cycle, they carry an important agronomic potential currently underexploited (Katic et al., 2014; Rodenburg et al., 2014). Due to their high water content, they can be cultivated offseason, and thus buffer the high climatic variability of the area (Nyamadzawo et al., 2015), as well as human pressure on uphill plots located closer to the villages (Lounang Tchatchouang et al., 2014). However, inland valley exploitation limits should be carefully studied, as over-exploitation may have consequences on these specific ecosystems (Böhme et al., 2016; Brouwer et al., 2014; Wood, 2006). Rodenburg et al. (2014) estimate that production derived from less than 10 % of the total inland valley area over Africa could meet the total current demand for rice in Africa. In these studies, little is mentioned about water exploitation sustainability. This is due to the heterogeneity of inland valleys and the difficulty to capture fundamental hydrological processes to be generalized. This again calls for documenting water redistribution processes within inland valleys, so as to include water use sustainability in the process of inland valleys selection and cultivation (Böhme et al., 2016; Schmitter et al., 2015).

Headwater inland valleys are characterized by a rapid decrease of permeability with depth due to the accumulation of clays, which is ultimately associated to a low permeability layer, allowing the formation of perched water tables in the valley thalweg (Blavet, 1997; Brabant, 1991; Hector et al., 2015; von der Heyden and New, 2003; Von Der Heyden, 2004). The hydrology of inland valleys is also controlled by classical catchment features like vegetation distribution and the functioning of ~~upstream~~

5   contributive area~~s~~ (Von Der Heyden, 2004). For instance, concerning vegetation distribution, Balek (2006) reports on increased flood flow when trees were removed from two of their observed catchments. The fast LULC changes occurring today call the scientific community to clearly understand the role of different vegetation distribution and the impact of their changes on the hydrology of inland valleys. These interactions between flow generation and vegetation require studying the hydrological functioning of inland valleys in an integrated, critical zone (CZ)-like approach. Concerning contributive areas, the dominance

10   of baseflow in the hydrology of inland valleys calls for investigating properties of subsurface regions prone to contribute to streamflow through water exfiltration in the valley thalweg.

In complement of ~~measurements of hydrological fluxes (e.g. precipitation, streamflow, evapotranspiration) and storage variables (soil moisture, water table levels, storage), hydrodynamic properties and geophysical imagery and monitoring,~~CZ observations, physically-based CZ models are appropriate tools to study the functioning of a hydrosystem ~~and the relationships~~

15   ~~between the components of its CZ~~ (e.g. Kollet and Maxwell (2008); Srivastava et al. (2014))~~, by conducting virtual experiments (Weiler and McDonnell, 2004)~~. These models explicitly link all hydrological compartments of the CZ, from the deep impermeable bedrock to the top of canopy and provide a robust framework to conduct virtual experiments (Weiler and McDonnell, 2004)~~.~~

In this paper, we seek to address the two following questions: 1) what are the main characteristics of the hydrological

20   functioning of inland valleys in the Sudanian ~~area~~ Savanna of West Africa? 2) What is the impact of LULC changes on such systems? The approach undertaken here is to build a set of virtual experiments in an idealized elementary V-shaped catchment to test the sensitivity of a physically-based CZ model to different features: a) the presence of the low permeability layer in the valley thalweg, which characterizes inland valleys, b) the pedology of contributive areas and c) the vegetation distribution (from natural woodland cover to herbaceous-like fallow/crops cover). ~~This deterministic modeling approach largely builds on~~

25   ~~the large panel of observations available within the AMMA-CATCH observation service (www.amma-catch.org (Galle et al., Submitted; Lebel et al., 2009) and several campaigns, as well as on a highly instrumented elementary catchment for which we previously built a conceptual lithological/pedological model (Hector et al., 2015).~~

~~In the first section, we briefly discuss the physical environment and how we model it using a physically-based CZ model.~~ ◄   [Mis]
~~Then, we present the results of a reference case, which are compared to observations from an elementary headwater catchment~~

30   ~~in the hard-rock area of the Sudanian region, to show that the model is able to reproduce to a large extent the complex critical zone behavior. We finally use the results of a set a virtual experiments to infer the model sensitivity to the main inland valley features (presence of a clay layer, hydrodynamic properties of the contributive areas, vegetation distribution), and discuss these results.~~ This idealized elementary V-shaped catchment is built based on the main features of elementary catchments comprising

an inland valley (topography, clay lens, vegetation distribution), but also following a highly instrumented elementary catchment for which we previously built a conceptual lithological/pedological model (Hector et al., 2015).

In the first section, we briefly discuss the physical environment and how we model it over a 7-years period using a physically based CZ model. Then, we present the results of a single simulation, which are compared to observations from the elementary headwater catchment, available within the AMMA-CATCH observation service (www.amma-catch.org, Galle et al., 2018; Lebel et al., 2009) and several campaigns, to show that the model is able to reproduce to a large extent the complex critical zone behavior. We finally use the results of a set of virtual experiments to infer the model sensitivity to the main inland valley features (presence of a clay layer in the valley thalweg and hydrodynamic properties of the contributive areas) and the vegetation distribution, likely to evolve, and discuss these results.

2 Material and methods

2.1 Description of the physical environment

In this section, we briefly describe our conceptual representation of the main soil and vegetation characteristics found in the hard-rock basement areas of the Sudanian climatic region (yearly precipitation amount between 700 and 1400 mm) dominated by metamorphic settings. This eco-physical model is built following the literature of the region and on inland valleys and the work of (Hector et al., (2015), who studied and described the functioning of an elementary catchment in North Benin, the Nalohou catchment (0.16 km²). This catchment, which is part of the regional AMMA-CATCH observatory, which belongs to the OZCAR network of Critical Zone observatories (Gaillardet et al., 2018). See for instance their Fig. 13 in Hector et al., (2015) for a conceptual sketch of their understanding of the Nalohou catchment: during the dry season the permanent water table is disconnected from the inland valley, while during the wet season, the permanent water table rises and a shallow perched water table appears in the inland valley which is fed by both rainwater infiltration and lateral subsurface transfers. This specific behavior is representative of inland valley functioning in similar geological/climatic contexts (see e.g. Brabant, 1991 in Cameroun, Diatta, 1996 in Ivory Coast or Giertz and Diekkrüger, 2003, in other location in Benin). In the Nalohou case, Llateral subsurface contributions to the inland valley differ from each bank: contributions from the layered left bank (highly permeable hard-pan over low permeability clay-rich horizons) exceed contributions from the sandier right bank. Fig. 1.a shows the actual catchment shape as a black line and cross sections of Fig. 1.b-c summarize the internal structure of the catchment.

2.1.1 Soil layers and properties

Our conceptual model of the physical environment is made of three layers through depths (H1: 0-0.5 m, H2: 0.5-2 m, H3: 2 m -10.5 m, Fig. 1.b-c), to which we prescribed specific hydrodynamic properties in a deterministic way and following the

literature, but also based on numerous field and laboratory measurements by Hector (2014); Richard (2014) and Robert (2012) in ~~this Sudanian area~~ the same area (Table 1). In the following text, we refer to sand-like and clay-like hydrodynamic properties in a broad sense~~:~~, sand-like relates to ~~of respectively~~ highly permeable/low retention media and clay-like relates to low permeable/high retention media.~~, but t~~ The reader may refer to Table 1 and Table 3 for actual properties ranges and values.

5 The thicknesses of the two shallowest soil layers (H1 & H2) are well defined from observations in the Nalohou catchment, and seem in accordance with other locations in (sub)tropical humid regions (de Condappa et al., 2008). The thickness of the deeper layer (H3) ~~thickness~~ is that of the regolith ~~thickness~~, located above the fissured basement and the hard rock basement, following (Lachassagne et al., 2011).

Figure 1

10 *Layer H1:*

In the tropical-humid Sudanian climate, top soils are usually permeable, due to microfauna bioturbation, or soil work from farmers (Giertz and Diekkrüger, 2003; Richard, 2012; Robert, 2012). As a consequence, the infiltration-excess overland flow is very limited in the area (e.g., Giertz et al.~~,~~ ~~(~~2006~~)~~; Masiyandima et al.~~,~~ ~~(~~2003). The top-soil layer, H1, is therefore permeable, with sand-like soil hydrodynamic properties. Some authors note a significant relationship between saturated hydraulic

15 conductivity and land cover in the area (Giertz et al., 2005; Giertz and Diekkrüger, 2003; Richard, 2014), yet in a limited range (less than one~~an~~ order of magnitude). The H1 layer is thus considered laterally homogeneous in this study.

Layer H2:

The second layer (H2) is usually more variable laterally, and variations in clay content in this potentially illuviation layer (a clay-accumulation horizon, as described by de Condappa et al. (2008)) may generate perched water tables (e.g. Giertz et al.,

20 ~~(~~2006~~)~~). In this layer, some macroporous hardpan units with high permeability may also be found (Bonsor et al., 2014; Hector et al., 2015).

It is beyond the scope of this study to analyse the effect of this layer (H2) on the hydrological processes~~, because it would likely necessitate an entire study~~. There is an extensive literature, using the same critical zone modeling framework that provides insights on the effect of lateral variability of soil properties through dedicated sensitivity studies (Atchley & Maxwell,

25 2011, Meyerhoff & Maxwell, 2011, Meyerhoff et al., 2014, Gilbert et al., 2016). We therefore chose to consider a rather sandy, permeable layer, to mimic a hardpan unit behavior (as part of the polycyclic soil profile ~~-~~described by Faure and Volkoff, ~~(~~1998~~)~~), and favor quick lateral subsurface transfer, which have been evidenced in the area (e.g Hector et al.~~,~~ ~~(~~2015~~)~~; Masiyandima et al.~~,~~ ~~(~~2003~~);~~ and Séguis et al.~~,~~ ~~(~~2011~~)~~).

Layer H3:

30 The composition of the third layer (H3) is variable laterally. ~~In this study, we are interested in two extreme cases of what can be found in this regolith layer, according to Faure and Volkoff (1998).~~ On the one hand, there is a low-permeability, clayey~~-accumulation like~~ horizon, similar to what is observed by Hector et al. (2015); Wubda et al. (2017) in the Western half of the Nalohou catchment, and also described as a major feature from larger scales observations by Faure and Volkoff (1998). On the other hand, there is a clay-eluviated, saprolite-like, sandy horizon, which is expected to produce a strongly contrasted

13

behavior. It is also similar to what is observed on the Eastern half of the Nalohou catchment, and being the second major feature from larger scales observations by Faure and Volkoff (1998). ~~Anticipating on the following sections, the two different cases for H3 layer (clay-like and sand-like saprolite) will be evaluated in the virtual experiments, together with an alternative case where the H3 layer in the left bank of the virtual V-shape catchment will be clay-like and the right bank will be sand-like.~~

5 ~~In the 'reference' simulation, H3 will have clayey hydrodynamic properties, in the 'saprolite' simulation it will have sandy hydrodynamic properties and in the 'mixed' simulation it will have clayey (resp. sandy) hydrodynamic properties in the West (resp. East) bank.~~

Inland valley:

The inland valley is located in the downstream part of the valley thalweg (circles of Fig. 1.a). It has a specific H1/H2/H3

10 sequence. It usually consists of sandy upper horizons. H1 and H2 layers are the same as elsewhere, and are considered to be of sandy nature and to favor quick vertical and lateral transfers, as observed in the field. At about 2m depth, in the upper-part of the H3 layer just below the H2 horizon is a low permeability, clayey layer, which actually characterizes the inland valley. This allows the formation of perched water tables during the rainy season (Masiyandima et al., 2003). Such shallow drainage system is the main contributor to baseflow, which represent roughly about 80% of total streamflow for such catchment (Giertz

15 et al., 2006; Hector et al., 2015; Kamagaté et al., 2007; Séguis et al., 2011). This clay-rich accumulation horizon is often found above a poorly weathered horizon (Brabant, 1991), as is the case in the Nalohou catchment. Therefore the H3 layer underneath the inland valley is made of low-retention, high-permeability fissured basement (in the sense of Lachassagne et al. ~~(~~2011~~)~~).

Hydrodynamic properties:

In a thesis work, Hector (2014) summarized the variability of field measurements to build up classes of main soil/lithology

20 units for the three main layers identified in this study (Table 1). Hydrodynamic parameters (following Van Genuchten, ~~(~~1980~~)~~) for this study are shown below on Table 3. Saturated conductivities of saprolite and fissured basement in the H3 is given by the range of observations derived both from pumping tests and magnetic resonance soundings in the area (Vouillamoz et al., 2014).

Table 1

25 **2.1.2 Topography:**

At the Upper Oueme catchment scale (14 300 km², which includes the Nalohou area), comprising many inland valleys (Giertz et al., 2012), a slope analysis from the 3'' (about 90m) Hydrosheds DEM (www.hydrosheds.org) provided an average slope of 2.6 %. On nearby Togo in similar geomorphological context (Région centrale, 13000 km²), Runge (1991), noted that 80% of the surface have slopes comprised in the range 1.7 – 5.2 %. The slope along the transverse axis ranges from 1.7 to 3.5% and

30 from 3.5 to 5.2% along the longitudinal axis. They further identified inland valleys to develop preferentially in the range 3.0 – 4.4 % along the steepest axis. For the specific Nalohou catchment, mean longitudinal slope (N-S) is 4% and mean transverse (E-W) slope is 2%, according to a 5m lateral resolution DEM derived from DGPS survey, as described in Hector et al., (2013).

2.1.~~2~~ 3 Vegetation

Non-disturbed natural vegetation in this area is mostly woodland, composed of trees with an herbaceous layer underneath. Under human influences, trees are usually cut in favor of agricultural plots. However trees in the riparian areas and the inland
5 valley fringes are generally kept alive, as well as specific species on the hillslopes for consumption purposes (agroforestry system). This is why we consider in this study two vegetation classes: trees and herbaceous. While the trees class refers to a fully tree-covered state with some herbaceous layer underneath, the herbaceous cover refers to a mixed fallow-field landscape with sparse trees, composed of either cultivated plots or young fallows under the influence of farmers, and with some isolated trees (with height <10 m) kept for local consumption.
10 Trees phenology mostly consists in defoliation around January, which occurs asynchronously between different species and different individuals of the same species (Seghieri et al., 2012). On the other hand, in the so-called herbaceous cover, the ground is commonly covered by scattered shrubs, while the actual herbaceous layer usually starts growing in April after the first rains and reaches its maximum height (up to 2.5 m) in October. At this time its height exceeds that of shrubs. Then, the herbaceous layer stops transpiring and dries up from October to January. Controlled fire is a traditional practice in Benin; the
15 vegetation (mainly the herbaceous layer) is burnt between November and February~~, when the soil and vegetation are dry~~. Hence, during the dry season, the soil is bare for about five months. Leaf area index (LAI) and Stem area index of trees and herbaceous classes are later shown on Fig. 6.a.

2.2 Critical zone model

The CZ model ParFlow-CLM (PFCLM) is composed by ParFlow, a three-dimensional integrated physical model that
20 simultaneously solves variably saturated flow and surface outflow coupled with CLM, a land surface model which solves both the water and energy budget at the surface. ParFlow uses a free-surface overland flow boundary condition which routes ponded water as overland flow using the kinematic wave equation and Manning equation (Kollet and Maxwell, 2006). In this study, the topographic effect is taken into account by a terrain following grid (Maxwell, 2013), and only requires two-dimensional surface slopes to be provided. ParFlow solves the Richards equation using cell-centered finite differences in space and an
25 implicit backwards Euler scheme in time. The Newton-Krylov method is used together with a multigrid preconditioner and shows excellent parallel scaling, which allows the simulation of large scale domains (i.e. continental US) at high resolution (i.e. < 1km) (Ashby and Falgout, 1996; Jones and Woodward, 2001; Maxwell et al., 2014a). ParFlow is coupled through the user-defined N-first cells from the surface, to a modified version of the Community Land Model (CLM) which solves both the water and energy budget at the surface (Dai et al., 2003; Maxwell and Miller, 2005). CLM has one vegetation layer and the
30 version within ParFlow currently only allows a single vegetation class per surface grid cell. PFCLM is an excellent candidate for this study because it allows to represent a number of physical processes that have been observed in Sudanian West Africa (perched water tables, groundwater and subsurface water baseflow, stormflow, plant transpiration and bare ground

evaporation…). This is achieved using physical parameters (hydrodynamic properties, vegetation parameters, complex 3-dimensional lithological or pedological units…) and without prior specification of the processes. The model has already been successfully applied in the region, using measured parameters for simulating vertical water fluxes (evapotranspiration, percolation) and specific features like perched water tables (Robert, 2012). We used the tagged version v3.3.1-IGE
5 (https://github.com/basileh/parflow/releases/tag/v3.3.1-IGE).

2.3 Model setup

We model an idealized elementary headwater catchment, comprising an inland valley, of 720m x 300m catchment (0.216 km²), with a 20m lateral (x,y) resolution (Fig. 1, Table 2). The idealized inland valley and its contributive area is a V-shape type (Maxwell et al., 2014b), sloping in the Y direction (Fig. 1.a). Y-direction slope is 4 % and X-direction slope is 2 %., following
10 Runge (1991) and specific values for the Nalohou catchment. The cells in the center represent the potentially overflowing section of the inland valley. These cells are further lowered by 2 m below the altitude of the inland valley fringes, to represent the classically observed banks.

Table 2

The vertical resolution varies with depth following a geometric progression of common ratio 1.2 for the first 13 cells (which
15 are coupled to CLM), ranging between 0.134 m to 1.195 m and four more 1 m-thick cells, uncoupled to CLM, are added at the bottom. The domain is therefore 10.5 m thick. Selected hydrodynamic parameters based on expertise-driven sensitivity studies within the range of observed values (Table 1) are shown on Table 3.

Table 3

No-flow boundary conditions are applied on the catchment edges (symmetric assumption) and bottom. The only way for the
20 water to leave the domain, apart from evapotranspiration, is through overland flow at the catchment outlet.

2.4 Model forcings

2.4.1 Atmospheric forcing

Forcing data is obtained from the Benin site of the AMMA-CATCH observatory, and is available on the data portal (http://db.amma-catch.org). (Lebel et al., 2009). The This meso-scale site comprisesof the upper Upper Ouémé catchment
25 (14300 km²) in northern Beninwhich is representative of the Sudanian climate. The meteorological variables used to force CLM (wind speed, air temperature and humidity, pressure and the incoming radiative long and short waves, Fig. 2) were measured at a 2 m height on a flux tower located on a cultivated site (the Nalohou catchment, lat. 9.74∘N, long. 1.60∘E, 449 m a.s.l). Rainfall is measured with a tipping-bucket rain gauge.

West African rainfall follows the monsoon dynamics and is characterized by a strong variability at interannual scales (see e.g.
30 Lawin (2007); and Le Lay and Galle (2005;) for detailed analyzes of the Sudanian rainfall regime). On the simulated years, yearly precipitation amounts rangeed from 913 mm to 1572 mm (Fig. 2).

16

Fig. 2 shows the meteorological variables used to force PFCLM. They have been described in Mamadou et al. (2014) for the year 2008 and recently compared to data from a 13 km-away site over a forested cover for the period 2008-2010 (Mamadou et al., 2016). The daily meteorological conditions of the two sites were expectedly close. Minimal values of incoming short waves radiations (SWin) are observed during the wet season due to cloud cover, and low values are also found at the core of the dry season, due to aerosols brought by the north-easterly Harmattan winds. Incoming long wave radiations (LWin) are low during the dry season due to the reduced cloud cover. Highest air temperatures are observed before the start of the wet season, while the wet season exhibits the lowest daily average and amplitude of temperature. Specific humidity clearly shows the monsoon/Harmattan signal: during the wet season, moist air is brought by the south-westerly to southerly monsoon winds and during the dry season north-easterly Harmattan winds bring dry air from the Sahara. The Harmattan blows as a light to moderate breeze. These weather types are typical for Sudanian regions (Lohou et al., 2010; Sultan and Janicot, 2003).

PFCLM is ~~being~~ forced at a 30 mn time step, over the 7-years period 2006-2012, with spatially homogeneous forcings. Initial conditions are set as a water table depth of 3 m, in accordance with several water table measurements. The model is spun up for one year which corresponds to the year 2007, a rather average year.

Figure 2

2.4.2 Vegetation forcings

In this study, we forced the model with observation-based time series of LAI (Leaf Area Index), SAI (Stem Area Index), displacement heights and roughness lengths for the two vegetation classes of our domain (trees and herbaceous).

Vegetation height was monitored over an herbaceous-covered site (Nalohou) and a forest site ~~(Bellefoungou)~~ 13 km away and further used to calibrate a simple API (Antecedent Precipitation Index)-like model which takes precipitation as input (Kohler and Linsley, 1951), and with the assumption that vegetation growth follows soil moisture availability. This allowed deriving vegetation heights during the growing period at daily time step for herbaceous cover for years where only precipitation data was available. Roughness lengths and displacement heights have been derived from these time series following Brutsaert approach (Brutsaert, 1982) calibrated on in-situ eddy covariance measurements. The LAI time series is a combination of satellite LAI products (CYCLOPE, MODIS, SEVIRI), constrained by in situ measurements derived from hemispherical photographs based on the method proposed by Weiss et al. (2004), both on the forested and herbaceous-covered site. Herbaceous SAI is also calculated from LAI ~~in respect with~~ using the equation *(LAI + SAI = LAI$_{max}$)* during the senescence period (See later Fig. 6.a for the LAI and SAI time series used in the model forcing).

For the herbaceous cover, the root distribution in the model follows that of Zeng (2001), which is an exponential shape for the cumulative root fraction (Y) to depth (d) of equation $Y = 1 - \frac{1}{2}(e^{-ad} + e^{-bd})$, with the two coefficients a= 9 and b=2. For the trees, the distribution is kept uniform over the first three meters below the surface, because we found the Zeng equation not relevant for most Sudanian trees for which efficient deep roots have been observed (Jourdan, Gnanglé, Seghieri and

17

Peugeot, pers. Communication). The closest published study on deep roots in natural forest is in a slightly different setting in tropical semi-deciduous rain forest where 95 % of all roots from *E. cylindricum* where distributed to depths of between 2.58 and 5.64 m (Freycon et al., 2015).

2.5 Evaluation data

5   As a first step, we evaluate the relevance of the model with respect to real world data (water table depths measurements, soil moisture, streamflow records, evapotranspiration and gravity data). This section describes the ~~validation~~ evaluation data obtained from the Nalohou catchment, which ~~has a comparable~~ size and structure are comparable to ~~the one~~that of our ~~conceptual physical model~~virtual V-shape catchment (Fig. 1.a). The Nalohou catchment comprises a small inland valley and is considered to be representative of a cultivated site. It has been the focus of previous studies (Descloitres et al., 2011; Guyot
10   et al., 2012; Hector et al., 2015; Richard et al., 2013). Land surface elevation ranges from 436 to 460 m.a.s.l., and topographic slopes are gentle (mean N-S and E-W slopes correspond to those imposed on the virtual V-shaped catchment).

Observations in P1 and P2 (Fig. 1.a) were used to evaluate the simulated groundwater dynamics. At the inland valley location in P1~~In this study, we attempt to reproduce the water table at the inland valley location (P1 in Fig. 1.a), where~~ there is a shallow, 1 m deep, piezometer which aims at documenting the seasonal perched water table, and a deeper (10 m) piezometer monitoring
15   the permanent water table. ~~We also investigate the ability of some model configurations ('saprolite' conditions in the H3 layer, see below) to reproduce the typical water table behavior observed in upstream locations (P2 in Fig. 1.a).~~

Streamflow measurements have been described in Hector et al. (2015). A Parshall flume was built in 2004 at the outlet of the inland valley (Q2 in Fig. 1.a) and recorded any level change above 10^{-3} m, using a level probe (*OTT Thalimedes*).

Two eddy covariance flux towers have been installed respectively on the Nalohou site (where the Flux tower footprint is
20   representative of cultivated, herbaceous-like areas), and on ~~a~~ the woodland site ~~13 km away~~ (Mamadou et al., 2016). Furthermore, an infrared large-aperture scintillometer (LAS) has been deployed from 2006 to 2008 on the Nalohou site (Guyot et al., 2009, 2012). LAS measurements give access to an average sensible heat flux over the footprint area and, by closing the energy budget, this allows to derive the average latent heat flux (i.e. evapotranspiration). In the Nalohou site, the beam path was 2.4 km long, and comprised much more trees than in the flux tower footprint area.

25   Time-Domain Reflectometry (TDR) probes have been set up on the East bank of the Nalohou catchment at about 150 m eastward of latitude point Y=300 m of Fig. 1.a. Soil moisture content is derived from the measurements at a hourly time step. Gravity instrumentation originate from the GHYRAF (Gravity and Hydrology in Africa) project, which sought at studying gravity to water storage changes (WSC) relationships (Hinderer et al., 2009, 2012). Gravity instruments were an absolute (AG hereafter) FG5 gravimeter (Hector et al., 2013), a relative superconducting gravimeter (Hector et al., 2014, SG hereafter) and
30   a CG5 relative portable spring gravimeter (Hector et al., 2015). ~~A specific software, pyGrav, was implemented to process the large CG5 dataset (Hector and Hinderer, 2016).~~ Relative spring microgravimeters measure differences in gravity between stations while other instruments such as SG or AG measure changes at a specific site. Hybrid gravimetry is the joint use of gravity surveys using relative microgravimeters and monitoring of temporal changes at a base station, using an SG and/or AG

(Hinderer et al., 2016). From the hybrid gravity dataset of Nalohou, Hector et al. (2015) produced a map of the seasonal amplitude of gravity changes (their Fig. 11). In this study, we convert gravity changes to water storage changes using a simple scalar admittance (gravity changes to WSC ratio) of 0.04 µGal/mm, in accordance with local topography, and following the admittance calculated by Hector et al. (2015).

2.6 Analysis tools

Water storage changes (WSC) analysis is conducted using Empirical Orthogonal Function (EOF) decomposition. EOF decompositions can be seen as principal component analysis applied to the time series of a spatial field. The method produces spatial patterns of variability (in terms of variance), their associated time variation together with a measure of the weight (importance) of each pattern (in terms of explained variance). In other words, the whole data set of coordinates (x,y,t) is decomposed into the weighted sum of modes, where each mode is the product of an EOF spatial pattern (an (x,y) map) with a normalized time series. The weights are given in terms of "how much of the total signal variance is contained in the associated mode". This method has been used on WSC from hybrid gravity data and neutron probe data at the Nalohou catchment size by Hector et al. (2015) who showed that the first mode could be interpreted as the seasonal signal.

To measure the goodness-of-fit between simulations and observations, ~~In this study,~~ we ~~make~~ use ~~of~~ the Kling-Gupta efficiency (KGE) criterion (Gupta et al., 2009):

$$KGE = 1 - \sqrt{(r-1)^2 + (\alpha - 1)^2 + (\beta - 1)^2}\,,\qquad(1)$$

Where~~,~~ r is the linear correlation coefficient between simulated and observed time serie and,

$$\alpha = \frac{\sigma_S}{\sigma_O};\ \beta = \frac{\mu_S}{\mu_O}\,,\qquad(2)$$

~~With r the linear correlation coefficient between simulated and observed time series,~~ and (μ_S, σ_S) and (μ_O, σ_O) are the mean and standard deviation of respectively simulated and observed time series. KGE has an ideal value at unity.

2.7 Overview of the three virtual experiments

We model an elementary headwater catchment and test its sensitivity to 1) the presence of a low permeability layer underneath an inland valley, 2) the vegetation distribution, and 3) the hydrodynamic properties of contributive areas (H3 layer). For doing so, we build a set of virtual experiments ~~(e.g. Weiler and McDonnell (2004))~~ that are compared to a ~~reference case~~benchmark simulation (~~Table 1, the grey shading represents the reference case~~named the 'reference' case hereinafter, Table 4). Th~~is~~e reference ~~case~~ simulation ~~represents satisfyingly the observed hydrological variables at the Nalohou catchment, as shown in the next section. It is the closest model that matches the authors understanding of the Nalohou system. It~~ includes an inland

valley characterized by an impervious layer ~~made of a clay lens,~~ underlying an upper sandy layer in the valley thalweg. ~~Vegetation distribution and H3 layer are both chosen arbitrarily in this simulation.,~~ ~~a~~An anthropized vegetation distribution (mostly herbaceous but also trees in the riparian areas) ~~allows comparing model outputs with observed hydrological variables at the Nalohou catchment., and a~~ A clay-like contributive area (H3 outside the inland valley cells) ~~is chosen between the two main pedological features (clay and saprolite).~~ The three ~~types of~~ virtual experiments are ~~detailed in the~~as follow~~sing~~. (Table 4):

- ~~The first experiment (first line of Table 4)~~ explores the impacts of the low permeability layer in the valley thalweg, ~~typical of inland valleys,~~ on the hydrological functioning of the catchment. ~~This experiment consists in removing This means that we either model~~ the impervious layer below the H2 horizon (upper part of H3 as shown in Fig. 1.b) in the valley thalweg ~~with respect to the reference case, or not.~~ Other parameters (hydrodynamic, vegetation…) are kept identical. ~~Note that the reference case includes this impervious layer.~~

- ~~In the vegetation~~The second~~ experiments (second line of Table 4)~~ explores the impact of the vegetation cover with three cases: the 'natural' state where ~~,~~ the catchment is ~~either~~ fully ~~tree~~ covered ~~with trees, which is considered as the natural state,~~ and the 'anthropized' state with two different vegetation cover: ~~or under human influence. Under this so-called anthropization, we consider two different cases~~: 1) either the catchment is covered with grass~~herbaceous-dominated, but~~ except ~~with trees kept~~ in the riparian and inland valley fringes areas ~~where trees remain~~ (as in Fig. 1.a~~)~~ — this is the reference case)~~,~~ or 2) the catchment is fully ~~herbaceous covered~~covered with grass (no trees). ~~First order elementary catchments usually drain into a second order channel, therefore the downstream trees actually represent the riparian area of the second order stream, here flowing along the X direction.~~

<center>Table 4</center>

- ~~The contributive area drives the subsurface and groundwater transfer toward the inland valley.~~ In the third experiment ~~(third line of Table 3)~~, we test three ~~distinct~~ different configurations for the H3 layer outside the valley thalweg, ~~and keeping~~with H1 and H2 ~~left unchanged, as the contributive area within H3 drives the subsurface and groundwater transfer toward the inland valley, properties identical. The configurations are based on two distinct soil profiles commonly found in the Sudanian landscape: a clayey H3 or a sandy to loamy saprolite H3 layer, both above the hardrock considered as impervious.~~ The reference case considers clay material only in the H3 layer, and the two other cases consider respectively 1) a sandy to loamy saprolite in the H3 layer and 2) a clay zone on the Western side of the virtual catchment and a sandy zone on the eastern side (asymmetric case), ~~both above the hardrock considered as impervious. These configurations are based on two distinct soil profile commonly found in the Sudanian landscape (Faure and Volkoff, 1998).~~

3 Results

3.1 Reference case and saprolite case face to Nalohou observations.

3.1.1 Water storage changes

Water storage changes (WSCs) are shown on Fig. 3 as the spatial and temporal patterns of the first mode of the EOF
decomposition. While the left panel shows the simulated WSCs, the right panel shows WSCs obtained from the hybrid gravity
data by interpolation from point-based values (blue dots). The first mode of the simulated WSCs represents more than 90 %
of the variance. This means that more than 90 % of the total signal variance is contained in the first EOF spatial pattern
multiplied by its associated time series (Fig. 3, lower panel, red line). The time series shows that this mode corresponds to the
seasonal cycle (the common part of the signal which explains most of the total variance). In that sense, we can directly interpret
the spatial patterns (i.e. the EOFs) as maps of seasonal water storage amplitudes. The first mode of gravity-derived WSCs also
explains a significant part (79 %) of the total variance. As this map derives from an interpolated field, and although gravity
data is spatially integrative, observed geometries should not be over-interpreted. Mode 2 (not shown) accounts for about 8%
of the total variance, and contains interannual storage variations together with some residuals at the seasonal level.

Figure 3

The reference simulation is built largely following our understanding of the Nalohou catchment. Particularly, it does includes
an inland valley (a low permeability layer in the upper part of the H3 horizon) and the clayey material in the H3 layer outside
the inland valley corresponds to what is found in the West bank of the Nalohou catchment. To this regard, the simulated spatial
pattern matches two important features of the observations: a high amplitude in the inland valley and a low amplitude on the
clayey, West bank, area. The high simulated amplitude in the downstream section (500 to 700 m) is due to tree withdrawals
during the dry season. Gravity data do not cover this part of the catchment which prevents the comparison with the simulated
data. The low amplitude on the sides of the catchment is due to the impermeable clay in the H3 horizon, which prevents water
to percolate downward and favors lateral transfer to the valley thalweg where water accumulates during the wet season, and
drains down toward the riparian areas during the dry season. High amplitude is simulated along the whole valley thalweg, and
not only in the inland valley as the observation show.

3.1.2 Water table

Fig. 4.a shows simulated time series of saturation profiles at P1, in the inland valley for the reference simulation. Red lines
show the simulated water tables, while white lines show the observed water tables. The model is able to reproduce seasonal
fluctuations of both the permanent water table and the temporary perched water table. Although numerous discrepancies exist
(e.g. the seasonal amplitudes of the permanent water table), mainly because of the horizontal and vertical variability of
hydrodynamic parameters which have been considered constant in layer H3, the first order of this complex behavior is

reproduced. Particularly, the interannual behavior of the permanent water table is rather satisfying, despite a slight phase shift, but also higher frequency responses of the shallow perched water table at the core of the rainy season are well reproduced. ~~In the virtual experiments later shown, the saprolite case (sandy H3 layer everywhere but in the inland valley) is considered, as it is a common feature of the environment, particularly in the East bank of the Nalohou catchment.~~ Fig. 4.b shows simulated

5   time series of saturation profiles at P2, in the upstream area for the saprolite simulation (sandy H3 layer everywhere but in the inland valley). This sandy H3 layer is a common feature of the environment, particularly in the East bank of the Nalohou catchment. The simulated permanent water table matches satisfyingly the observation representative of this sandy H3 unit.

Figure 4

3.1.3 Streamflow

10   Fig. 5 shows simulated and observed streamflow expressed in mm/h, which allows the comparison between the Nalohou catchment (0.16 km²) and the V-shape model (0.~~216~~ 22 km²). We chose to focus the plot on the baseflow part of the time series, cutting the highest flow peaks, for two reasons: 1) Hector et al. (2015), noted that in such settings baseflow is the major contributor to total measured streamflow (about 80%) and 2) the following sections will present semilog plots of the different experiments simulated, which allow to display the whole range of streamflow values, but with less intuitive interpretation.

15   Overall, the match is satisfying, and the simulation respects baseflow onset, and recession behavi~~o~~urs. The only negative KGE value for the year 2009 ~~is~~ composed by ($r = 0.96, \alpha = 1.56, \beta = 1.84$), ~~and~~ is ~~therefore~~ mostly explained by a high bias and too high simulated variance, while the time phasing matches well. It has to be noted that the simulation produces higher flow peaks than observed for some events, but not all (see further Fig. 9). Discrepancies between observed and simulated streamflow are higher in drier years (i.e. 2011). This is due to the complexity of connectivity between different contributive compartments,

20   ~~and for~~ which is over-simplified in our idealized simulation ~~probably still lacks some significant components~~. The simulated diurnal cycle in the ponded water (from which streamflow is calculated) is a model artifact due to the ponded cell size (20 m wide here).

Figure 5

3.1.4 Evapotranspiration

25   Fig. 6.a shows the LAI and SAI forcing time series used in this study for the two vegetation covers. Fig. 6.b (resp. 6.d) shows the simulated daily evapotranspiration spatially averaged over herbaceous-covered cells out of the thalweg in light blue line for the reference simulation (resp. the saprolite simulation). The shaded area gives the whole spatial range of daily values between minimal (lower black line) and maximal (upper black line) spatial evapotranspiration. Fig. 6.c (resp. 6.e) is similar, but for tree-covered cells. Reference (clay in the H3 unit everywhere but below the inland valley) and saprolite simulations

30   are compared because the Nalohou Flux tower is located on a saprolite-like material. The saprolite simulation actually matches more closely the observed evapotranspiration in the dry season.

During the dry season, trees renew their leaves and show a low LAI and limited evapotranspiration. The herbaceous have been burnt, and only some scattered shrubs and trees imply a non-zero LAI and little evapotranspiration. During the transition period between dry and wet seasons, trees LAI increase, herbaceous grow and evapotranspiration increase with both soil moisture (not shown) and plants ability to transpire with a higher LAI. During the wet season, the evapotranspiration is never water limited (Mamadou et al., 2016). During the transition period between wet and dry seasons, the herbaceous layer dries up, and LAI is being replaced by SAI which diminishes drastically the evapotranspiration. Herbaceous are eventually burnt at the end of this transition period (SAI drop on Fig. 6.a), while trees start renewing their leaves.

Overall, the spatially averaged simulated evapotranspiration matches the observationsdata, over both herbaceous and tree covers. At the end of the wet season, the simulated evapotranspiration (dominated by transpiration) is a little higher than the EC observations, but not higher than the LAS observations in 2008. EC is known to underestimate evapotranspiration (Foken, 2008).

Figure 6

3.1.5 Soil moisture

Because soil moisture probes are located on the East side of the Nalohou catchment, and the reference simulation is built based on our understanding of the West side (hence with H3 properties different to those at the physical location of the soil moisture probes), observed soil moisture are here compared to the 'saprolite' simulation where H3 outside the inland valley is composed by sandy-like saprolite (Fig. 7). Simulations match the observed temporal patterns in a satisfying way, including recession behaviors.

Figure 7

3.1.6 Annual water budget

The water budget simulated for the reference case is shown in Table 5. As expected, evapotranspiration dominates the water budget (from 58 to 83 % of yearly precipitation amount) but shows a marked interannual variability as simulated in the area at basin scale (Cornelissen et al., 2013; Séguis et al., 2011) and from a review on different other spatial scales (Hector, 2014). For dry years, the ET part (resp. Q part) of the budget is higher (resp. lower) than for wet years. Interannual water storage changes are rather limited and do not seem to exhibit memory effects. In other words, the relative part of (ET+Q) in the water budget is stable over years. If we now consider the absolute values of the water balance terms, the difference between a wet year (2010) and the following dry year (2011) is 593 mm in rainfall, 135 mm in evapotranspiration, 420 mm in streamflow and 38 mm in water storage. Streamflow is the most affected term in a dry year: it undergoes a drastic loss of water, about 3 times greater than that of evaporanspiration, almost equal to its interannual average (454 mm). It results that the interannual standard deviation of Q is more than twice as large as the standard deviation of ET: the interannual variability in precipitation (standard deviation = 225 mm) is mostly compensated by streamflow (151 mm) and to a lesser extent by evapotranspiration (64 mm) and water storage changes (26 mm).

23

Table 5

3.2 Virtual experiments

3.2.1 Annual water budgets

The most important variations in yearly water budgets occur when comparing a tree-covered catchment versus an herbaceous-

5 covered catchment (Table 6). Mean interannual evapotranspiration is higher (resp. lower) and streamflow is lower (resp. higher) for the trees (resp. herbaceous) -covered catchment, while the reference case shows a somewhat intermediate behavior. Interannual variability (i.e. as shown by the standard deviation) shows the opposite behavior: it is lower (resp. higher) for the trees than for the herbaceous. Unlike other cases, interannual water storage changes may become significant in the tree-covered experiment, with a net decrease in water storage during the dry years. It results in a higher interannual standard deviation of

10 the storage term.

The presence of the impermeable layer (in the reference case) has very little effect on the water budget, lowering the streamflow of 2 % (9 mm) on average, in favor of evapotranspiration, with respect to the case without the impermeable layer.

The reference case, (clayey), ~~contributive area~~ evapotranspirates slightly more than the saprolite-like ~~contributive area~~case, of 5% on average, while the mixed simulation (clayey left bank, saprolite right bank) shows an intermediate behavior.

15 ~~The impact of the different simulations on the baseflow to streamflow ratios is very limited. The absence of the impermeable layer increases the baseflow of less than five points depending on years. For wet years (i.e. 2010), there is relatively less baseflow when there is an impermeable layer. The vegetation seems not to influence the baseflow to streamflow ratio, while a more permeable (saprolite-like) contributive area exhibit slightly more baseflow (less than five points) than a low-permeability, clayey contributive area.~~

20

Table 6

3.2.2 Water storage

Fig. 8 shows water storage changes as the first modes of the Empirical Orthogonal Function (EOF) decompositions for all tested cases. In all cases, the first mode represents more than 90 % of the variance.

25 The most striking discrepancies arise when comparing the results related to the contributive area experiments (Fig. 8.a,e,f). While the ~~clayey~~ reference case (clayey H3 layer, Fig. 8.a) shows low seasonal amplitude in the valley banks and higher amplitude along the valley axis including the inland valley, the saprolite case ~~like contributive areas~~ (Fig. 8.e) show a rather opposed behavior with higher amplitude on the banks and lower amplitude in the valley axis. In the reference case, the southern, upstream edge of the inland valley exhibit a break in the seasonal amplitude, while this is not visible in the saprolite case (in

30 this case there is no specific imprint of the inland valley). In the mixed case (Fig. 8.f), the southern, upstream edge of the inland valley also exhibits a different seasonal amplitude, but of opposite behavior as in the reference case.

In the vegetation experiment (Fig. 8.a,c,d), the tree-covered catchment (Fig. 8.c) shows higher seasonal amplitude than the herbaceous-covered catchment (Fig. 8.d), while the reference case shows ~~a closer~~ pattern closer to the herbaceous-covered catchment. In the time series, seasonal WSC increase occurs earlier on herbaceous cover than on trees.

The ~~presence~~ absence of the impermeable layer in the inland valley ~~diminishes~~ increases the seasonal water storage amplitude along~~of~~ the thalweg (Fig. 8.b).

In all cases, there is low seasonal amplitude at the catchment outlet (the northern blue patch). This is the imprint of the topography (all cells converge to that point) and the model boundary condition: the only way for the water to exit the domain, apart by evapotranspiration, is through this outlet.

The mixed simulation characteristics are actually the closest to the conceptual model presented by Hector et al. (2015). And the observed spatial pattern (Fig. 2) matches several features of the mixed simulation: a high amplitude in the inland valley, a low amplitude on the clayey, left bank, area, and some intermediate amplitude in the saprolite-like right bank area. While this is satisfying, it has to be noted that the ~~descriptive~~conceptual model proposed by Hector et al. (2015) lacks some details.~~,~~ ~~because in~~In the~~is~~ mixed simulation (which follow their descriptive model), while streamflow, evapotranspiration and spatial pattern of WSC are well reproduced, the simulated permanent water table completely fills up the inland valley due to high permeability in the H3 layer on the right bank (see further), which is not observed. Hence t~~T~~here must ~~hence~~ be some barrier to the lateral flow feeding the inland valley. However, it would be interesting to investigate the existence of other inland valleys which do not show such disconnexion between the upper perched water table and lower permanent water table. Our study would anticipate that, all scaling issues discarded, such an inland valley would produce a similar water budget.

Figure 8

3.2.3 Streamflow

Yearly simulated streamflow time series (sampled on cell Q1, Fig. 1) are shown on Fig. 9 for the year 2011 and as semilog plots, with the reference time series repeated in all plots in black. Overall, streamflow simulations are rather similar. Much of the differences among the cases are related to the first part of the rainy season, in the timing of the streamflow onset and the streamflow amplitude during this period (this is also true for other years, not shown). Differences in the dry season are very low in terms of water amount (remind the log scale), but exhibit clearly different behaviors: some cases are able to sustain a low baseflow during the dry season, while some others including the reference case prevent water flow during the dry season. The presence of the impermeable layer in the inland valley (reference case) induces a higher streamflow in August (Fig. 9, upper panel). On the other hand the absence of the impermeable layer favors infiltration and maintains a low baseflow longer in the dry season, fed by the permanent water table which is then connected all across the catchment.

The tree-covered catchment (Fig. 9 middle panel) tends to exhibit lower streamflow in August. The storm peaks are much attenuated, as compared to the reference case. The herbaceous-covered catchment shows a higher streamflow in the dry season and the early wet season, with slightly higher storm peaks than in the reference case. One may note how the reference Q follows the trees Q in the early season before August and then migrates to meet the herbaceous Q that it follows until the

reverse migration is observed in November. This likely denotes the course of the contributive area extension through the ~~season~~years, trees being only in the downstream section in the reference case.

The simulation with saprolite-like contributive area (Fig. 9 lower panel) shows a higher dry season and early wet season streamflow as compared to the reference case and the mixed case. At the core of the rainy season, in august-september, the saprolite simulation shows a lower streamflow.

<div align="center">Figure 9</div>

3.2.4 Water table

Fig. 10 shows the simulated water tables at two locations, in the inland valley (P1, Fig. 1), and in the upstream contributive area (P2, Fig. 1). When present, perched water tables are shown too.

As expected, the presence of the impermeable layer (Fig. 10.a, as in the reference case) creates two water tables: a deep permanent, low amplitude, water table, and a shallow seasonal water table within the sandy layer of the inland valley (around P1, see Fig. 4). This is not seen when the impervious layer is removed (no I. valley experiment), and where only a strong amplitude permanent water table is present. On the upstream contributive area (around P2, Fig. 10.d), no difference is observed. All vegetation experiments (Fig. 10.b, P1) simulate a perched water table in the inland valley. The tree-covered catchment shows a deeper water table than the herbaceous-covered catchment, while the reference simulation shows an intermediate behavior. On the upstream contributive area (Fig. 10.e, P2), the herbaceous cover matches the reference simulation. The strong water table drawdown induced by tree water uptake lowers the water table down within the clay layer, and no more seasonal variations are observed. In fact, the simulation did not even reach an equilibrium state in that point.

When the whole catchment or half of the catchment deeper layer (H3) is saprolite (Fig. 10.c), the fissured basement below the inland valley (in H3) fills up and no perched water table is observed. On the upstream contributive area (Fig. 10.f, P2), however, there is a strong seasonal water table amplitude (as also shown in Fig. 4), not observed in the clayey, reference simulation.

<div align="center">Figure 10</div>

4. Discussion

4.1 Inland valley

The presence of the impermeable layer in the inland valley does not influence much the yearly water budget (1 % -resp. 2 %-change in the interannual mean for ET -resp. Q-), although the water table behavior in the valley thalweg (Fig. 10.a) and the spatial pattern of seasonal water storage changes are much different (Fig. 8.a,b). The impervious layer prevents vertical infiltration of water below the inland valley, which ~~participates in~~contributes to the creation of a perched water table. Without the impervious layer, the permanent water table would fill up during the rainy season until it would reach the same depth as that of the perched layer ~~of the inland valley (as~~ simulated with an impermeable layer~~)~~, and act similarly. The period when th~~is~~e permanent water table would reach ~~the level of the perched water table (of the reference case)~~this depth would correspond

to the period of matching streamflow in Fig. 9 (upper panel). Despite little differences in terms of annual water budget, the sustained low baseflow during the dry season in the absence of the inland valley, could have significant eco-hydrological consequences downstream. This should be investigated at the scale of larger hydrosystems (as the Upper-Ouémé catchment). In a similar context, Giertz and Diekkrüger (2003) observed significantly higher total runoff amount, peak flow and a longer

5 runoff period in a catchment containing a larger inland valley area (catchment size: 3.5 km², inland valley area: 0.19 km²), than in a nearby catchment ~~area~~ (catchment size: 3.2 km², inland valley area: 0.07 km²), both located in the Sudanian ~~area~~ Savanna in northern Benin. Although we do not observe significant differences in the water budget, we do observe longer runoff period. The catchment size may play a role in the differences with the ~~observations~~ results from Giertz and Diekkrüger (2003), and this could be further investigated. One has to note that the size of the inland valley this study is based on (0.3 ha) is in the low

10 range of inland valley size distribution ~~in the area~~, following a survey conducted in the area on 817 inland valleys (Giertz et al., 2012). According to ~~this~~ their study, 18 % of inland valleys ~~of the area~~ have ~~surface~~ an area~~s~~ lower than 1 ha (and 80 % lower than 10 ha)~~, as the inland valley comprised in the Nalohou catchment (0.3 ha)~~.

4.2 Vegetation distribution

The vegetation distribution does influence the yearly water budget. For evapotranspiration, for instance, average yearly amount

15 vary between 74 % and 62 % of the precipitation for respectively a fully tree-covered and an herbaceous-covered catchment (68 % for the reference case). The relative difference between trees and herbaceous simulations in average yearly amount is 16 % (with respect to the trees simulation) with larger difference for dry ~~years~~ (24 % for 2011) than for wet~~test~~ (12 % for 2010) years. More important, the interannual variability of evapotranspiration (~~i.e.~~ as ~~shown~~ estimated by the standard deviation) is strongly reduced (26 %) for a tree-covered catchment (53 mm) as compared to an herbaceous-covered catchment (72 mm).

20 Evapotranspiration is higher for the tree-covered catchment, mostly because trees are able to get water from the ground for a longer period than herbaceous cover during the dry season. This is because trees have a longer non-zero LAI period, as they take a short time to renew their leaves and are not ~~burnt~~ impacted by the provoked fires ~~by farmers~~ as the herbaceous do. They also have access to deeper water thanks to the deeper root system. Finally, trees undergo higher interception and subsequent evaporation thanks to their low angle leaf orientation and higher LAI and SAI, specified in CLM. Between a herbaceous

25 covered catchment and a tree-covered catchment, yearly average interception losses increases from 3.2 % to 6.5 % of annual precipitation. Herbaceous dry up at the end of the rainy season, and are further burnt by local farmers. When transpiration ceases, evaporation is also limited due to the lack of shallow soil water.

The consequence of a higher evapotranspiration for the tree-covered catchment is a low yearly streamflow budget of 28 % on average as compared to a herbaceous-covered catchment, ranging from 20 % for the wettest year (2010) to 47 % for a dry year

30 (2011). This occurs because during the dry season, when there is no or negligible streamflow, the trees lower the total water storage of the catchment, as shown by the lower simulated water tables (Fig. 10.b,e) and the higher seasonal water storage amplitudes (Fig. 8.a,c). In the early ~~period of the~~ rainy season, in the tree-covered simulation, rainwater takes a longer time to infiltrate and sufficiently recharge the water table until streamflow finally reaches the streamflow level of the herbaceous-

covered simulation (Fig. 9. Middle panel). This is particularly visible in dry years (i.e. 2011), where highly intermittent rainfall and long dry periods during the rainy season ~~prevent significant~~reduce percolation and further delay the "saturated" condition of the catchment.

These results must be tempered by the fact that we used a highly idealized "herbaceous cover", which is, in the actual catchment, ~~actually~~ a mixture of different vegetation classes (perennial shrubs, isolated trees and perennial and annual grass species, mainly *~~graminae~~poacea*); the same holds for the ~~and~~ "trees" case which do~~es~~ not take into account differences among species. For instance, in the Sudanian ~~area~~Savanna, a recent case study showed ~~an example where~~ that the woody cover of an agroforestry systems transpires less than a forest cover, not only due to lower tree density but also to the composition and the physiology of the tree species ~~composition~~ that are selected in agroforestry practices (Awessou et al., 2016). This effect is only partially taken into account by the forced LAI which is derived from observations that integrates this local variability.

As a consequence, tree covers buffer the hydrological cycle by 1) lowering streamflow, 2) reducing interannual variability of evapotranspiration, 3) increasing interanual water storage change by decreasing the water storage during the dry season and 4) increasing interception losses. In the Sudanian ~~area~~Savanna, streamflow has decreased since the 80's, following precipitation decreases, sometimes twice as much (Descroix et al., 2009). LULC changes occurred simultaneously, mostly by conversion of savannah or woodlands to crops (e.g. Eva et al., ~~(~~2006~~)~~). The question of the attribution of the hydrological changes to either climate forcings or LULC changes has not yet been solved. While it is likely that LULC changes played a minor role since the 80's (because of the observed streamflow decrease), if the still ongoing deforestation maintains its pace, there is a chance that the hydrological cycle could be significantly altered in the future due to LULC changes. For instance, Yira et al. (2016) used a process-based hydrological model to show that converting savannah to crops in the last 25 years in a ~~sudanian~~ Sudanian catchment in Burkina Faso led to Q increase and ET decrease, a result consistent with ~~what we can anticipate from our~~this study.

4.3 Contributive areas

When sand-like transmissive hydrodynamic properties are set for lateral and upstream areas of the inland valley (the saprolite case, as opposed to the clay-like reference case), the simulation allows the permanent water table to fill up the area below the inland valley (Fig. 10.c). This means that simulated seasonal water storage amplitudes are lower in the valley thalweg than in the valley sides (Fig. 8.e), showing the opposite pattern of the reference case, where water storage amplitudes are stronger in the valley thalweg (Fig. 8.a). Despite these strong spatial differences, the annual water budget exhibit little differences.

In terms of streamflow generation, the subsurface behavior of the inland valley is rather similar in the saprolite case and the reference case, as whether the shallow perched water table is connected or not to the deeper permanent water table does not matter in its ability to supply the streamflow. In both cases, there is a sufficiently high permeability layer (H2 Hardpan layer in the reference simulation, and H3 in the saprolite-like simulation) which allows lateral transfer to feed the inland valley.

However, although the annual water budgets show little differences, there may still be significant differences in temporal distribution of fluxes. For instance, the saprolite case sustains a higher baseflow (Fig. 9 lower panel). Also, the simulated evaporation differences during the dry season, over herbaceous cover (see Fig. 6.d) imply different surface feedbacks on the atmosphere, which may control larger scale atmospheric features. Evapotranspiration is known to be linked to soil properties through soil moisture availability. Descloitres et al. (2011) showed in the area, for instance, that evapotranspiration as measured by a large aperture scintillometer was controlled by soil properties. To check the consistency of these simulated evaporation differences during the dry season, evapotranspiration should be monitored on a hardpan-clay soil profile, as they are widely present in the region. Furthermore, one should note that Fig. 4.a and 4.b show results from different simulations (reference and saprolite, respectively), although both associated water table levels are real world data of the same catchment. This means that some features are still missing in the simplified Vshape model, in order to comprehensively reproduce the behaviors of this specific catchment. If a high permeability is set to the valley banks (as in the saprolite simulation), it will result in the filling of most of the valley thalweg by the permanent water table and the absence of the perched water table, which is not observed. On the opposite, in the low permeability scenario (reference simulation), the simulated water table on the valley banks mismatches the observed data. To successfully match all the observations, lateral variations in the permeability are needed, but this was not the target of this study, which was instead the extraction of main features and behaviors of inland valleys.

4.4 Discussion on topographic impacts on water budgets

The goal of the paper is to derive the controlling factors of inland valley critical zone systems -through virtual experiments- among factors that are either susceptible to evolve (land cover), that characterize inland valleys (thalweg clay lens) or are still largely unknown (subsurface lithology). To this respect, slopes and topographic effects are not unknowns nor susceptible to evolve much (as land cover which have been observed to change significantly, and are also projected to do so) and are not targets of this study. However, as topography drives lateral flow, catchment slopes may significantly impact the water budgets. We ran two extra experiments, using the reference case, and multiplying the slopes by a factor 2 and a factor 0.5 to extract the effect of extreme topography ranges found in this environment (Runge, 1991). Table 7 compares the results from these experiments to the reference case and show that there is weak impact on the interannual variability (standard deviation), but a marked impact on yearly averages. The impact of slopes is comparable to the impact of vegetation distribution (in Table 6: Trees case ~ slope ref x0.5 ; Herbaceous case ~ slope ref x2). Lower slopes (resp. higher) decrease (resp. increase) lateral transfers to the benefit (resp. cost) of evapotranspiration.

Table 7

5. Conclusions

In this paper, we studied the hydrological functioning of Sudanian inland valleys and their sensitivity to land cover and their main features (pedology of contributive areas, clay lens), through deterministic sensitivity experiments using a physically-based critical zone (CZ) model applied on a virtual generic catchment which comprises an inland valley. This is a first approach to try to understand what controls and explains the behavior of an inland valley.

~~In this paper, we studied the hydrological functioning of Sudanian inland valleys and their sensitivity to land cover and contributive areas through deterministic sensitivity experiments using a physically-based critical zone (CZ) model applied on a synthetic catchment which comprises an inland valley. This is a first approach to try to investigate what can control and explain the behavior of an inland valley.~~

We first showed that a CZ model could be used to reproduce the complexity of a small hydrosystem (0.16 km²) as an inland valley and most of observed water fluxes and temporal dynamics as streamflow, evapotranspiration, soil moisture, water table levels, or water storage. Particularly, we confirmed that the interannual variability in precipitation (standard deviation = 225 mm) is mostly compensated by streamflow (151 mm) and to a lesser extent by evapotranspiration (64 mm) and water storage changes (26 mm).

Using numerical experiments comprising different virtual configurations of the catchment, ~~W~~we found that yearly water budgets were almost insensitive to the presence (or absence) of the low permeability layer commonly found below inland valley, although intra-seasonal variations in water storage and water table showed ~~significant~~ marked differences. Early season streamflow was ~~affected by a slight delay~~slightly delayed when the low permeability layer of the inland valley was virtually removed, which corresponds to the time required for water to percolate below the inland valley. Higher water table levels ~~allowed by~~were -obtained ~~the enhanced~~when infiltration below the inland valley was ~~then simulated~~enhanced, ~~which could sustain~~resulting in a low but permanent baseflow during the dry season, which could have significant impact downstream. This virtual experiment confirms that the observed streamflow dynamics, particularly in the dry season, is partly due to the low permeability layer, a typical inland valley feature due to the accumulation of clays (Blavet, 1997; Brabant, 1991; Von Der Heyden, 2004).

On the other hand, yearly water budgets were much more sensitive to the vegetation distribution: average yearly ET for a tree-covered catchment (944 mm) exceeds that of herbaceous-cover (791 mm). ET differences between the two covers vary between 12 and 24 % of the annual precipitation ~~of the year~~ for the wettest and driest year, respectively. Therefore, the tree-covered catchment produces a yearly streamflow ~~budget~~ 28 % lower on average ~~as compared to~~than that of an herbaceous-covered catchment, ranging from 20 % for the wettest year to 47 % for a dry year. Trees also buffer interannual variability in ET by 26 %. Extensive LULC changes in the last thirty years, resulting in forest and woodland conversion to agricultural lands, still undergoing today, calls for paying a closer attention to the distinct roles of climate changes and land cover changes on the resulting hydrological functioning of Sudanian systems.

We also found little sensitivity of the yearly water budget to the hydrodynamic properties of upstream and lateral areas, although ~~these~~ they implied completely opposite behaviors in the intraseasonal space-time patterns of water storages and ~~significant~~ marked changes in water table depths together with different dynamics and amplitudes of fluxes (e.g. streamflow, soil evaporation). Higher water table levels in the valley thalweg, ~~allowed~~ induced ~~when materials that are~~ by more permeable
5   ~~are taken into account~~materials, foster a low but permanent dry season baseflow.

To summarize, it is shown that while vegetation cover significantly change water budgets, pedological features have much more impacts on intraseasonal hydrological processes (sustained/unsustained baseflow in the dry season, catchment water storage redistribution…) than on yearly water budgets amounts~~.~~, Both factors~~and~~ may therefore potentially ~~significant~~ impact~~s~~ ~~on~~ water-dependent ecosystems, but also water uses as hydropower generation or irrigation from surface water bodies.

10 This study was limited to an elementary headwater catchment, and results derived here may not apply at larger scales like basins with larger inland valley/catchment area ratios, or different soil profile distributions. Larger scales models should be run to investigate these effects, and thus large scale spatial features should be mapped, which poses significant issues regarding subsurface structure. Indeed the in situ measurements of the underground structure are missing and the structure is not directly available through remote sensing products for instance.

	θ_S	θ_r	Ks (m/s)	|hg| (m)	n
H1	0.35-0.45	0.01-0.05	$5.8.10^{-6}$-$5.7.10^{-5}$	0.2-0.6	1.6-2.2
H2	0.35-0.45	0.05-0.1	$1.2.10^{-7}$-$3.5.10^{-5}$	0.2-0.6	1.5-1.8
H3 (Clay)	0.4-0.5	0.05-0.1	$1.2.10^{-8}$-$1.2.10^{-6}$	1-1.5	1.15-1.5
H3 (Saprolite)	0.4-0.45	0.05-0.1	$1.2.10^{-6}$-$5.7.10^{-5}$	0.7-1.5	1.2-2
H3 (Inland Valley)	0.2-0.35	0.01-0.05	$1.2.10^{-6}$-$5.7.10^{-5}$	0.7-1.5	1.5-2.2

Table 1: ranges of hydrodynamic properties in the area, following Van Genuchten, 1980. From Hector, 2014.

Property	Value
Extension X	300m
Extension Y	720m
Extension Z	10.5m
DX (grid resolution)	20m
DY	20m
DZ	variable: 0.13 – 1.19m
duration	8yrs
Dt	0.5hr
Slope X	2 %
Slope Y	4 %

Table 2: model setup

	θ_S	θ_r	Ks (m/s)	|hg|(m)	n
H1	0.4	0.01	$1.11.10^{-4}$	0.3	1.8
H2	0.36	0.01	$2.8.10^{-4}$	0.3	1.65
H3 (Clay)	0.45	0.056	$5.6.10^{-9}$	1	1.3
H3 (Saprolite)	0.3	0.004	1.10^{-5}	1.3	1.76
H3 (Inland valley)	0.3	0.004	$2.8.10^{-5}$	0.33	1.65

15   **Table 3: hydrodynamic properties for the virtual V-shaped catchment , following Van Genuchten, 1980.**

Inland valley low permeability layer	yes	no	–
Vegetation	anthropized (trees only in riparian area and inland valley fringes)	tree covered	Fully anthropized (no trees)

contributive area (H3 outside the valley thalweg)	clayey	sandy to loamy (saprolite)	Asymmetric (clay in the West, Sand in the East)

	Clay lens in the valley thalweg	**H3 layer**	**Vegetation**
Reference case	yes	Clay	Trees & Herbaceous
Exp 1. : Inland valley	no	Clay	Trees & Herbaceous
Exp 2. : Vegetation	yes	Clay	Trees only
			Herbaceous only
Exp 3.: Contributive areas	yes	Saprolite	Trees & Herbaceous
		Clay in the West, Saprolite in the East	

Table 4: virtual experiments. ~~Reference case is shown in grey~~ **'Trees & Herbaceous' refers to trees only in riparian area and inland valley fringes, as shown in Fig. 1**

Year	P(mm) [(%)]	ET (mm) [(%)]	Q (mm) [(%)]	S (mm) [(%)]
2006	913 [100]	775 [85]	197 [22]	-59 [-6]
2007	1214 [100]	829 [68]	374 [31]	11 [1]
2008	1211 [100]	799 [66]	400 [33]	12 [1]
2009	1496 [100]	931 [62]	551 [37]	14 [1]
2010	1527 [100]	881 [58]	644 [42]	3 [0]
2011	934 [100]	746 [80]	224 [24]	-35 [-4]
2012	1423 [100]	848 [60]	529 [37]	45 [3]
Mean ± std (2007-2012)	1301 ± 225	839 ± 64	454 ± 151	8 ± 26

Table 5: water budgets for the reference case. Mean and standard deviations are calculated on the period 2007-2012

5

	ET (mm)	Q (mm)	S (mm)
reference	839 ± 64	454 ± 151	8 ± 26
No Inland valley	830 ± 64	463 ± 153	8 ± 24
trees	944 ± 53	361 ± 144	-5 ± 54
herb	791 ± 72	500 ± 151	10 ± 17
saprolite	793 ± 60	495 ± 153	13 ± 36
mixed	816 ± 62	475 ± 154	10 ± 28
Slope ref x 0.5	933 ± 62	354 ± 154	14 ± 28
Slope ref x 2	773 ± 64	526 ± 157	1 ± 21

Table 6: Interannual mean and standard deviation of simulated evapotranspiration (ET), streamflow (Q) and storage (S) for the different virtual experiments and for the period 2007-2012

reference	**839 ± 64**	**454 ± 151**	**8 ± 26**
Slope ref x 0.5	933 ± 62	354 ± 154	14 ± 28
Slope ref x 2	773 ± 64	526 ± 157	1 ± 21

Table 7: Interannual mean and standard deviation of simulated evapotranspiration (ET), streamflow (Q) and storage (S) for the period 2007-2012 for the reference case and two extreme slope cases

5
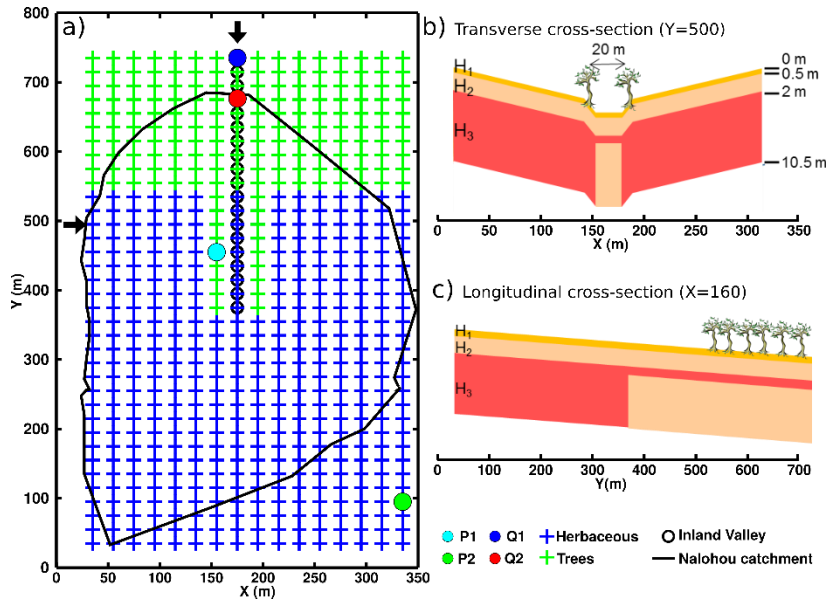

Figure 1 : a) catchment mesh. Blue and green crosses indicate the vegetation distribution for the reference case. Inland valley cells are shown as black circles. P are water table sampling locations and Q are streamflow sampling locations. b-c) domain cross sections schematically made of three soil types: high-permeability sandy soils (yellow), hard-pan, or fissured basement (orange) and low permeability clay accumulation (red).
Figure 2 : Model forcing: upper panel: daily precipitation. SWin = incoming short waves, LWin = incoming long waves, Ta = air temperature, SH = specific humidity, wind spd = wind speed. Data is shown as daily mean (black curve) and daily minima and maxima (shaded area)
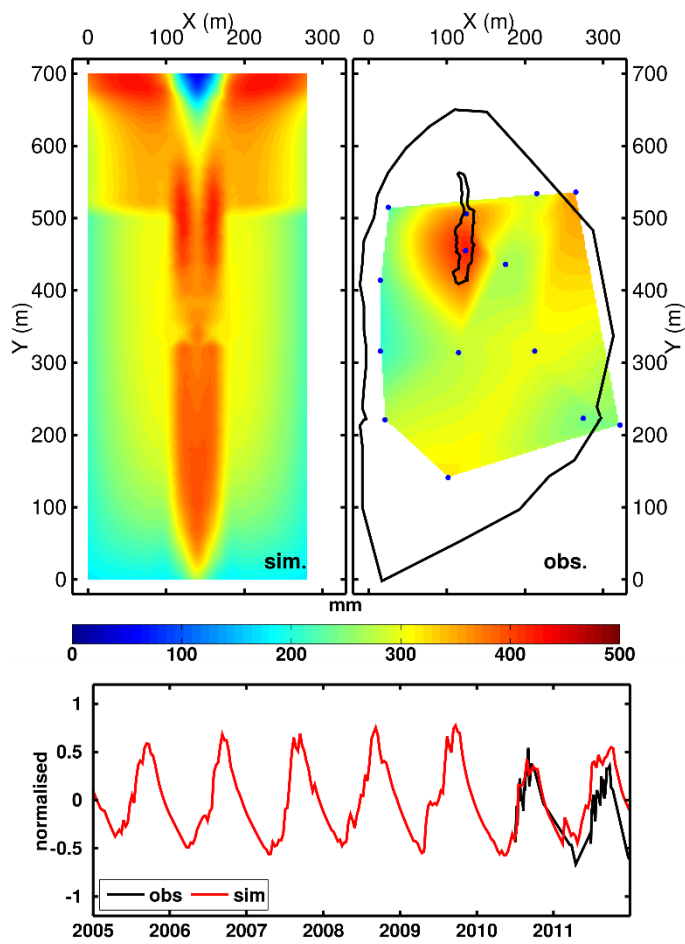

Figure 3 : Empirical Orthogonal Function decomposition of water storage changes (WSC). Upper panels: spatial patterns of WSC for the 1st mode of EOF. Left: simulated WSC, right: observed, gravity-derived WSC at the Nalohou catchment (blue points are station locations). The outline of the inland valley is shown for the Nalohou catchment. Lower panel: temporal pattern of the first mode of simulated and observed WSC.
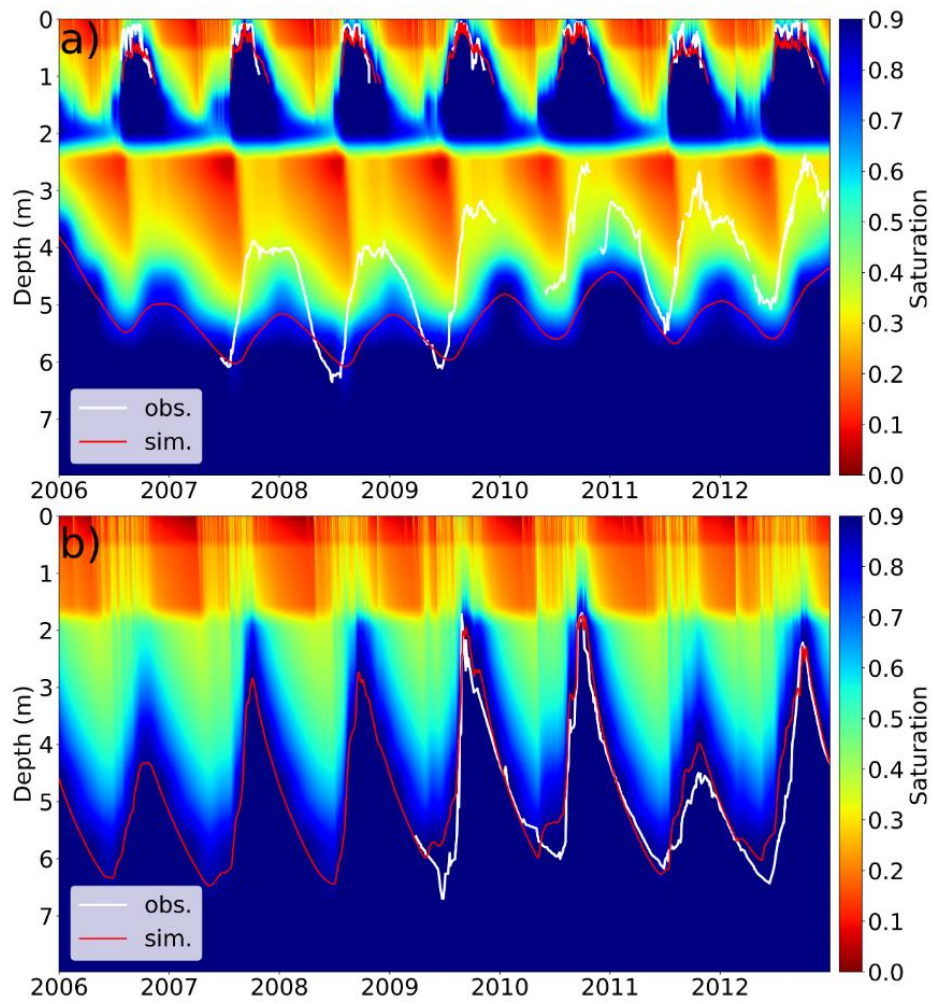

Figure 4 : simulated saturation, and observed and simulated water table. a) In the inland valley (at P1), and for the reference simulation (clayey H3 layer), b) in the upstream area (at P2) and for the saprolite simulation (sandy H3 layer)
Figure 5 : Observed and simulated streamflow for the wet seasons of the period 2008 to 2012 at station Q2
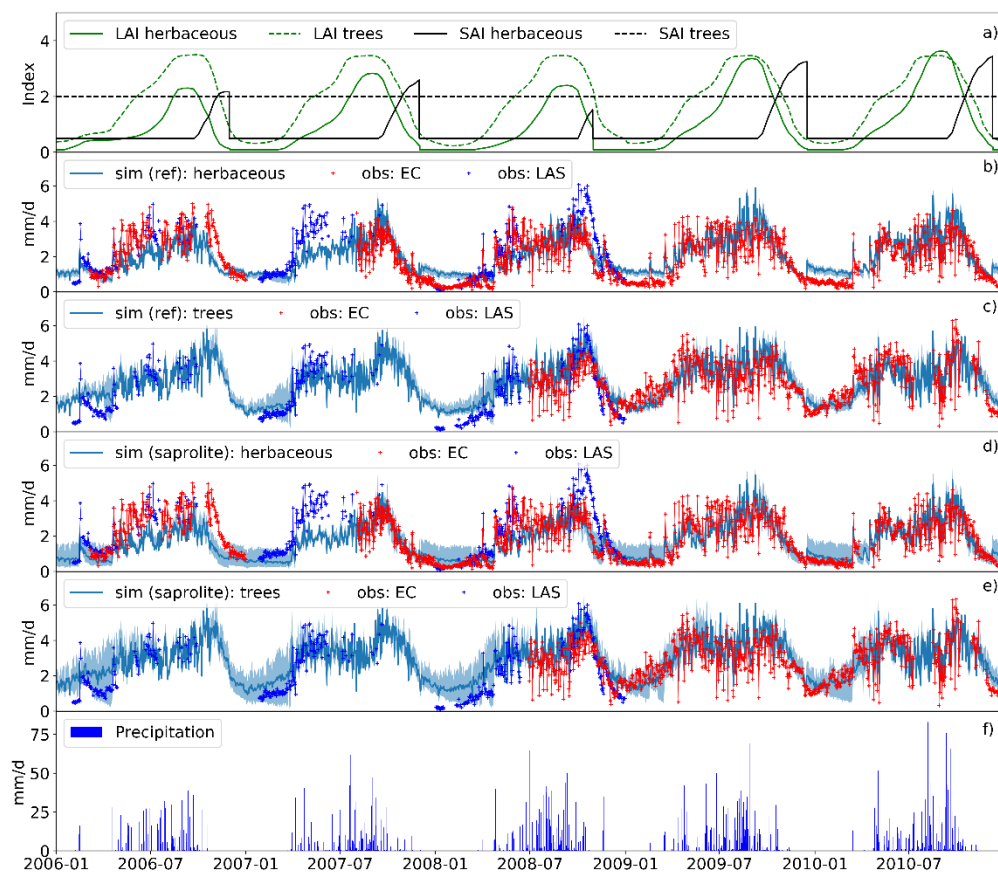

Figure 6 : a): LAI and SAI forcings for tree and herbaceous covers. b-e): Observed and simulated evapotranspiration over herbaceous cells (b) and trees cells (c) for the reference simulation, and the saprolite simulation (d and e). Blue line shows the spatial average over all cells of the respective cover out of the inland valley, and the shaded area show the extent of spatial maxima and minima. f) precipitation.
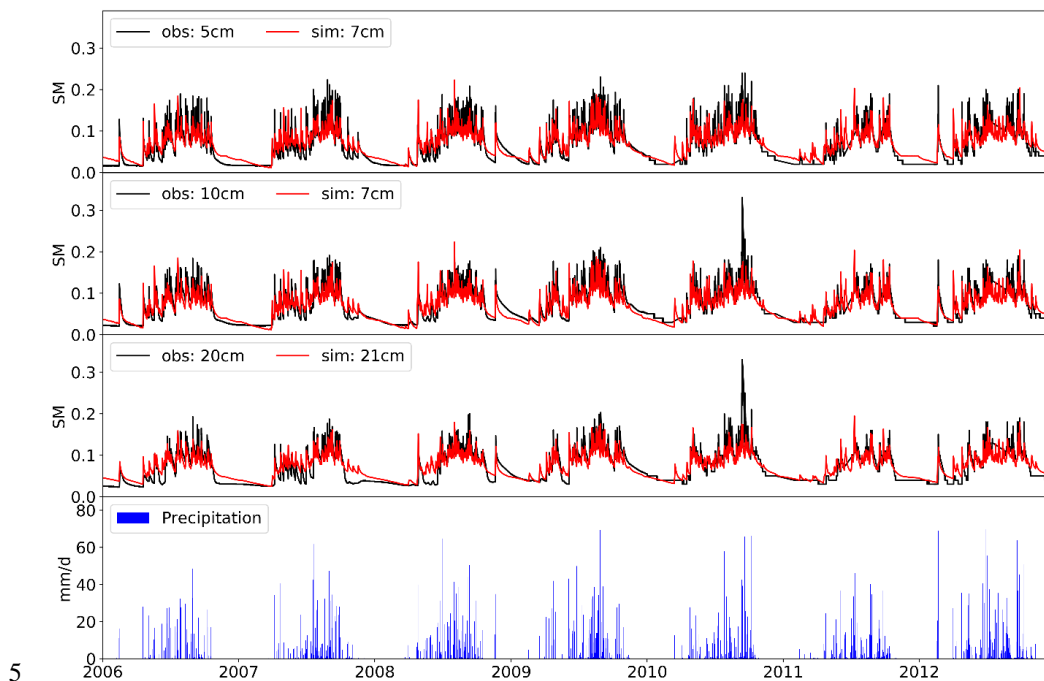

**Figure 7   : observed and simulated soil moisture for the saprolite simulation at location P2**

Figure 8 : Simulated water storage changes : First mode of the EOF for all cases: upper panel: spatial patterns. Lower panel: temporal patterns.

46

Figure 9 : Simulated streamflow of year 2011 for the three virtual experiments. The reference run is always displayed as a black line. In the lower panel, the clay+saprolite refers to the 'mixed' case where H3 layer is made of clayey material on the left bank and saprolite material on the right bank.
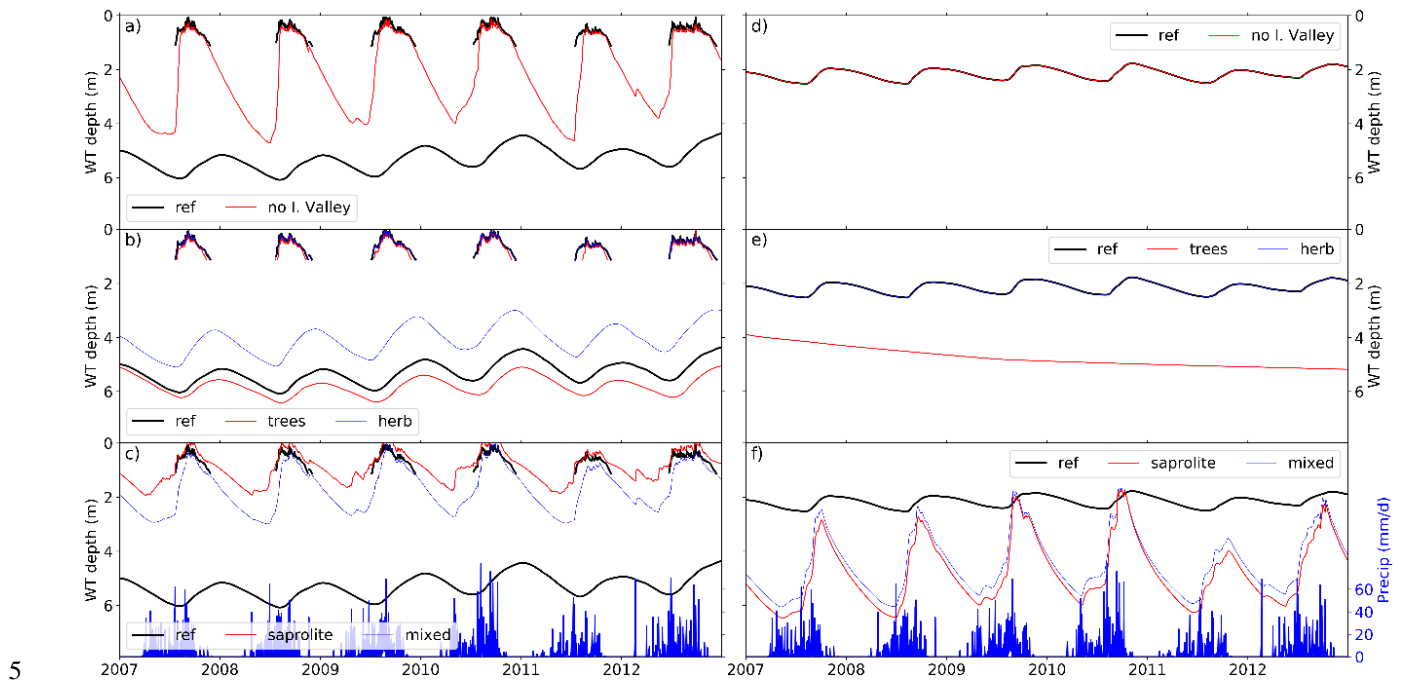

Figure 10: Simulated water table in the valley thalveg (left) at P1 and on the upper contributive area (right) at P2
