9 **Abstract.** The coupled poro-mechanical behaviour of geologic-fluid systems is fundamental to numerous processes in
10 structural geology, seismology and geotechnics but is frequently overlooked in hydrogeology. Substantial poro-mechanical
11 influences on groundwater head have recently been highlighted in the Bengal Aquifer System, however, driven by terrestrial
12 water loading across the Ganges-Brahmaputra-Meghna floodplains. Groundwater management in this strategically important
13 fluvio-deltaic aquifer, the largest in south Asia, requires a coupled hydro-mechanical approach which acknowledges poro-
14 elasticity. We present a simple partially-coupled, one-dimensional poro-elastic model of the Bengal Aquifer System, and
15 explore the poro-mechanical responses of the aquifer to surface boundary conditions representing hydraulic head and
16 mechanical load under three modes of terrestrial water variation. The characteristic responses, shown as amplitude and phase
17 of hydraulic head in depth profile and of ground surface deflection, demonstrate (i) the limits to using water levels in
18 piezometers to indicate groundwater recharge, as conventionally applied in groundwater resources management; (ii) the
19 conditions under which piezometer water levels respond primarily to changes in the mass of terrestrial water storage, as applied
20 in geological weighing lysimetry; (iii) the relationship of ground surface vertical deflection to changes in groundwater storage;
21 and (iv) errors of attribution that could result from ignoring the poroelastic behaviour of the aquifer. These concepts are
22 illustrated through application of the partially-coupled model to interpret multi-level piezometer data at two sites in southern
23 Bangladesh. There is a need for further research into the coupled responses of the aquifer due to more complex forms of surface
24 loading, particularly from rivers.

26 1 Introduction

27 Throughout the Bengal Basin, the floodplains of the Ganges, Brahmaputra and Meghna (GBM) rivers (Fig. 1) are underlain
28 by the Bengal Aquifer System (BAS), the largest aquifer in south Asia and the source of water to over 100 million people
29 (Burgess et al., 2010). More than 10 million tubewells throughout the basin provide water from BAS for domestic use and for

30 irrigation of the rice crop (Ravenscroft et al., 2009); these include hand-pumped tubewells, normally between 15 and 30 m
31 depth below ground level (bgl), for domestic use, and tubewells installed with motor-driven pumps to abstract water from
32 between 50 and 75 m depth bgl for irrigation of the dry season rice crop (January to April). Municipal water supplies commonly
33 abstract year-round from depths between 200 and 300 m bgl (Shamsudduha et al., 2018). Management of the BAS groundwater
34 resource relies on monitoring water levels in networks of observation boreholes, taking the conventional approach that changes
35 in groundwater heads represent volumetric changes in groundwater storage through recharge and drainage (Shamsudduha et
36 al., 2011). This approach presumes the hydraulic behaviour of the aquifer to be decoupled from its mechanical response to
37 changes in stress. Recently, however, the distinctively poroelastic behaviour of the BAS has been recognised (Burgess et al.,
38 2017), by which groundwater heads are subject to substantial mechanical perturbation driven by changes in the mass of
39 terrestrial water storage (TWS) above the surface of the aquifer. A coupled hydro-mechanical approach is necessary for
40 understanding groundwater conditions and managing resources in this environment, particularly in relation to recharge
41 (Shamsudduha et al., 2012), sustainability of groundwater abstraction for irrigation (Shamsudduha et al., 2008) and municipal
42 water supply (Ravenscroft et al., 2013), and the security of schemes for mitigation against groundwater arsenic (Michael and
43 Voss, 2008) and salinity (Rahman et al., 2011; Sultana et al., 2015).

44
45 The generally coupled poro-mechanical nature of geologic-fluid systems is well-established (Neuzil, 2003); porewater
46 pressures affect the stress state and vice-versa. These interactions are accepted as important where groundwater conditions are
47 related to faulting (Roeloffs, 1988; Rojstaczer and Agnew, 1989; Sutherland et al., 2017), earthquakes (Manga et al., 2012),
48 pumping-induced aquitard responses (Verruijt, 1969), ground subsidence (Burbey et al., 2006; Erban et al., 2014), glacial
49 loading effects (Bense and Person, 2008; Black and Barker, 2016) and surface water interactions (Acworth et al., 2015; Boutt,
50 2010). Use of ground surface vertical displacements to infer aquifer or groundwater conditions (Chaussard et al., 2014; Reeves
51 et al., 2014) is also predicated on coupling of the hydraulic and mechanical behaviour of aquifer sediments. For simulation of
52 transient groundwater flow in aquifers, however, a decoupling simplification is frequently applied such that the elastic equation
53 does not need to be solved simultaneously. Thus, the flow equation is solved without consideration of internal stresses and
54 strains or mechanical boundary conditions. Despite this, the poro-mechanical nature of confined aquifers is embedded in the
55 concept of specific storage which incorporates the elastic compressibility of the aquifer materials (Domenico and Schwartz,
56 1998; Green and Wang, 1990; Narasimhan, 2006). Furthermore, it is associated with the well known concept of barometric
57 efficiency (Spaine, 2002), which describes the response of groundwater pressure to variations in atmospheric pressure, perhaps
58 the example of surface loading effects most familiar to hydrogeologists. The decoupling assumption is reasonable where the
59 effects of mechanical loading can be considered insignificant, either when the changes in load are small, or when the applied
60 load is mostly borne by the solid rather than the fluid (Black and Barker, 2016). Neither of these conditions apply to the BAS
61 sediments, which are highly compressible (Steckler et al., 2010) and subject to substantial and extensive TWS mechanical
62 loads due to heavy rainfall, deep flooding and large river discharges as a consequence of the annual monsoon (Shamsudduha
63 et al., 2012).

65 In the event of laterally-extensive changes to mechanical loads and/or hydraulic heads above the surface of an aquifer, and
 66 laterally-homogeneous aquifer properties, by symmetry it may be deduced that lateral strains are zero. This condition gives
 67 rise to a *partial* coupling of the elastic and fluid pressure equations (Neuzil, 2003). In the case of *partial* coupling, changes to
 68 the mechanical load due to the changing mass of water near or at the surface may be included within the flow equation, one-
 69 dimensionally in the vertical direction, and the solutions will satisfy all the equilibrium and compatibility requirements for
 70 stress and strain. There is no need to solve the elastic equation in order to calculate pressures in the aquifer, although once the
 71 flow equation is solved, the pressures can be substituted into the elastic equation to provide stresses and strains (Anochikwa
 72 et al., 2012). A sub-set of this partially-coupled condition occurs where there is negligible groundwater flow, due to very low
 73 hydraulic gradients, low permeability or a combination of both. This can be the situation in extensive fluvio-deltaic aquifers
 74 of low topographic relief such as the BAS (Burgess et al., 2017) if mechanical loading is imposed at the surface in a manner
 75 which does not induce significant vertical hydraulic gradients. Under these conditions, porewater pressures are determined by
 76 changes to surface mechanical loading alone, and changes in groundwater head may be taken as a measure of changes in TWS
 77 mechanical loading above the surface of the aquifer. This is the conceptual basis for geological weighing lysimetry (van der
 78 Kamp and Schmidt, 1997;Bardsley and Campbell, 1994, 2007;van der Kamp and Schmidt, 2017) as used in diverse
 79 environments to determine Δ TWS at the scale of individual catchments (Marin et al., 2010;Lambert et al., 2013;Barr et al.,
 80 2000;Smith et al., 2017). Geological weighing lysimetry has been suggested as suitable for mapping the variability of Δ TWS
 81 within the Bengal Basin (Burgess et al., 2017;Bardsley and Campbell, 2000), complementary to basin-scale estimates based
 82 on the Gravity and Climate Recovery Experiment (GRACE) satellite mission (Tapley et al., 2004;Tiwari et al.,
 83 2009;Shamsudduha et al., 2012).

84

85 The purpose of this paper is to explore the behaviour of the BAS as a poroelastic aquifer subject to a variety of extensive TWS
 86 mechanical and hydraulic loads. Poro-elastic theory is very well-established, but has not previously been applied in the
 87 context of a thick and extensive aquifer such as the BAS to show the implications for groundwater pressures together with
 88 solid strains and ground surface displacements.

89

90 The Bengal Basin has a tropical climate dominated by the Indian monsoon, with annual rainfall increasing from 1500 mm in
 91 the south and west to 5500 mm in north-east Bangladesh, of which 85% falls during the summer rainy season (May to
 92 November) when individual storm events can contribute over 100 mm per day (Ravenscroft, 2003). During the monsoon
 93 season, river levels rise by 2-8 m leading to widespread flooding (Steckler et al., 2010) with up to 30% of the land surface
 94 routinely being flooded to a depth up to ca. one metre. During the Boro rice irrigation season (January to April), groundwater
 95 pumping for irrigation throughout rural areas commonly provides standing water across rice paddies to a depth of ca 0.1 m
 96 (Hasanuzzaman, 2003). For the purpose of this paper, we treat the separate components of TWS across the GBM floodplains
 97 as *inundation* (free-standing surface water such as paddy, floods, beels, and ponds), *unconfined storage* (water in the

98 unsaturated zone and in saturated pores in the intermittently saturated zone of the aquifer), *elastic storage* (water in the
99 saturated pores in the permanently saturated zone), and *rivers* (surface water flowing in rivers and drainage channels).
100 Processes that alter the TWS loads include rainfall and evaporation, rising and falling river stage, flooding and drainage of the
101 land surface, varying soil moisture storage and a fluctuating water table. Groundwater pumping modifies the water balance
102 and induces additional hydro-mechanical responses. These processes differ in their timing, the geometry of the TWS stores
103 they affect and the relationship between their resultant hydraulic and mechanical expressions. First, we apply the concept of
104 *partial* coupling to seek characteristic responses of the aquifer to extensive TWS loads originating as (a) surface water
105 inundation, (b) water table fluctuation and (c) water bodies hydraulically isolated from the aquifer. These loading styles are
106 examined with and without pumping. The results address important questions for the BAS which are likely also relevant to
107 similarly extensive and strategically important fluvio-deltaic aquifer systems elsewhere in south Asia (Fendorf et al.,
108 2010; Benner et al., 2008; Larsen et al., 2008; Tam et al., 2014; Xu et al., 2011): how can piezometer heads in the poroelastic
109 aquifer be used to indicate recharge, as required for conventional groundwater resources management; under what conditions
110 can piezometer heads be used to measure Δ TWS using geological weighing lysimetry; can ground surface deflections be related
111 to changes in groundwater storage; and what errors may arise if the poroelastic behaviour of the aquifer is ignored? Second,
112 we apply the partial coupling approach to these questions in the BAS, with reference to multi-level piezometer data from
113 Khulna and Laksmipur in southern Bangladesh (Fig. 1).

114 **2 Methods**

115 We firstly set out the partially-coupled 1D poromechanical approach that we use to examine the implications of specific surface
116 (upper boundary) loading scenarios, with aquifer parameters set to represent the BAS underlying the GBM floodplains (Fig.
117 1). We consider an equivalent homogeneous uniform medium, as well as a layered structure based on lithological sections.
118 The results provide a diagnostic framework which we apply to analysis of loading styles at Khulna and Laksmipur in southern
119 Bangladesh.

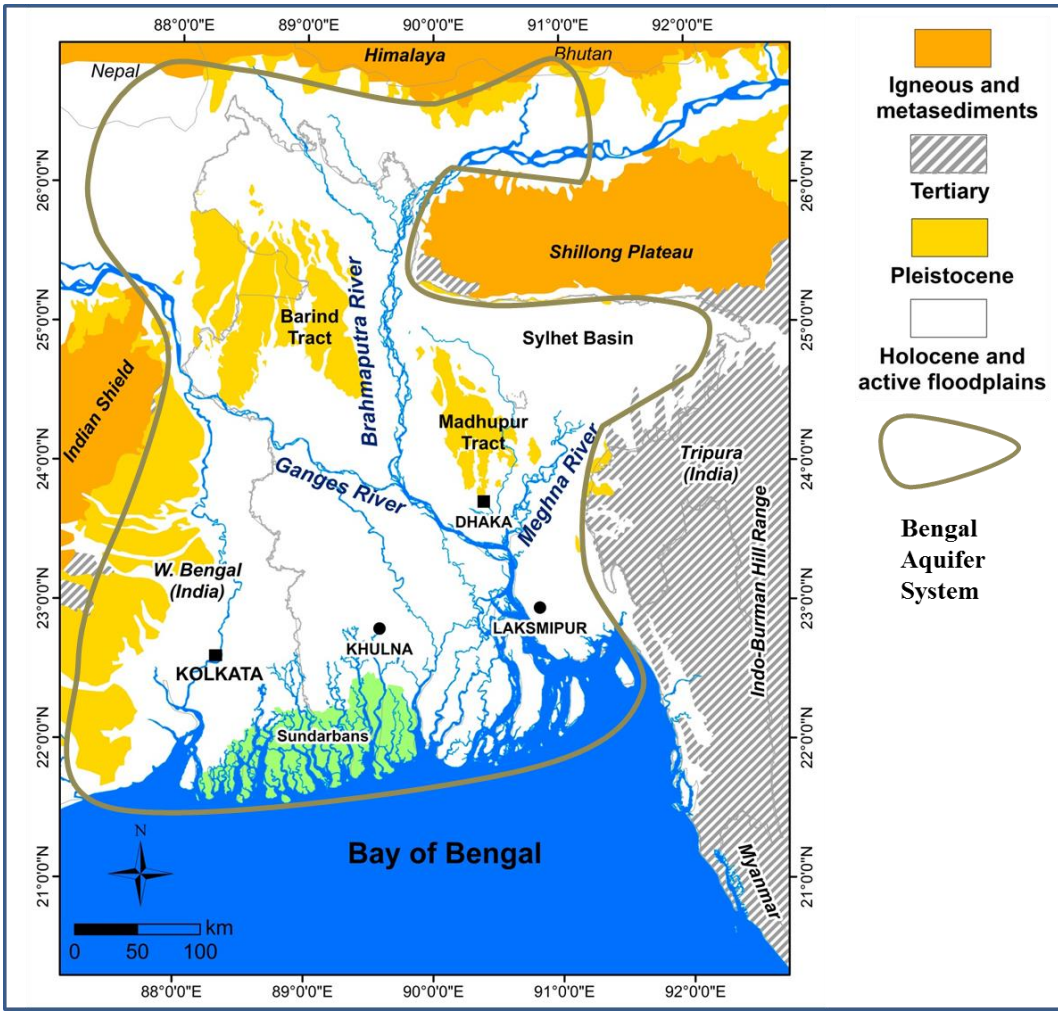

Figure 1. Location map showing the extent of the Bengal Aquifer System (BAS) and the Ganges-Brahmaputra-Meghna (GBM) floodplains.

2.1 Poromechanical equations

We concentrate on the coupling between water flow and the mechanical behaviour of the BAS sediment, assuming isothermal conditions and that the aquifer material behaves in a linear-elastic way. This is likely to be reasonable under repeated mechanical load-unload cycles, provided there is no secular decline in groundwater level sufficient to cause effective stress to exceed the previous loading maximum.

The 3D flow and mechanical equations are given in the Appendix. In the event of uniform (1D) areal mechanical loading, and where lateral strains are negligible, the system simplifies to a flow equation coupled to a mechanical equation for 1D loading:

$$\nabla \cdot \kappa(\nabla p + \rho g \nabla z) = S_s \frac{\partial p}{\partial t} - S_s \xi \frac{\partial \sigma_{zz}}{\partial t} - gJ \quad (1)$$

131 where κ is the hydraulic conductivity (m s^{-1}), ρ is the fluid density (kg m^{-3}), p is the pore pressure (Pa), z is the elevation (m),
 132 J ($\text{kg m}^{-3}\text{d}^{-1}$) is a fluid source term used here to simulate groundwater abstraction by pumping, ξ is the one-dimensional loading
 133 efficiency (given in Appendix A5), ν is Poisson's ratio (-), S_s is the one-dimensional specific storage typically used in
 134 groundwater analyses (van der Kamp and Gale, 1983).

135

136 The sediment is assumed to sit on a rigid base, with the top surface free to move, so strain can only be vertical. Thus from
 137 Equation A1, the vertical stress and strains are related by:

$$\sigma_{zz} = K' \varepsilon_{zz} + \alpha_B p \quad (2)$$

138 where $K' = 3K(1 - \nu)/(1 + \nu)$, α_B is the Biot-Willis coefficient (assumed equal to 1 to simulate incompressible particle
 139 grains) and the bulk modulus, K and shear modulus, G are related to Young's modulus E by $K = \frac{E}{3(1-2\nu)}$ and $G = \frac{E}{2(1+\nu)}$.
 140 Changes to the total vertical stress, σ_{zz} (here termed 'mechanical loads') are applied as a boundary condition at the surface,
 141 and are transmitted by the solid skeleton to the entire solid at the acoustic velocity. This represents 'partial coupling'; if there
 142 are negligible internal loads and provided the changes to the surface load are known, then the flow equation (1) can be solved
 143 without a need to solve the elastic equations. Deformations can be found from Eq. (2), in conjunction with the compatibility
 144 relationships.

145

146 The simplified system considered here is given in Fig. 2. On the upper boundary, the changing TWS is simulated by means of
 147 a changing head and a changing mechanical load, according to the nature of the contributing hydrological components. Under
 148 this simplification, vertical displacement at the surface will arise in only two ways: by contraction or expansion of the pore
 149 space where there is a net change in the volume of water in the column, and by contraction or expansion of the pore water.
 150 Being limited to 1D movement, these volume changes are entirely taken up by vertical displacement.

151

152 The reference frame is the base of the model which is assumed fixed in space and set at 1 km depth, acknowledging the
 153 variation in aquifer thickness between south-east Bangladesh, 3000 m (Michael and Voss, 2009a) and West Bengal, 300 m
 154 (Mukherjee et al., 2007). Within this domain, equations (1) & (2) are solved analytically for a homogeneous uniform material
 155 in the absence of pumping, and numerically where layers of individually homogeneous materials are simulated, with and
 156 without pumping. Where pumping is simulated, the water is assumed to be taken uniformly from the pumping-interval. For
 157 simplicity, earth-tides are neglected.

158

159 2.2 Analytical solution

160 Taking Eq. (1) and assuming homogeneous K , E and that $J = 0$, converting p to metres head, h (i.e. $h = \rho g p + z$), and σ_{zz} to
 161 metres of load (i.e. $L = \sigma_t / \rho g$, where ρ (kg m⁻³) is the density of water and g (m s⁻²) is the acceleration due to gravity)
 162 (Anochikwa et al., 2012; van der Kamp and Schmidt, 1997) gives:

$$D \frac{\partial^2 h}{\partial z^2} = \frac{\partial h}{\partial t} - \xi \frac{\partial L}{\partial t} \quad (3)$$

163 where 1D hydraulic diffusivity is defined as $D = \frac{k}{S_y}$.

164 Applying the following sinusoidal hydraulic and mechanical loading boundary conditions to Eq. (9) where we introduce
 165 parameter, α , which can be set to zero to give the case of a load in the absence of a varying head, and otherwise is kept at 1:

$$h(0, t) = H(t) = \alpha H_0 \cos(\omega t) \quad (4)$$

$$L(t) = S_y H_0 \cos(\omega t)$$

166 The following solution is obtained:

$$h(z, t) = \alpha B \cos(\omega t - \psi) \quad (5)$$

167 where ψ is the lag (in radians) behind the head $H(t)$ and mechanical loads $L(t)$ at the boundary and:

$$B = \sqrt{\gamma^2 + 2\gamma(\alpha - \gamma)e^{-\theta} \cos(\theta) + (\alpha - \gamma)^2 e^{-2\theta}} \quad (6)$$

$$\psi = \tan^{-1} \left(\frac{(\alpha - \gamma) \sin(\theta)}{(\alpha - \gamma) \cos(\theta) + \gamma e^{\theta}} \right)$$

$$\theta = z \sqrt{\frac{\omega}{2D}} = z \sqrt{\frac{\pi}{DT}} \quad \text{and} \quad \gamma = S_y \xi$$

168

169 In the event that the mechanical load, L , is negligible compared to applied head H (e.g. where either S_y is very small or ξ is
 170 very small), the hydraulic-only solution is well known (van der Kamp and Maathuis, 1991):

$$h(z, t) = H_0 \exp(-\psi) \cos(\omega t - \psi) \quad (7)$$

171 where the lag is now $\psi = \theta$. Thus, the lag increases with depth or with increasing forcing frequency and the amplitude
 172 decreases exponentially with θ .

173 Displacement and change in groundwater storage can be calculated as the time integral of velocity at the surface. Applying
 174 Darcy's law at the surface ($z=0$) and integrating gives:

$$u = \Delta S = \int_0^t K \left. \frac{dh}{dz} \right|_{z=0} dt' \quad (8)$$

175 Equation (8) can be computed by differentiating Eq. (5) w.r.t. z and then numerically integrating over time. Alternatively, the
 176 change of storage can be reported from the numerical model.

177 **2.3 Numerical solution**

178 We used the COMSOL Multiphysics® software, validated against the analytical solutions for uniform permeability, to solve
179 the stress and flow equations (1) and (2). The finite-element model is unrestricted in terms of spatial distribution of parameter
180 properties and in terms of the boundary condition functions.

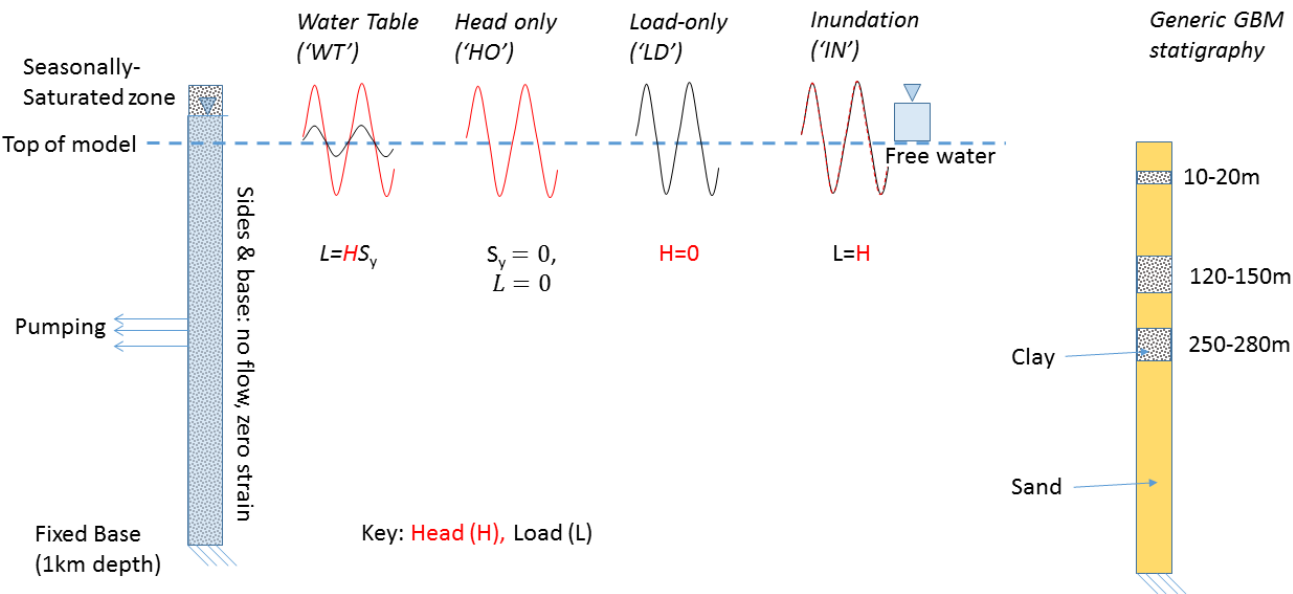

181 **2.4 Parameter allocation**

182 Selected parameter values for the BAS underlying the GBM floodplains are given in Fig. 2. The bulk values for the uniform
183 representations are close to the harmonic average of the series components. We next discuss the context in which these
184 parameter selections are made.

185 **2.4.1 Modulus of elasticity, storativity and loading efficiency**

186 Text-book S_s values (Domenico and Schwartz, 1998) for the materials in the Bengal Basin range between approximately 1×10^{-5}
187 m^{-1} (dense sandy gravel) and $1 \times 10^{-2} \text{ m}^{-1}$ (plastic clay). In large-scale modelling of head recession data in the basin Michael
188 & Voss (Michael and Voss, 2009b) achieved their best fits when S_s was $9.4 \times 10^{-5} \text{ m}^{-1}$ taking pumped abstraction to be areally
189 uniform. This is the basis for the range in specific storage, S_s , for the BAS (Fig. 2).

190

197 **0.1 throughout; $\nu=0.25$; E , and ξ are calculated using Equations (A3, A4 and A5). ¹ (Shamsudduha et al., 2011); ² (Burgess et al.,**
198 **2017); ³ (Michael and Voss, 2009a).**

Specific storage S_s and Young's Modulus E are related through Eq. [A3] and to the loading efficiency ξ via Eq. (A4). These inter-relationships are plotted in Fig. 3. It is notable that for $E < 1$ GPa, $\xi > 0.95$ and $S_s > 1 \times 10^{-5} \text{ m}^{-1}$. Thus the loading efficiency only falls significantly below 1 for materials stiffer than around 1 GPa, and where the specific storage is less than $1 \times 10^{-5} \text{ m}^{-1}$. Uncemented sediment is thus expected to have $\xi \sim 1$ (Bakker, 2016); on this basis the BAS sediment is unlikely to be sufficiently stiff in the top few hundred metres to allow decoupling of the stress and flow equations. This is corroborated by in situ, high-pressure dilatometer measurements (de Silva et al., 2010) giving E within the broad range for sediments given in Fig. 3.

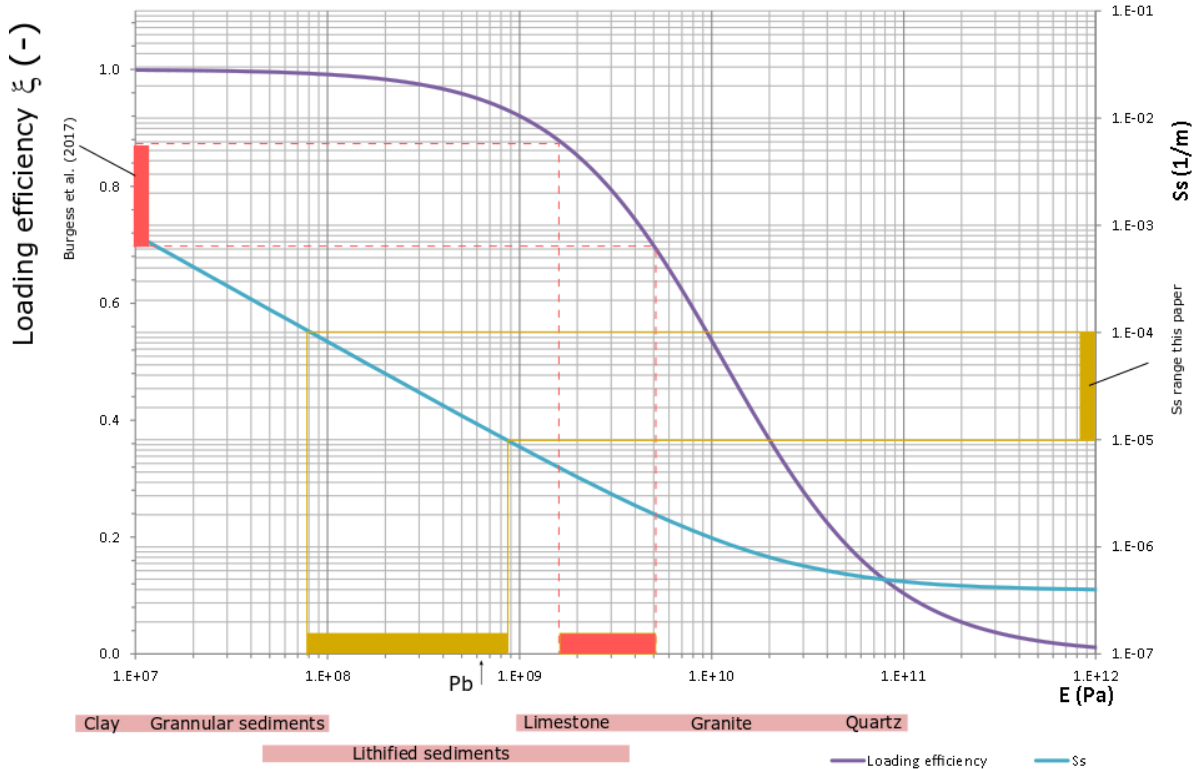

Figure 3. Relationship between 1D Specific storage (S_s), Young's modulus (E) and 1D loading efficiency (ξ) using equations (A3, A4 and A5) assuming porosity of 0.1 and Poisson's ratio of 0.25. Projections show the corresponding inferred ranges of E based on the S_s range applied ($1 \times 10^{-5} - 1 \times 10^{-4} \text{ m}^{-1}$) and the loading efficiencies calculated via barometric efficiency estimates (0.69-0.87) by Burgess et al. 2017. Pink bars show indicative ranges for common geological materials. Arrow indicates data from 73 m depth at Padma Bridge (Pb) (De Silva et al., 2010).

Estimates of (1D) loading efficiency based (Jacob, 1940) on barometric efficiency are rather lower: a range of 0.69-0.87 has been determined at Laksmipur in the GBM sediment (Burgess et al., 2017). This is potentially indicative of a considerable stiffening due to burial (E in the range 6-17 GPa), indicating S_s in the range 1×10^{-6} to $9 \times 10^{-8} \text{ m}^{-1}$. Such a condition might be expected in a Gibson soil (Gibson, 1974; Powrie, 2014). However, the Laksmipur estimates do not decrease systematically with depth, possibly due to changes in stiffness in different materials. The discrepancy may alternatively be related to the

timescale of processes responsible for changes in groundwater pressure. Barometric efficiency measurements operationally consider short-term pore pressure changes likely corresponding to the response of relatively stiff aquifer sands, whereas pressure changes in clays are expected to become significant in the longer term. Where short-term moisture loading effects are the key interest (Anochikwa et al., 2012; Bardsley and Campbell, 2000), values for loading efficiency derived from barometric efficiency may be the most appropriate. Here however our main concern is for poromechanical consistency and for water load changes operating over a range of time scales, therefore we adopt S_s estimates based on aquifer pumping tests and use the corresponding ξ and E values (Figure 3).

2.4.2 Hydraulic conductivity

Basin scale modelling suggests a horizontal-vertical anisotropy for hydraulic conductivity in the BAS of $\sim 10,000$ (Michael and Voss, 2009b; Ravenscroft et al., 2005). This may be explained as an effective, large-scale value incorporating finer-scale detail of the highly heterogeneous sedimentary record of the past deltaic environment where low permeability lenses and drapes are laterally discontinuous (Hoque et al., 2017). Michael and Voss (Michael and Voss, 2009a) cite aquifer tests (Hussain and Abdullah, 2001) conducted by the Bangladesh Water Development Board (BWDB) giving a range for hydraulic conductivity (κ) from 3×10^{-5} to $1 \times 10^{-3} \text{ m s}^{-1}$. Accounting for anisotropy, κ_v may therefore locally be in the range $\sim 1 \times 10^{-9}$ to $1 \times 10^{-7} \text{ m s}^{-1}$. The κ_v values of the uniform and layered representations of the BAS underlying the GBM floodplains (Fig. 2) and of silty-clay in layered representations of the Khulna and Laksmipur sites (Sect. 4) lie within this range.

2.4.3 Specific yield

Specific yield is the drainable porosity of the material in which the water table moves. Michaels and Voss (Michael and Voss, 2009b) cite a range from 0.02 to 0.19 in Bangladesh, noting that much of the Basin has a specific yield in the range of 0.02–0.05. We take $S_y = 0.1$ and 0.01 as order-of-magnitude values typical for sand and clay respectively (Domenico and Schwartz, 1998).

2.5 Upper boundary conditions and groundwater abstraction

Changes to the shallow water budget which have the potential to be laterally-extensive and uniform include: water arriving as rainfall at the surface and either ponding or moving to the shallow water table as recharge; and water departing the surface or the water table by evaporation, or as runoff to the extensive network of drainage channels. Pumping for domestic and irrigation supply may potentially be considered as areally-uniform, where sufficiently common and over a wide area (Michael and Voss, 2008). The changing shallow water budget causes a change in mechanical loading to the aquifer system, and if in direct hydraulic continuity with the saturated water column it also causes a change in head. If the shallow water is not hydraulically connected to the saturated aquifer system, the effects of the changing water budget are transmitted to depth by mechanical compression/extension of the sediment, but not by hydraulic diffusion. Changes to the barometric pressure also apply a laterally-extensive changing force to the surface of the aquifer and to the water column, and earth tides are also laterally-

248 extensive. The daily perturbation on water heads by atmospheric pressure changes is of the order of 0.01m (Burgess et al.,
249 2017), which is small compared to the annual hydrograph amplitude of the order of 1 m. Barometric pressure and earth tides
250 are both neglected for simplicity here.

251

252 To explore the consequences of these hydraulic and mechanical loading sources, the groundwater dynamics associated with
253 three upper surface boundary conditions are modelled here (Fig. 2). Firstly, the effect of a changing level of free water is
254 examined, such as would be seen in paddy-fields, ponds or during floodwater inundation. This condition is here termed 'IN'.
255 The change in free-water level is equal to both the change in head and the change in mechanical load at the upper surface (load
256 is here parameterised in metres of water rather than as a stress). Secondly, the effect of changes to unconfined storage due to
257 a moving water table is examined. This condition is here termed 'WT'. The change in load is the specific yield times the head.
258 For very small specific yields this condition approaches the hydraulic-only ('HO') loading case, whereby there is insignificant
259 mechanical load, despite the change in head. Thirdly, we examine the effect of a changing surface water store (which could be
260 either free water held above an impermeable barrier, or a perched phreatic aquifer) which is hydraulically isolated from the
261 main aquifer system. A mechanical load only is applied, therefore no head change is applied to the aquifer and this condition
262 is termed 'LD'.

263

264 These three TWS loading scenarios are applied in turn to a uniform and a layered representation of the BAS underlying the
265 GBM floodplains. The loading is applied as sinusoidal functions with unit amplitude and time period of 1 year to simulate the
266 annual hydrological cycle. Additionally, the effects of groundwater abstraction are simulated. Abstraction is taken evenly from
267 the depth interval 50-100 m at an average rate of 0.2 m a^{-1} , either as continuous pumping or as discontinuous pumping π out
268 of phase with the TWS load, as a coarse representation of seasonally-varying pumping for irrigation during the dry season.

269

270 **3 Forward modelling results**

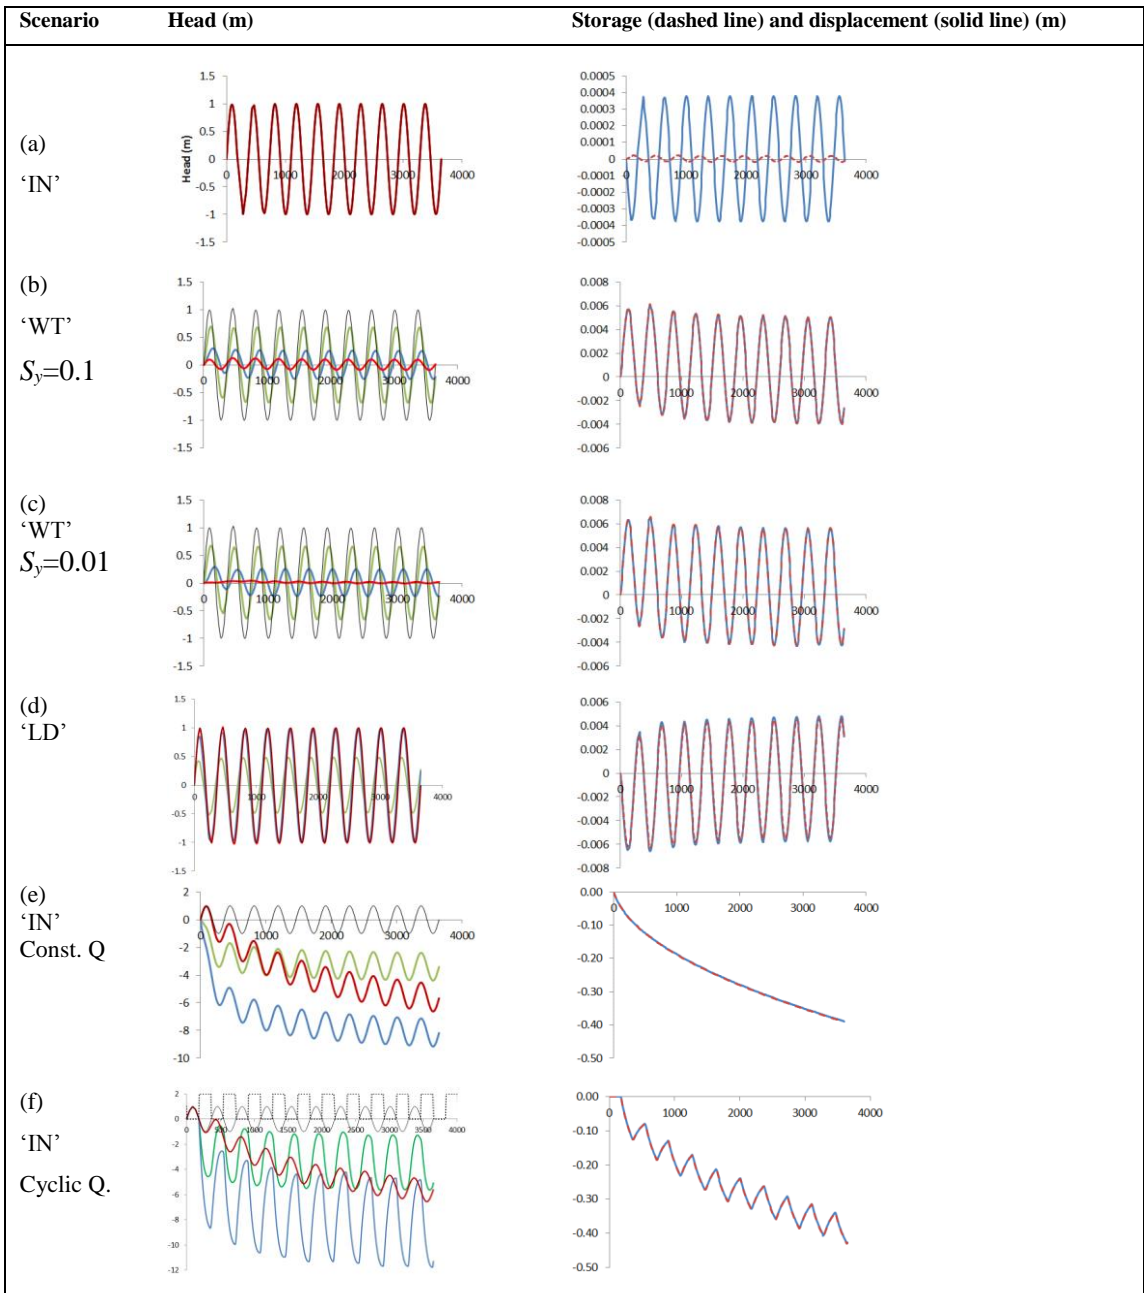

271 The modelled responses of groundwater head to sinusoidal hydraulic and mechanical source terms, together with changes in
272 groundwater storage and ground surface vertical displacements, are illustrated for the GBM environment with uniform
273 properties in Figures 4 and 5. Figure 4 shows the modelled responses over ten years at depths of 30, 100 and 300 m,
274 approximating typical BWDB multi-level piezometers (BWDB, 2013). The depth variations of amplitude and phase for
275 groundwater head and the phase-lag for surface displacement are summarised in Fig. 5. The effect of layering (Supporting
276 Information) is to cause departure from the uniform cases, so interpretation of data in a real, heterogeneous aquifer should take
277 into account local deviation from idealised uniform conditions. However, in general, the loading style ('IN', 'WT', 'LD') and

278 pumping regime are of more significance for the head responses and surface displacements than the detail of the BAS
279 stratigraphy.

280 **3.1 The free surface water inundation scenario ('IN')**

281 Under free-surface water inundation, head changes are characteristically equal in amplitude at all depths and in-phase with the
282 inundation signal. Away from the top boundary, the instantaneous head due to loading in this case is $h = \xi L$. Since ξ is close
283 to 1 and $H = L$, the head is everywhere almost equal to the mechanical load given that at the top boundary the head is also
284 $h = H$. Therefore under free-surface water inundation in the absence of pumping, piezometers at all depths can be expected to
285 record the surface water mechanical load, effectively operating as weighing lysimeters. The vertical displacement of the ground
286 surface is extremely small (amplitude ~ 0.4 mm), being due to the small compression of porewater itself over the 1 km
287 simulated depth, and is out of phase with the load (i.e. the ground surface moves downwards under an increasing load). The
288 amplitude of change in saturated storage is infinitesimal (~ 0.02 mm). The system is essentially 'un-drained'; water does not
289 flow in or out of the pores which therefore experience only minimal strain.

290

291 **Figure 4.** 1D model simulations for the GBM environment, showing results for the scenarios (a) 'IN', (b) 'WT' ($S_y=0.1$), (c) 'WT'
 292 ($S_y=0.01$), (d) 'LD', (e) 'IN' with constant pumping, (f) 'IN' with cyclic pumping, (see text for explanation). The x-axis is time in
 293 days, shown to 10 years (i.e. 3650 days). The amplitudes reported in the text are calculated from the max-min of the last annual
 294 cycle. Left: The y-axis is head, in metres (m). The surface head and/or mechanical load boundary conditions (black line) are
 295 expressed as equivalent m head (for the WT condition the unit variation of head is given and the S_y variation in mechanical load is
 296 not shown); results are in green (30 m depth), blue (100 m depth) and red (300 m depth) in all cases. For (a) results are co-linear at
 297 all depths; for (f) the intermittent pumping is shown as off/on by the square-wave dotted line. Right: The y-axis has dimension of
 298 length, in metres (m), showing changes in storage (dashed red line) and surface displacement (solid blue line) for each scenario.

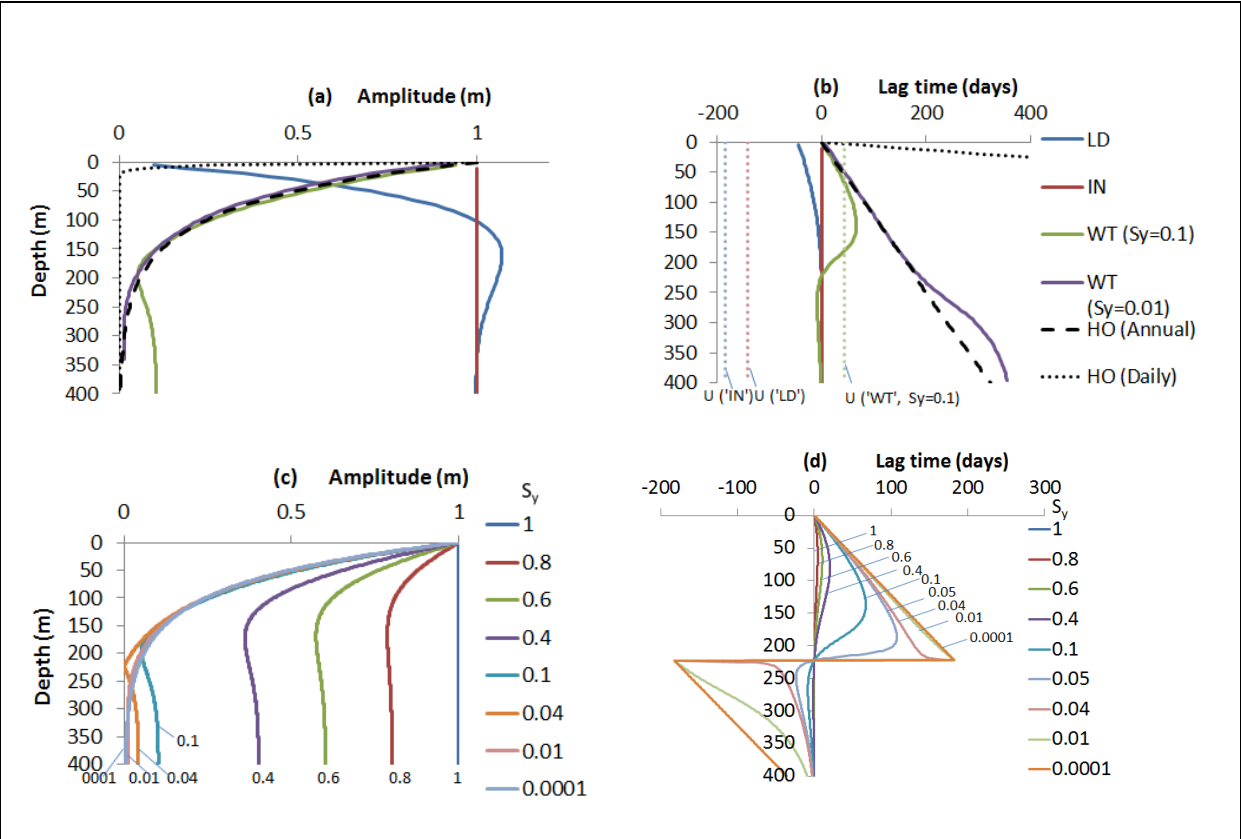

Figure 5. Profiles with depth for (a) amplitude of head response, (b) phase of head response and surface displacement (U), (c) sensitivity of amplitude to S_y for the 'WT' boundary condition, (d) sensitivity of phase to S_y for the 'WT' boundary condition. For (a) and (b) the colour code for the scenarios 'LD', 'IN', 'WT' ($S_y=0.1$), 'WT' ($S_y=0.01$), and HO, is shown in the top right panel (see text for explanation); in (b), displacement for the WT, $S_y=0.01$ scenario overlies that for the WT, $S_y=0.1$ scenario, so is not shown. (Note, in the instance that ξ is not close to 1, S_y in these plots can be substituted by $\gamma = S_y \xi$)

3.2 The variable water table scenario ('WT')

By contrast with the 'IN' scenario, head changes determined by a moving water table are depth-variable in amplitude and phase. When $S_y \rightarrow 0$ the 'WT' condition tends to the head-only end-member ('HO') and when $S_y \rightarrow 1$ the 'WT' condition tends to the 'IN' scenario. The maximum lag for $S_y = 0.1$ is at 137 m depth (or $\theta = 1.94$), beyond which it reduces (Fig. 5b). The sensitivity in head to S_y for the 'WT' scenario is illustrated in Fig. 5c. The amplitude of head responses is less than the water table fluctuation at all depths. Moreover, only a deep piezometer such as the one indicated at 300 m (Fig. 4b) will behave as a weighing lysimeter in this scenario. Here, heads are in phase with the water table and have approximate magnitude, $h = \xi L = \xi S_y H$, as in the study by van der Kamp and Maathuis (van der Kamp and Maathuis, 1991) of a thick aquitard overlying a confined aquifer. At 100 m the amplitude of head change is greater than at 300 m, and lags behind the water table. At 30 m the amplitude of head change is greatest and the lag is less than at 100 m. The difference in the head responses compared to

315 the 'IN' scenario is due to the difference in magnitudes of the applied head and applied load under the 'WT' scenario, causing
316 an instantaneous internal head gradient which subsequently diffuses. Ground surface displacement is ~4 mm and lags the load
317 by 44 days. With increased head at the top boundary, the upper surface moves upwards because as higher heads penetrate the
318 aquifer the effective stress is reduced. The lag is due to the time taken for the surface head to diffuse downwards.

319 3.3 The hydraulically disconnected load scenario ('LD')

320 Heads in the case of a surface load hydraulically isolated from the aquifer show a third characteristic behaviour. In this case
321 the amplitude of head change increases from zero at the top boundary (Fig. 5a), reaching a peak which is greater than the load,
322 1.07 m at 162 m (or $\theta = 2.29$). The amplitude thereafter tends to ξL at greater depth, whilst the lag tends to zero. Therefore
323 heads in relatively deep piezometers potentially represent the surface load under a 'LD' boundary condition, as in Fig. 4d
324 where the heads at 300 m match the surface load, whereas at 30 m they do not. This is due to upward head diffusion towards
325 the surface where the head boundary condition is $h=0$. The lag which occurs in the 'WT' scenario due to the applied head
326 exceeding the mechanical load is reversed in this 'LD' scenario, becoming a lead time as the applied load exceeds the applied
327 head. Surface displacement is out of phase with the load, leading by $\sim\pi$ radians. The ground surface displacement amplitude
328 of ~4 mm is ten times greater than for the 'IN' scenario but is still very small in comparison to the annual variability of order
329 10 cm measured by GPS (Steckler et al., 2010). The 'LD' behaviour can be interpreted by means of a decomposition of heads
330 in the manner shown by Anochikwa et al. (Anochikwa et al., 2012) (see Supporting Information).

331 3.4 The influence of pumping

332 Introduction of pumping from the depth interval 50-100 m causes hydraulic dis-equilibrium which continues well beyond the
333 ten years' simulation, as the head drawdown propagates deep into the profile. As well as drawing water from storage at depth,
334 pumping induces recharge from the surface, there being a downward hydraulic gradient from the surface to the pumped
335 horizon, and upwards from the deeper levels to the pumped horizon. Variable perturbation due to the 'IN' surface load is
336 nevertheless clearly evident in the deep groundwater head measurements following correction for secular decline (Fig. 4e).
337 Elastic displacement, manifested as ground surface decline, exceeds 40 cm after ten years of pumping but, as in the un-pumped
338 'IN' scenario, the annual fluctuation due to surface loading is vanishingly small (0.03 mm). Thus, in addition to the possibility
339 of irreversible plastic deformation, elastic strain may gradually increase due to continuous pumping as stored water is drawn
340 from increasing depths.

341

342 Intermittent pumping strongly increases the seasonal variation in heads at the depth of pumping and this disturbance diffuses
343 to adjacent levels. However, as in the case of continuous pumping, the surface load signal is largely preserved in the deep
344 groundwater head response at 300 m. Also, intermittent pumping induces the same average long-term secular decline in stored
345 water volume and ground surface displacement as continuous pumping, but with additional annual fluctuation caused by the

346 pump switching on and off (decline/drawdown during the dry period when the pumps are used for irrigation and recovery
347 during the rainy season when the pumps are off).

348 **3.5 Model results for ground surface displacement**

349 Taking into account a small correction for the compressibility of water, surface displacement in the model is almost equal to
350 the total change in elastic storage in the permanently saturated aquifer. For the cases where pumping dominates the removal
351 of water, surface displacement is in phase with the pumping (Fig. 4f). For the cases which set up a diffusion of the hydraulic
352 signal between the surface boundary and the aquifer, the phase of surface displacement depends on the hydraulic (non-loading)
353 head changes at all depths (Fig. 4b, c, d). Therefore the lag for vertical displacements under the 'LD' surface condition is $\sim\pi$
354 out of phase with displacement under the 'WT' condition. Note from Eq. [6] that the amplitude and lag are both a function of
355 $\theta = z \sqrt{\frac{\omega}{2D}} = z \sqrt{\frac{\pi}{DT}}$ and therefore the solutions given here would be scaled in z by any changes to bulk diffusivity, D , and signal
356 frequency (or time period, T): higher frequency would give the same distribution but for a smaller z and the reverse would be
357 true for diffusivity. Intermittent pumping produces the largest cyclic displacements, however, in the order of centimetres,
358 because this condition causes the greatest volume of seasonal drainage from the formation itself. Where there is non-uniform
359 loading, as produced for example by a variable river stage, lateral groundwater drainage may occur and surface vertical
360 displacements may be greater under these conditions too.

361

362 **4 Applying the partial coupling analysis to field data**

363 Applying the 1D partial-coupling analysis to field data, we examine poromechanical perturbations at two sites, Khulna and
364 Laksmipur in southern Bangladesh (Fig. 1). Hourly measurements of groundwater pressure made between April 2013 and June
365 2014 in three closely-spaced piezometers between 60 and 275 m depth at each site are illustrated as hydrographs of equivalent
366 freshwater head in Supporting Information. Data on changes of the actual water table at the field sites are unfortunately not
367 available.

368 The objective here is to apply the principles and assumptions of the partially-coupled hydro-mechanical approach to reproduce
369 the characteristic features of the multi-level groundwater hydrographs using broadly representative aquifer parameters, rather
370 than to attempt an exact match by inverse modelling. Inspection of the hydrographs at both sites indicates, by reference to
371 Figures 4 and 5, that mechanical loading significantly influences the measured heads. Additionally, the presence of thick clay
372 aquitards at both sites (Figures 6, 7) suggests conditions under which heads may be determined solely by mechanical loads
373 and piezometers might behave as geological weighing lysimeters; a possibility which we put to the test.

374

375 The approach at each site is as follows:

- 376 i. A two-component sand-clay stratigraphy is based on site data, and parameter values are selected from the ranges described
377 in Section 2.
- 378 ii. The piezometric readings are compared to examine possible pumping influences which need to be taken into account in the
379 model by means of a simple abstraction pattern. Based on what is known about nearby abstractions an appropriate pumping
380 depth interval is determined. The magnitude of the extraction rate is manually adjusted as a fitting parameter.
- 381 iii. Where a piezometer is uninfluenced by pumping we test its behaviour as a geological weighing lysimeter. The heads in the
382 chosen piezometer are assumed to define the mechanical load at the surface, and this assumption is tested for self-consistency
383 by comparison of the simulations to the data from all three piezometers.
- 384 iv. The nature of the upper head boundary is then examined by reference to the implications for a variety of hydraulic loading
385 conditions. For a 'WT' boundary, changing S_y manually as a fitting parameter adjusts the magnitude of the applied heads
386 concomitant with the mechanical load.

387 **4.1 Groundwater levels at Khulna, south-west Bangladesh**

388 At Khulna town (Burgess et al., 2014) piezometers KhPZ60, KhPZ164 and KhP271 (the numbers indicate depth to the
389 piezometer screen in metres) are located 700 m from the ~300 m wide tidal Rupsa River, in a grassy compound which also
390 contains municipal water-supply pumping boreholes (Supporting Information). The lithological sequence (Fig. 6) comprises a
391 surface clay layer overlying sand in which KhPZ60 is screened, and a deeper layer of clay at 100 m separating the shallow
392 sand from a deeper sand formation in which KhPZ164 and KhP271 are screened. Year-round pumping from 250-300 m depth
393 maintains a consistent downward head difference of ~3 m between the uppermost and the lower two piezometers. It is the
394 transient head variations rather than the absolute steady-state head differences that are of interest here. Bodies of standing
395 water in the vicinity, water in the unsaturated zone, and shallow groundwater combine with the sinuous Rupsa River as sources
396 of TWS load; groundwater pumping is an additional source of hydraulic variation.

397

398 The three Khulna hydrographs are characterised by periodic variations containing tidal frequency components throughout the
399 rising and falling limb of the annual cycle, and a series of episodic increments superimposed on the rising limb during the
400 monsoon season; the annual amplitude of groundwater head variation is ~2.5 m. Amplitude of the tidal frequency components
401 increases between 60 m and 164 to 271 m depth, with no phase lag and with a consistent synchronicity between the piezometer
402 heads and the Rupsa River water level fluctuations including the semi-diurnal and spring-neap cycles (Fig. 6 and Supporting
403 Information). Episodic deflections on the hydrograph rising limbs, coincident with rainfall events, are likewise simultaneous
404 at all measurement depths (Burgess et al., 2014). Therefore by reference to the partial coupling analysis (Figures 4 and 5) it is
405 evident that heads in the Khulna piezometers respond primarily to mechanical loading by a combination of monsoon water
406 and tidal loading.

407

408 At a daily level the time series of groundwater heads in KhPZ164 and KhPZ271 include an additional frequency component
409 which simple analysis of head differences confirms as the hydraulic influence of the daily municipal pumping schedule from
410 which KhPZ60 is protected by an intermediate clay layer. Therefore KhPZ60 alone is taken as recording a solely mechanical
411 loading response and the KhPZ60 head record is applied as the upper boundary condition to represent the varying TWS load
412 at the surface in a 1D hydro-mechanical model of the Khulna site (Fig. 6), assuming $\xi = 1$. The upper boundary resolves all
413 sources of load acting at the site including from the Rupsa River, which is a linear rather than an areally-extensive load. The
414 ratio of daily (tidal) variability in head at KhPZ60 and in the Rupsa River level is ~ 0.06 . At an equivalent loading efficiency,
415 the 1.23 m annual variation in river stage would explain ~ 0.07 m head variation in KhPZ60, only 3% of the total. While the
416 response of KhPZ60 to the annual changes of the Rupsa River may be greater than to the tidal changes, depending on the
417 details of aquifer structure and hydraulic connection to the river, 97% of the annual variation in head at the piezometer is taken
418 here as attributable to changes in TWS other than load transmitted from the river, representing areally-extensive loads as
419 required by the 1D partially-coupled analysis. This is likely an over-estimate; measurements of true water table fluctuation and
420 surface flooding depths in the vicinity are necessary to constrain the hydro-mechanical model more closely. Given the
421 relatively well-drained urban context at Khulna and the absence of areally-extensive open water that otherwise characterises
422 the rural areas of the GBM floodplains, a 'WT' condition is most likely the dominant loading style, but other sources of loading
423 may also contribute. The layered structure of the Khulna model (Fig. 6) has clay at 0-50 m and 100-150 m with sand in between.
424 The daily municipal pumping cycle is implemented as a source term of 2.4 m a^{-1} for 12 hours of each day applied over the
425 interval 200 to 350 m, the rate having been manually adjusted by reference to the daily head fluctuations in KhPZ164 and
426 KhPZ271.

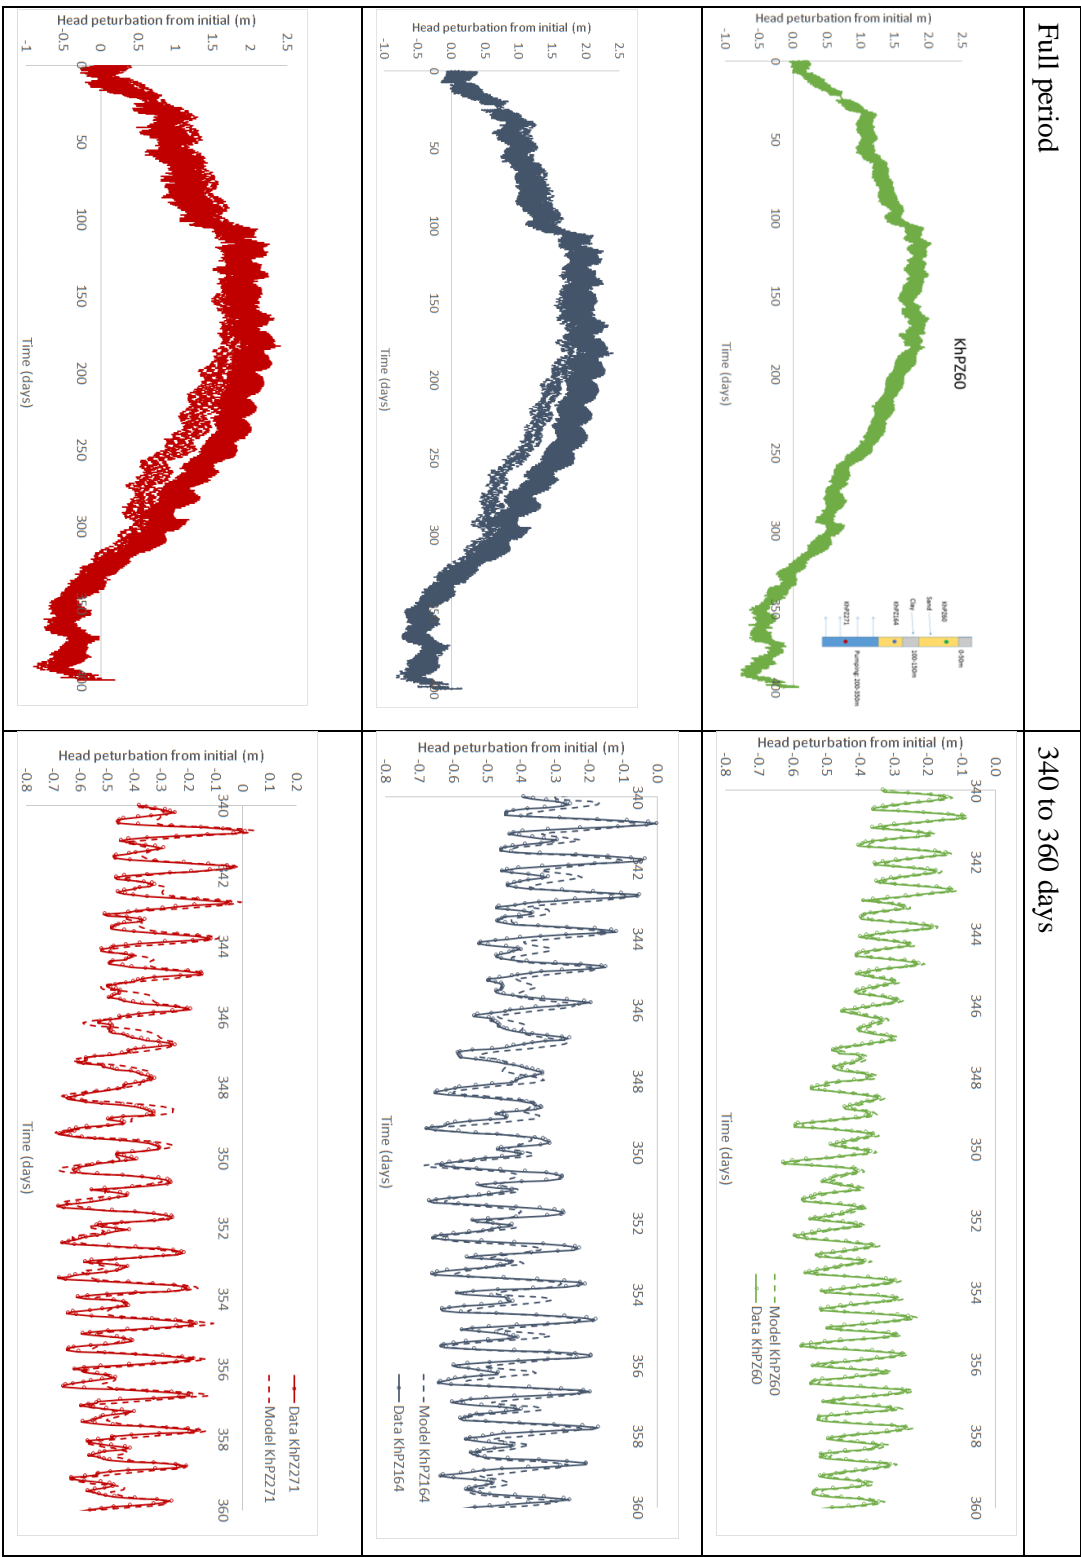

Figure 6. Knuha: comparison of observed heads (solid lines) and simulated heads (dashed lines), starting 27 April 2013, for WT upper boundary condition ($S_2=0.4$). X-axis is time in days. The surface loading is set equal to the observed head in KhPZ60 divided by S_2 . The pumping rate is $2.4 \text{ m}^3 \text{ a}^{-1}$ for 12 hours of each day, switching on at 05:45 am. Top (green) is KhPZ60, middle (blue) is KhPZ164, bottom (red) is KhPZ271.

438

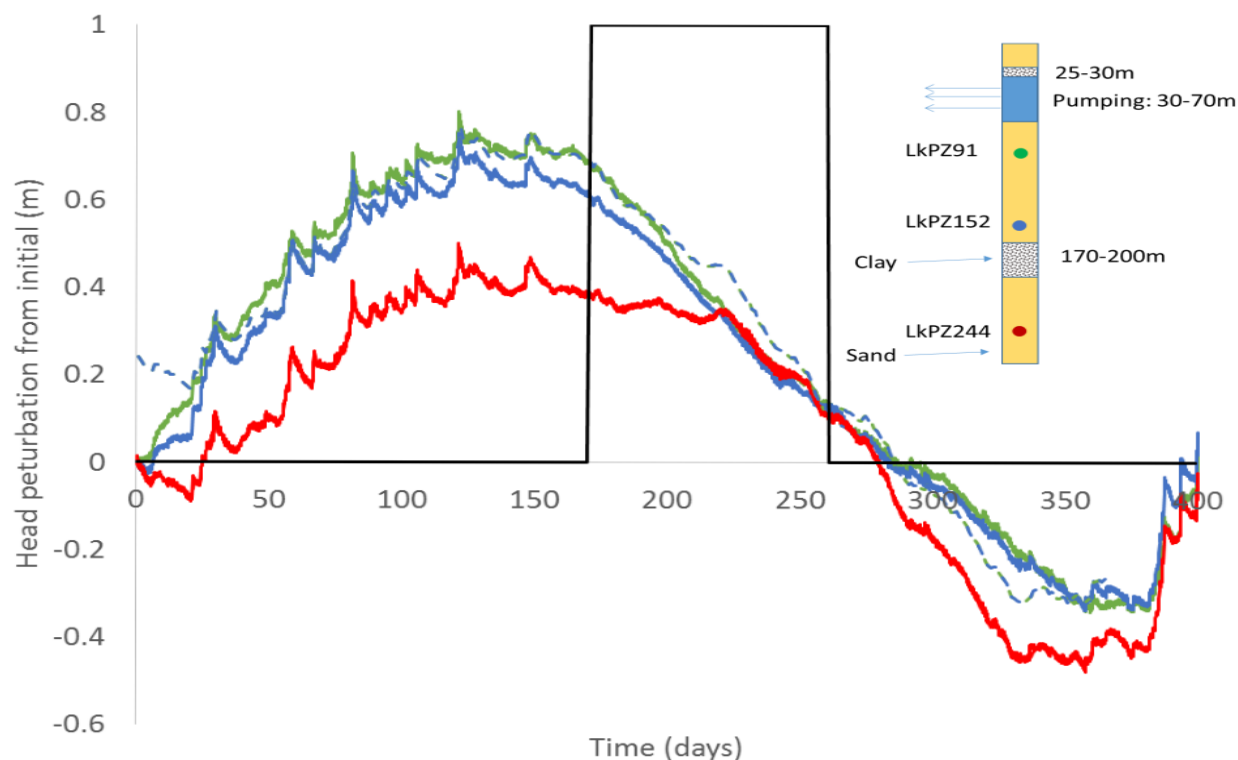

439 Figure 6 compares the measured groundwater heads with the heads simulated by the model under the assumption of a ‘WT’
 440 boundary with S_y assigned a value of 0.4, with $\kappa_{sand} = 1 \times 10^{-5} \text{ m s}^{-1}$, $\kappa_{clay} = 1 \times 10^{-9} \text{ m s}^{-1}$, $S_s = 10^{-4} \text{ m}^{-1}$ (corresponding to
 441 $E = 82.07 \text{ MPa}$), $\nu = 0.25$ and $n = 0.1$. The results are insensitive to S_y being varied in the range from 0.1 to 1 (the latter being
 442 equivalent to an ‘IN’ boundary), and are near-identical in the case of a ‘LD’ boundary (Supporting Information). This is
 443 because the upper clay effectively isolates the piezometers from the surface hydraulically.

444 4.2 Groundwater levels at Laksmipur, south-east Bangladesh

445 At Laksmipur (Burgess et al., 2017) the piezometers LkPZ91, LkPZ152 and LkPZ244 are situated in a rural region of rice-
 446 paddy and tree plantations on the Lower Meghna floodplain (Supporting Information), 10 km distant from the River Meghna
 447 and 8 km from municipal boreholes which pump from 270–300 m depth. Seasonal pumping from depths up to 100 m for rice
 448 irrigation is common in the vicinity. The lithological sequence indicates fine sand with occasional silty clay layers. The
 449 hydrographs are characterised by a sequence of episodic increments in groundwater head associated with periods of heavy
 450 rainfall producing a rising limb of amplitude $\sim 1 \text{ m}$ through the monsoon season; during the dry-season recession, minor
 451 periodic fluctuations of order 0.01 m containing atmospheric frequency components become more clearly evident (Burgess et
 452 al., 2017). The episodic increments are almost synchronous and of consistent magnitude at all piezometer depths, indicative
 453 by reference to Figures 4 and 5 of groundwater heads responding dominantly to mechanical loading and unloading due to
 454 changes in TWS above the aquifer surface.

455

456 Here, cyclical head differences between LkPZ244 and the shallower two piezometers indicate hydraulic influences of dry-
 457 season pumping on the LkPZ91 and LkPZ152 hydrographs, whereas downward propagation of the hydraulic signals to
 458 LkPZ244 is prevented by the clay layer at 170 m depth. Therefore LkPZ244 is taken as recording a solely mechanical loading
 459 response and the LkPZ244 head record is applied as the upper boundary condition to represent the varying TWS load at the
 460 surface in a 1D hydro-mechanical model of the Laksmipur site (Fig. 7), with a small offset applied to the initial heads above
 461 170 m depth, consistent with the observed head perturbations being shown as starting from a common zero value. The
 462 stratigraphy as modelled draws from the detail of the drillers log at Laksmipur (Burgess et al., 2017) and the general form of
 463 the stratigraphy as seen across the GBM floodplains (Fig. 2). All styles of upper boundary were applied (‘IN’, ‘LD’, and ‘WT’
 464 with a range of S_y values, see Supporting Information) in an attempt to distinguish the dominant source of TWS load around
 465 the site from the boundary style leading to the best fit with piezometer measurements. In all other respects the models
 466 incorporate the dimensions and assumptions as described in Sect. 3, with sand ($\kappa_{sand} = 1 \times 10^{-5} \text{ m s}^{-1}$) and two clay layers
 467 (BWDB, 2013) at 25–30 m and 170–200 m ($\kappa_{clay} = 1 \times 10^{-8} \text{ m s}^{-1}$), and $E = 82.07 \text{ MPa}$. A simple dry-season pumping regime
 468 over a 105 day period starting 17 November 2013 is implemented as a source term of 0.04 m a^{-1} applied over the interval 30
 469 to 70 m in the model, manually adjusted by reference to the LkPZ91 and LkPZ152 hydrographs.

471

472 **Figure 7. Laksmipur: comparison of observed heads (solid lines) and simulated heads (dashed lines) starting 31 May 2013, for ‘WT’**
473 **upper boundary condition ($S_y=0.8$), for LkPZ91 (green), LkPZ152 (blue) and LkPZ244 (red). X axis is time in days. The surface**
474 **loading is set equal to the observed head in LkPZ244, and the surface head is set to the observed head in LkPZ244 divided by S_y .**
475 **The pumping rate is 0.04 m a^{-1} for the period shown (1 for ‘on’, 0 for ‘off’).**

476

477 For LkPZ244 the simulated heads are an excellent match with measurements over the entire period. The simulated heads for
478 the shallower two piezometers LkPZ91 and LkPZ152 most closely match the measurements under a ‘WT’ boundary with S_y
479 assigned a value of 0.8 (Fig. 7 and Supporting Information). The model results therefore confirm that LkPZ244 is isolated
480 from the hydraulic effects of water table variation and of seasonal pumping, and the LkPZ244 groundwater head variation over
481 the observation period is determined solely by mechanical loads at the surface. Therefore LkPZ244 is validated as acting
482 effectively as a geological weighing lysimeter (Burgess et al., 2017).

483

484 For the shallower piezometers, the best fit value for S_y is higher than is reasonable for fine sand and more likely indicates the
485 combined effects of a variable water table and fluctuating levels of standing water, in drainage channels and on paddy fields
486 around the piezometer site, consistent with the field situation. As a consequence of seasonal pumping at 0.04 m a^{-1} , the model

shows groundwater is both drawn from storage and induced as recharge from the upper surface, but the amplitude of saturated storage fluctuation is only 6 mm, therefore changes to the water budget are dominated by recharge to the water-table. The surface displacement is predicted at 6 mm amplitude, in phase with the changes in storage.

5 Discussion

5.1 Aquifer responses to discrete modes of terrestrial water variation

Models based on the 1D partially-coupled hydro-mechanical analysis confirm that substantial poroelastic influences should be expected in the Bengal Aquifer System, and that groundwater heads respond characteristically to changes in specific terrestrial water stores (Figures 4 and 5). Only laterally-extensive flooding above an aquifer fully saturated to the ground surface (the ‘IN’ loading style) will drive instantaneous and synchronous head variations at all depths determined by the loading efficiency, inducing negligible flow of groundwater. In any situation involving a variable water table (the ‘WT’ loading style) and for any variable loads hydraulically disconnected from the aquifer (the ‘LD’ style), hydraulic gradients are imposed due to the unequal magnitude of stress and head at the surface. These gradients take time to dissipate, depending on the frequency of the signal fluctuation and the aquifer hydraulic diffusivity, and so lead to differences in amplitude and phase of the head response with depth. In these situations, the relative importance of the hydraulic and mechanical influence is controlled by the aquifer hydraulic diffusivity, the loading efficiency and the depth of interest. In the case of a fluctuating water table, the difference between the head and stress signals is a function of the specific yield, S_y , in the zone of fluctuation.

The characteristic responses of the aquifer might therefore provide a key to identifying the terrestrial water store dominating ΔTWS , by monitoring vertical profiles of groundwater head. Multiple terrestrial water stores will normally contribute, however, as at Laksmipur and Khulna, so a unique identification may not be possible. This limitation is inherent to the 1D analysis, which resolves all the contributions to load into one upper boundary condition respectively for head and stress. The analysis indicates how different loads and dynamic responses superpose to produce the observed groundwater hydrographs. In principle, key aspects of the water balance may be better estimated by de-convolving known components of the ΔTWS signal. Anochikwa et al. (Anochikwa et al., 2012) assembled field measurements of rainfall and evapotranspiration at a site in Saskatchewan, Canada, using them to define the upper boundary conditions in a one-dimensional model to examine their hydraulic and mechanical loading separately, before summing the outcomes to simulate the overall hydro-mechanical influence on groundwater pressure. Having determined loading efficiency by reference to barometric effects, they then calibrated their 1D model against observed groundwater pressures by varying hydraulic conductivity. At Khulna and Laksmipur, measurements of the separate components of the terrestrial water cycle were not available, hence an indirect demonstration of hydro-mechanical effects was desirable. The simulated and observed heads are in good agreement, consistent with the local conditions, so confirming the 1D partially-coupled analysis as a suitable basis for representing the poroelastic behaviour of the BAS.

519 5.2 Significance for groundwater monitoring and geological weighing lysimetry

520 In terms of the extent to which piezometer water levels indicate recharge and drainage, it is only where there is a rapid hydraulic
521 connection between the piezometer and the water table that the piezometer will be sensitive to head change at the water table
522 and therefore to changes in unconfined storage. If a piezometer is hydraulically isolated from surface water and/or the water
523 table and is beyond other transient hydraulic influences, it can respond to changes in the weight of the TWS load, acting as a
524 geological weighing lysimeter (van der Kamp and Maathuis, 1991; Smith et al., 2017). In this case, where the changing load
525 is due to a moving water table, knowledge of the loading efficiency allows the load measurement to be converted into an
526 estimate of recharge and discharge.

527

528 In all other situations, a wide range of coupled hydro-mechanical responses can be expected, as we have shown for the BAS
529 (Figures 4 and 5). Seasonally-variable groundwater heads (Fig. 4) are therefore open to misinterpretation as seasonally-variable
530 groundwater storage, leading to error in determination of recharge if the poroelastic nature of the response is neglected.
531 Consider heads at 30 m, a common depth for Bangladesh Water Development Board (BWDB) monitoring boreholes
532 (Shamsudduha et al., 2011). For the case of a variable load hydraulically disconnected from the aquifer (Fig. 4d) the annual
533 water level rise is equal to half the amplitude of the load yet augmentation of elastic storage, by definition in this case, is nil.
534 For the case of variable TWS inundation (Fig. 4a) the annual groundwater level rise is equivalent to the annual depth of
535 inundation yet augmentation of elastic and unconfined storage is insignificant. Conversely, relative to a variable water table
536 (Fig. 4b,c) groundwater fluctuation at 30 m depth is attenuated. Failure to account for this would lead to an underestimate of
537 recharge to unconfined storage by about 30%. The error increases as hydraulic diffusivity decreases, therefore errors could be
538 expected to be greater in the coastal regions of the Bengal Basin where the thickness of silty-clays is greater (Mukherjee et al.,
539 2007). Considerable caution is therefore necessary in the use of even relatively shallow piezometers as indicators of recharge
540 to the water table. A true indication of recharge requires either a shallow tubewell screened over the depth interval of actual
541 water table fluctuation, or a deep piezometer responding as a geological weighing lysimeter to the varying mass provided by
542 a fluctuating water table. In the latter case it is recharge to the shallow water table that is measured, not recharge at the depth
543 of the piezometer.

544

545 The 1D hydro-mechanical framework can be applied as a test for the special cases where groundwater head responds solely to
546 mechanical load, and hence to validate the use of geological weighing lysimetry. The laterally-extensive loading criterion
547 inherent to the 1D analysis must apply, and the piezometer screen must be isolated or distant from hydraulic transients
548 originating at the surface or from pumping. We have shown for the BAS that these requirements most likely occur at depths
549 beyond about 250 m, as in the case of 'WT' and 'LD' loading styles in the absence of pumping (Fig. 5). The inundation ('IN')
550 style of TWS variation leads to instantaneous transmission of head without loss of amplitude at all depths; in this case
551 piezometers at all depths provide a mechanical record of Δ TWS rather than a hydraulic record of storage variation and to infer

recharge would lead to 100% error. Our analysis demonstrates a solely mechanical loading response at 244 m depth at Laksmipur, below the level of seasonal irrigation pumping, and at 60 m depth at Khulna, above the level of deep pumping for municipal water supply.

5.3 Significance for ground surface displacements and groundwater storage changes

The models also demonstrate the amplitude and phase of ground surface displacement as a hydro-mechanical consequence of varying terrestrial water stores, and the significance of pumping (Fig. 4e and 4f). Under simplifications associated with the 1D model, vertical surface displacements relative to a fixed model base at 1 km depth are approximately equal to the change in elastic storage, the small difference being due to compressibility of water. These changes are minor in the BAS under all TWS loading styles, in the order of mm, compared to the displacements in the case of seasonal groundwater pumping which are in the order of cm. Seasonal surface displacements in the order of cm have also been attributed to strain acting over a depth scale of hundreds of kilometres due to the load applied by monsoonal inundation over the entire Bengal Basin (Steckler et al., 2010). Strains due to seasonal groundwater pumping at shallow depths may therefore be in the same order of magnitude but out of phase with crustal strain, making ground surface deflections a poor proxy for changing elastic storage in the aquifer. As a corollary, interpretation of seasonal ground surface fluctuations across the GBM floodplains solely in terms of deep crustal deformation (Steckler et al., 2010) potentially requires reassessment in the light of BAS aquifer poroelasticity.

5.4 Limitations and further consequences

In our analysis we have based values for the 1D loading efficiency, ξ (0.932-0.993) and Young's Modulus, E (82-851 MPa) in the BAS on field measurements of S_s , for the sake of internal hydro-mechanical consistency, but we have noted a discrepancy with lower values for the 1D loading efficiency ξ (0.69-0.87) derived from determinations of barometric efficiency (Burgess et al., 2017). These differences require attention, but the overall conclusions on the significance of poroelastic behaviour in the BAS and the pattern of poroelastic responses characteristic of specific upper surface TWS boundary conditions are unaffected. Although we omitted barometric effects in the generic simulations for the sake of simplicity, it is straightforward to superpose a further loading signal on top of the existing one if required, as for example when deconvolving deep piezometric signals to make water resources assessments (Anochikwa et al., 2012).

Data on changes of the water table would have greatly helped the analysis of loading effects at Khulna and Laksmipur. It is strongly recommended that in future hydro-mechanical analyses of the groundwater dynamics of large layered aquifers such as the BAS, both water table data and deeper head data should be obtained. For the water table, this requires a shallow piezometer to be screened across the full range of fluctuation of the true water table.

Under certain circumstances the extensive load assumption inherent in the 1D analysis may break down. Rivers, as linear sources of head and load, can be accommodated within the 1D framework where their contribution to the TWS load is minor as demonstrated at Khulna. In general however, rivers should be expected to impose laterally variable heads and require a

584 more generalised 2D or 3D fully-coupled poro-mechanical treatment (Boutt, 2010; Pacheco and Fallico, 2015). An equivalent
 585 constraint applies to strains, an additional reason for surface displacement not to offer a secure proxy for groundwater storage
 586 in the BAS. The dense distribution of rivers, distributaries and drainage channels in the Bengal Basin makes the BAS widely
 587 vulnerable to loading effects that may not adequately be reduced to a 1D description; 13% and 47% of 1035 piezometers in
 588 the BWDB groundwater monitoring network lie within 1 and 5 km respectively of a river.

589 **6 Conclusions**

590 We argue that a 1D *partially-coupled* approach to hydro-mechanical processes, whereby the loading term is included in the
 591 flow equation without the need to simultaneously compute the elastic equation, is a suitable basis for representing the
 592 poroelastic behaviour of the Bengal Aquifer System when surface conditions can be treated as areally extensive. Applying a
 593 1D *partially-coupled* hydro-mechanical analysis we have shown how the BAS responds characteristically to specific sources
 594 of terrestrial water storage variation. Rivers can be incorporated as a component of the 1D load where their contribution is
 595 small, but in general will require a 2D or fully 3D treatment.

596
 597 Groundwater levels, groundwater recharge, vertical groundwater flow and ground surface elevations are all influenced by the
 598 poroelastic behaviour of the BAS. Our results expose the error of the conventional assumption of de-coupled hydraulic
 599 behaviour which underlies previous assessments of recharge to the BAS. Also they demonstrate the complexities in applying
 600 ground surface displacements as a proxy measure for variations in groundwater storage. We propose that the 1D *partially-*
 601 *coupled* analysis can be applied to validate when geological weighing lysimetry is applicable in the BAS. In some situations,
 602 geological weighing lysimetry offers an alternative approach to recharge assessment.

603

604 **Appendix: Poromechanical equations**

605 The constitutive isotropic relation between elastic stress and strain, coupled to the pore-pressure by Terzaghi's effective stress
 606 law is given by (Neuzil, 2003):

$$\sigma_{ij} = 2G\varepsilon_{ij}\delta_{ij} + 2G\frac{\nu}{1-2\nu}\varepsilon_{kk}\delta_{ij} + \alpha_B p\delta_{ij} \quad (A1)$$

607 where δ_{ij} is the Kronecker delta (which is zero when $i \neq j$ and one when $i = j$) and following the Einstein Summation
 608 convention; stresses (σ_{ij}) and strains (ε_{ij}) are positive in compression; p is the porewater pressure (Pa), ν is Poisson's ratio (-
 609), G is the shear modulus (MPa), and $\alpha_B = 1 - K/K_s$, where, K (MPa) is the bulk modulus of the porous medium and K_s
 610 (MPa) is the bulk modulus of the solid grains.

611

612 Just as the elastic equations have a pore pressure term, the isothermal, Darcian groundwater flow equation contains a coupled
 613 stress term (Neuzil, 2003):

$$\nabla \cdot \kappa(\nabla p + \rho g \nabla z) = S_{s3} \frac{\partial p}{\partial t} - S_{s3} \beta \frac{\partial \sigma_t}{\partial t} - gJ \quad (\text{A2})$$

614 where κ is the hydraulic conductivity (m s^{-1}), p is the pore pressure (Pa), z is the elevation (m), J is a source term used here
 615 to simulate groundwater abstraction by pumping and $\sigma_t = (\sigma_{xx} + \sigma_{yy} + \sigma_{zz})/3$ (Pa).

616

617 The 3D specific storage is defined as:

$$S_{s3} = \rho g \left[\left(\frac{1}{K} - \frac{1}{K_s} \right) + \left(\frac{n}{K_f} - \frac{n}{K_s} \right) \right] \quad (\text{A3})$$

where n is the porosity, and K_f is the modulus of the water (MPa).

The (3D) loading efficiency, or Skempton's coefficient, β , is defined as:

$$\beta = \frac{\left(\frac{1}{K} - \frac{1}{K_s} \right)}{\left(\frac{1}{K} - \frac{1}{K_s} \right) + \left(\frac{n}{K_f} - \frac{n}{K_s} \right)} \quad (\text{A4})$$

618 Where there is areally extensive loading, the 1D loading efficiency is given by

$$\xi = \beta(1 + \nu)/[3(1 - \nu) - 2\alpha_B \beta(1 - 2\nu)] \quad (\text{A5})$$

619

620 The 1D specific storage is given by:

$$S_s = S_{s3}(1 - \lambda\beta) \quad (\text{A6})$$

621 where $\lambda = 2\alpha_B(1 - 2\nu)/3(1 - \nu)$.

622 **Author contributions**

623 WGB conceived the study; NDW led the modelling; all authors contributed to the scenario descriptions and consideration of
 624 the modelling results; NDW and WGB drafted the manuscript; all authors reviewed the manuscript.

625

626 **Acknowledgments**

627 We acknowledge funding from the UK EPSRC Global Challenges Research Fund (UCL/BEAMS EPSRC GCRF award
 628 172313) to WGB for research on *Poroelasticity in the Bengal Aquifer System and groundwater resources monitoring in*
 629 *Bangladesh*. NDW thanks the University of Southampton for leave of absence during the course of the project. Field
 630 measurements at Khulna and Laksmipur were made with the kind assistance of the Bangladesh Water Development Board
 631 (BWDB) and financial support from the UK Department for International Development (DfID) under the project *Groundwater*

632 *Resources in the Indo-Gangetic Basin* (Grant 202125-108) managed by Professor Alan MacDonald of the British Geological
633 Survey. We are grateful to Professors Mike Steckler, Columbia University, and Humayun Akhter, Dhaka University, for useful
634 discussions on ground surface vertical motions in the Bengal Basin, and to John Barker and William Powrie for helpful
635 discussion of the fundamental processes at the start of the research. Dr. Mohammed Shamsudduha, University College London,
636 and Ms. Sarmin Sultana, Dhaka University are thanked for discussions on the hydrological context of the groundwater level
637 monitoring piezometers. The data used are listed in the references and illustrated in the Supporting Information. We thank one
638 anonymous reviewer whose comments and advice helped improve the manuscript.

639 **Nomenclature**

640	α	Proportion of mechanical load as head
641	α_B	Biot-Willis coefficient, $1 - K/K_s$
642	β, C	3D loading efficiency, Skempton's coefficient, or 'tidal efficiency'
643	δ_{ij}	Kronecker delta
644	ε_{ij}	Strain
645	θ	$z \sqrt{\frac{\omega}{2D}} = z \sqrt{\frac{\pi}{DT}}$
646	λ	$2\alpha_B(1 - 2\nu)/3(1 - \nu)$
647	ν	Poisson's ratio
648	ξ	1D loading efficiency
649	κ	Hydraulic conductivity
650	ρ	Water density
651	σ_{ij}	Stress tensor
652	σ_t	Total stress
653	ψ	Lag (radians)
654	ω	Angular frequency
655		
656	a	River half-width
657	B	Barometric efficiency
658	E	Young's Modulus
659	D	Hydraulic diffusivity
660	g	Acceleration due to gravity
661	G	Shear Modulus
662	h	Head

663	$H(t)$	Top boundary head
664	H_0	Amplitude of top boundary head
665	J	Fluid source term
666	K	Bulk Modulus of porous medium
667	K_f	Bulk modulus of the water
668	K_s	Bulk modulus of the solid grains
669	$L(t)$	Top boundary load
670	L_0	Amplitude of top boundary load
671	n	Porosity
672	p	Pore pressure
673	S_y	Specific Yield
674	S_s	Specific storage
675	S_{s3}	3D Specific storage
676	t	Time
677	u	Vertical displacement
678	x	Perpendicular distance from a river
679	z	Vertical coordinate
680
