

# Integrating multiple satellite observations into a coherent dataset to monitor the full water cycle Application to the Mediterranean region

## Editor

### COMMENTS

- I am pleased to say that both reviewers agree on the fact that this paper presents a significant contribution to the scientific community, in particular with respect to the estimation of water balance from satellite observations, that deserves to be published in HESS. However, the reviewers highlighted several major points that will need to be corrected before this manuscript can be published. Hence, I encourage you to submit a new version of the manuscript, which takes into account the comments made. The new version of the manuscript will be submitted to the reviewers.  
- Thank you for your decision, we hope that the new version of the manuscript is now in a better shape.
- In addition, I indicate below a few remarks from my side, which generally overlap with the reviewers' remarks.
- The paper is sometimes difficult to read due to the description of a large amount of technical information that mask the main message of your work. It is important to describe the scientific objective well throughout the manuscript. For example, the current introduction is very descriptive, lacking the authors' analysis, as well as the presentation of the paper's precise objectives, before the presentation of the plan. Similarly, it is important for each section to recall the scientific context.  
- thank you for this remark, Several updates have been done to underline the main message of our work through the manuscript.

1. the abstract clearly states the article objectives : *The Mediterranean region is one of the more complex environments and is a hot-spot for climate change. The HyMeX (Hydrometeorological Mediterranean eXperiment) aims at improving our understanding of the water cycle at the meteorological to the inter-annual scales. However, monitoring this water cycle with Earth Observations (EO) is still a true challenge: EO products are multiple, and their use still suffer from large uncertainties and incoherencies among the products. Over the Mediterranean region, these difficulties are exacerbated by the coastal/mountainous regions and the small size of the hydrological basins. Therefore, merging/integration techniques have been developed to solve these issues. We introduce here an improved methodology that closes not only the terrestrial but also the atmospheric and ocean budgets. The new scheme allows to impose a spatial and temporal multi-scaling budget closure constraint. A new approach is also proposed to downscale the results from the basin to the pixel scales. The provided Mediterranean WC budget is for the first time based mostly on observations such as GRACE water storage or the netflow at the Gibraltar strait. The integrated dataset is in better agreement with in situ measurements, and we are now able to estimate the Bosphorus strait annual mean netflow.*
2. The introduction has been re-written to better focus on methodological aspect with an enhance on the scientific objective and does not present the water cycle equation (Eq. (1)) anymore (The Eq. (1) is now at the beginning of Section 3).
3. The scientific objectives are now propagated along the article and Section 3 is better introduced : *This section presents the integration techniques used to optimize the EO datasets.* As well as Section 4 : *In this section, the obtained integrated datasets are first evaluated in terms of WC budget closure. Our EO datasets integration technique is based on the closure of the WC budget. This is a physical constraint but in some cases (e.g. missing important water component), this constraint could result in a degraded estimation of the components. Therefore, available in situ data (precipitation, evapotranspiration and sea water level) are used to validate some of the water components of the integrated dataset. This evaluation is performed at two different spatial scales: the sub-basin scale and the pixel scale.*

- **In your answers, you indicate that this dataset would be available from the authors. It seems to me that HyMeX has developed**

**a strategy to make the data produced available to the scientific community, with different levels of access as appropriate. Even if you do not wish to widely publish this dataset, the use of this database could contribute to better promote your work. Is it possible to use this architecture to make this data available?**

- It is agreed that all datasets that are outputs of the WACMOS-MED project will be available on the hymex dataserver. This is now explicit in the conclusion: *The multiple-components dataset INT shows promising aspect for forcing, calibrating or constraining regional models with a water conservation constraint (as required by the community). Some developments and evaluation need are still required before the production of a Climate Data Record (Su et al., 2018) can be started. The two databases (INT and CAL) can however be obtained under request to the corresponding author or via the HyMeX data-server architecture (<http://mistrals.sedoo.fr/HyMeX/>)*

**• Please check again the Figures and the legends. Some still need to be improved as suggested by the reviewers.**

- Figures and legends have been corrected and color change made.

## Reviewer 1

### COMMENTS

**• The MS presents a substantial effort in integrating multiple satellite observations into a coherent data set for monitoring the water cycle of the Mediterranean basin. From a technical point of view, many data products and acronyms are introduced but the reader is rather overwhelmed by the details and misses the central message the MS is trying to convey**

- Thank you for your valuable comments, we tried to simplify a bit the presentation but the introduction of complex notations is necessary. Several updates have been done to make the manuscript simpler:

1. The abstract now focuses on the integration methodologies, which represent the central message of the manuscript : *The Mediterranean region is one of the more complex environments and is a hot-spot for*

climate change. The HyMeX (Hydrometeorological Mediterranean eXperiment) aims at improving our understanding of the water cycle at the meteorological to the inter-annual scales. However, monitoring this water cycle with Earth Observations (EO) is still a true challenge: EO products are multiple, and their use still suffer from large uncertainties and incoherencies among the products. Over the Mediterranean region, these difficulties are exacerbated by the coastal/mountainous regions and the small size of the hydrological basins. Therefore, merging/integration techniques have been developed to solve these issues. We introduce here an improved methodology that closes not only the terrestrial but also the atmospheric and ocean budgets. The new scheme allows to impose a spatial and temporal multi-scaling budget closure constraint. A new approach is also proposed to downscale the results from the basin to the pixel scales. The provided Mediterranean WC budget is for the first time based mostly on observations such as GRACE water storage or the netflow at the Gibraltar strait. The integrated dataset is in better agreement with in situ measurements, and we are now able to estimate the Bosphorus strait annual mean netflow.

2. The Optimal Selection (OS) Section 3.2 is now suppressed, this method is simply described at the beginning of the SW section 3.3: *A general approach to deal with EO datasets in the analysis of the WC is to choose the best individual dataset for each one of the water components. This is the approach developed, for example, in the GEWEX project. In (Pellet et al. 2017), an Optimal Selection (OS) was based on the minimization of the water budget residuals to select the best combination of individual dataset. Using the OS principle facilitates finding datasets coherent to each other and with independent errors (Rodell et al. 2015). But this kind of strategy limits the use of several source of information to reduce the uncertainties. On the other hand, SW approach benefits from the multiplicity of the observations.*

We hope that the new version of the manuscript is now easier to understand.

**• Since the described project and the MS aims to produce a satellite observations of water cycle, I would suggest that the logic and methods proposed for generating climate data records be followed and organized as such (see e.g. Su et al.,2018, BAMS).**

- At this stage, the authors do not pretend yet to produce a Climate Data Record (CDR). The generation of a CDR as presented in Su et al.,2018

(BAMS) is complex, and raises many issues related to long time records (such as absolute or inter-calibration, evaluation procedures, etc.). In our manuscript, we would like to present several EO dataset merging methodologies, discuss their pros and cons. The fact that our dataset is available to the community is for research purpose, and we will consider the full CDR task only after more evaluation, and when we get enough funding to implement such a framework. The abstract is now clearer and does not propose the database anymore, only the conclusion does. Nevertheless, the production of CDR based on a the constrain of the water cycle might be a perspective of our work and this is now explicit in the conclusion: *This multiple-components dataset shows promising aspect for forcing, calibrating or constraining regional models with a water conservation constraint (as required by the community). Some developments and evaluation need are still required before the production of a Climate Data Record (Su et al.,2018, BAMS) can be started. The two databases (INT and CAL) can however be obtained under request to the corresponding author or via the HyMeX data server (<http://mistrals.sedoo.fr/HyMeX/>).*

**• There is a need to make sure that the used datasets are independent of each other. For example, the GLEAM v3c evaporation dataset is used, but the GLEAM dataset uses also precipitation dataset as input. Could the authors check and verify the independence of such datasets?**

- Thank you for this remark. Indeed, the version of GLEAM used in our work is the v3.b (1980-2014) that used multi-source precipitation inputs (TMPA 3B42.v7, MSWEP and ERA-I). The independence of the EO datasets used in an analysis is theoretically desirable, but in practice, this is always difficult to obtain. For instance, most water cycle analyses use a reanalysis (such as ERA-Interim) that does not assure independency between precipitation and evapotranspiration. The merging methodologies that we present are based on the idea that multiple observations should reduce the uncertainties in the estimation of a water component. This is for instance the strategy that is used by ensemble climate models (even if these models are not independent to each other since they use similar physical parameterisations or forcings). It is not a perfect solution but it has advantages. Using the Optimal selection principle could facilitate finding more independent datasets (like in the NEWS project) but we would not benefit from this multiplicity of information. This is now clearer in the text : *Using the OS principle facilitates finding datasets coherent to each other and with independent errors (Rodell et al. 2015). But this kind of strategy limits the use of several source of*

information to reduce the uncertainties. On the other hand, SW approach benefits from the multiplicity of the observations.

• In the first ESA WACMOS project (Su et al., 2014, JAG), an independent evaporation product was generated and is updated continuously. The monthly evapotranspiration for global land area from satellite data (global land 5 km spatial resolution monthly ET dataset, 2000-2017) is produced with a revised SEBS algorithm (Su et al., 2002, HESS; Chen et al. 2013, JAMC) with input as MODIS LST, NDVI, Global forest height, GlobAlbedo and meteorology from ERA-I. A recent comparison of the SEBS ET has reported by Bhattarai et al, 2018, HESS, with the MOD16 ET and a method by integrating radiometric surface temperature (TR) into the Penman-Monteith (PM) equation (STIC). The authors are advised to take a look. The data may be accessed at: <http://en.tpdatabase.cn/portal/MetaDataInfo.jsp?MetaDataId=249454>.

- Thank you. The SEBS evapotranspiration estimate (Su et al., 2002) presents the major advantage of not computing the relative evaporation based on a surface index, precipitation is not used as an input. This estimation is different to others evapotranspiration estimates based on PM and PT equation. The use of such dataset is a nice perspective that is now mentioned in the conclusion section in the context of closing the water cycle within the energy cycle: *There are still large uncertainties on the water cycle components but the INT methodology appear to be a valuable approach, in particular to include coherency among these components. Several improvements will be considered in the near future: (1) more accurate in situ observations (e.g. Bosphorus netflow estimate or coastal discharges) should lead to improved estimates. (2) New water cycle inputs could be considered (e.g. ground water exchange or horizontal exchange at oceanic sub-basin scale) to better characterize the flux and stock terms in the WC. (3) The use of other source of EO estimate would be considered. For example, the evapotranspiration estimate based on the closure of the energy cycle (SEBS algorithm, Su et al., 2002, HESS; Chen et al. 2013, JAMC)) could be tested. This dataset could be a opportunity to (4) close simultaneously the water and the energy cycles and should lead to a better estimate of the evapotranspiration over land.*

• The authors presented statistics as a quality criteria of the WC closure. I suggest spending some effort in checking the dynamics and physics of the different datasets. I am not sure the correlation coefficients and RMSDs are the most suitable relevant statistical

**criteria for spatial-temporal datasets.**

- The correlation coefficient and RMSD are classic quality criteria. For example, Pan and Wood (2012), Sahoo et al. (2011), and Zhang et al. (2016) use correlation and RMSD to compare spatial dataset. We also considered the  $R^2$  and Mean Absolute Error (not shown) but this was adding no information, just adding confusion. To evaluate the dynamics of the products, we used in Section 4.2 the EOBS precipitation dataset. Beyond the evaluation of the coherency in the water cycle closure (Section 4.1) at monthly scale, the coarse temporal resolution limits deeper evaluation of the dynamic such as extreme rainfall which can hardly be analyzed at monthly scale.

**• The English needs improvement. There are lots of typos and awkward expressions.**

- The typos and English writing have been improved, we hope that the manuscript is now in a better shape.

## Reviewer 2

### MAJOR COMMENTS

**• Overall, I found this to be a strong and well-written paper. It makes two (worthwhile) contributions. First, a methodological contribution regarding the appropriate approach for simultaneously enforcing water closure within land, atmosphere and ocean domains. Second, it advances the state-of-the-art in terms of water balance estimates for the Mediterranean Basin. These contributions are significant and worthy of publication in HESS. Nevertheless, there are three major points that the authors should address before final publication. I suspect that some of my concerns arise from misunderstandings on my part (rather than actual flaws) and can be addressed via re-writing for improved clarity.**

- Thank you for your valuable comments, we hope that the new version of the manuscript is now in a better shape.

**The paper needs to do a better job of describing the INTegration (INT) methodology and its impact on subsequent stock and flux**

predictions. My understanding is that the INT approach is applied with two aims: 1) to downscale sub-basin scale results down to the pixel scale and 2) to extrapolate (balance-constrained) results OUTSIDE of the Mediterranean. This raises two questions:

- If INT down-scales and extrapolates outside of the Mediterranean Basin why does it have any impact on sea-level results in Figure 3 (which presumably reflect spatially averaged conditions within the Basin...neither of which are impacted by INT)? To me, it seems like SW+PF and INT should yield the same results for a sea-level metric. However, these results are used specifically to motivate the added value of INT (line 15 of page 17). Is the improvement in INT versus SW attributable to INT? Or would it also occur for SW+PF?

- You are right, the text is not clear enough in this subsection. The altimeter measures are available only for the Mediterranean Sea, so when the closure constraint is applied over the two seas at once, only the Mediterranean Sea (not the black sea) level is used for the evaluation. You are right, INT and SW+PF would give the same sea level estimates if the Black sea was considered within the Mediterranean Sea in Figure 3. There is no inter/extrapolation of the closure for the Mediterranean Sea and the improvement in INT versus SW is attributable to SW+PF, however the representation of the closure impact of the two seas in the Mediterranean Sea is attributable to INT since SW+PF represents the spatial average over the Mediterranean within the Black Sea. We added additional comments in the associated section: *No inter/extrapolation have been used in INT for the "Mediterranean Sea plus the Black Sea" sub-basin and the improvement of INT versus SW is due only to the impact of the closure constraint. Nevertheless, the SW+PF approach closes the water cycle over the Mediterranean within the Black Sea (no information about the Bosphorus netflow) and the spatial downscaling in INT is needed to discriminate the closure correction above the two seas.*

- **What exactly is the rational for the extrapolation portion of INT? Why would you ever want to extrapolate?**

- This has been a long discussion between the co-authors. The rational is twofold: (1) The extrapolation of a closure constraint is interesting at the technical level because for other regions, or when working at the global scale, some form of inter/extrapolation is required (See for instance: Munier and Aires, A new global method of satellite dataset merging and quality

characterization constrained by the terrestrial water cycle budget, RSE 205, 119-130, 2018). (2) The extrapolation outside of the Mediterranean region also allow us to use more in situ observation for the evaluation, and this helps better testing the generalisation ability of our extrapolation scheme. Another minor justification is that users often prefer to use a simpler dataset with a rectangular domain, especially in the modelling community.

The justification of this interpolation is based on the assumption that most of the water cycle imbalance is due to satellite errors (this assumption is used for the CAL methodology too). The closure constrain is supposed to improve the satellite estimate by reducing the bias and random errors. If no other information is used (such as surface type, see Munier and Aires 2018), the EO errors should have a spatial continuity and it then makes sense to extrapolate results based on this spatial continuity. We added this discussions in section 3.5: *The extrapolation of a closure constraint is interesting at the technical level because for other regions, or when working at the global scale, some form of inter/extrapolation between the monitored sub-basins is required (Munier and Aires, 2018). The extrapolation outside of the Mediterranean region will also allow us to use more in situ observation for the evaluation, this will help better testing the generalisation ability of our extrapolation scheme. The justification of this inter/extrapolation is based on the assumption that most of the water cycle imbalance is due to satellite errors (this assumption is used for the CAL methodology too). The closure constrain is supposed to improve the satellite estimate by reducing the bias and random errors. If no other information is used (such as surface type, see (Munier and Aires 2018)), the EO errors should have a spatial continuity and it then makes sense to extrapolate results based on this spatial continuity.*

**• Why not just apply terrestrial closure (at a minimum) to Northern Europe SW results?**

- You are right, Northern Europe is better monitored and river discharge could had been used to constrain Northern Europe basins at the SW+PF stage. As mentioned earlier, we prefer here to perform the main analysis over the Mediterranean basin and then test the extrapolation scheme over well monitored locations. This is now clearer in the text

**• Also, how does this extrapolation contribute to the (bottom-line) analysis in Figure 6?**

- The extrapolation does not contribute to the analysis in Figure 6 since only the Mediterranean basins are considered for computing the annual fluxes. This is now clearer in the text, Section 5.1: *The water cycle is analyzed over*

*its natural sub-basin's boundaries.*

• **I presume it facilitates the application of a larger atmospheric water balance analysis, but given that this is a Mediterranean Basin analysis - it seems strange to extrapolate BEYOND the Mediterranean Basin. It would improve the manuscript if this extrapolation step was better motivated.** - We understand your concerns. We hope that our motivation in the extrapolation is now better explained.

**I feel like the paper could do a better job describing its approach to error estimation (and the effect of these estimates on its merging results).**

- There are two error estimations in our paper: *a priori* EO uncertainty assumption, before the merging, and the *a posteriori* uncertainties estimated after the merging. we hope we will not be confused in the following.

• **I was confused by the treatment of EO uncertainty throughout the manuscript. First, in Line 8 of page 8, the manuscript says states "...we considered the same uncertainty for all data sets of given parameters following de-biasing..." However, later in Section 3.3, it seems as if a different uncertainty is assigned to various precipitation estimates when applying Equation (5). Can these descriptions be made more consistent?**

- Sorry for this ambiguity, Eq. (5) gives the general formula, with different uncertainties, but we considered, you are right, same uncertainties in this application over the Mediterranean basin. This is now clearer in section 3.3: *Since no specific uncertainty estimates were available in the literature for the Mediterranean basin, the uncertainties are assumed to have same standard deviation  $\sigma_i$  in the following.*

• **in Section 3.4, the authors invoke a filter-based closure constraint that varies as a function of a  $\Sigma$  matrix but do not describe how this matrix was derived. It would be helpful if this was clarified.**

- In our approach, we decided to close the water budget with a relaxation term: we assume an uncertainty in the closure. Such a relaxation on a constrain is commonly used in optimization, it generally follows a Gaussian distribution centred with a standard deviation  $\Sigma$  chosen *a priori* in a had hoc way. The matrix  $\Sigma$  must include the uncertainty for the continental, oceanic and atmospheric water cycles, it is not provided explicitly in Eq. (2):

$$\Sigma = \begin{pmatrix} \sigma_l & \mathbf{0} \\ \mathbf{0} & \sigma_o \end{pmatrix}$$

where  $\sigma_l = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$  represents the standard deviation of the constrained terrestrial and atmospheric water budget residual over land; and  $\sigma_o = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$  represents the standard deviations of the constrained oceanic and atmospheric water budget residual over sea.  $\Sigma$  assumes no correlation in the imbalance of the 3 water cycles at monthly and annual scales, at sub-basin or entire basin scales.

• **Equation (5) appears to use the temporal standard deviation of individual products (precipitation products in the example given) after seasonal bias correction as a proxy for the magnitude of their random error. This seems like a dangerous assumption. Assume, for example, that you had a precipitation product that simply mimicked the TMPA seasonal climatology (used here as the de-biasing reference). Given large interannual variability in rainfall, this product would be a poor rainfall product to use in a water balance context. However, it would have a low temporal standard deviation, and (therefore) be heavily weighted by Equation (5).**

- Sorry for the ambiguity. Eq. (5) represents the uncertainty of the EO products, not the temporal standard deviation. This is now clearer in the text: *“let us consider the  $p$  precipitation observations  $P_i$  associated with Gaussian errors  $\epsilon_i \sim \mathcal{N}(O, \sigma_i)$ ”*

• **Also - on a related point - after you de-bias the precipitation products, does it really matter (for a long-term water balance study) how - or even IF - you merge the products? After de-biasing, they all have the same long-terms means and will thus produce the same long-term water balance analysis.**

- You are right, the seasonal de-biasing is an important step, especially for the precipitation. Although the season de-biased products will have same season, their inter annual, long-term or short term variations will not be the same. This is now clearer in the text: *After the seasonal de-biasing, all the precipitation products will have a similar season, but their long-term trend, inter-annual or monthly variations will still be different. In particular, the*

*seasonal de-biasing will not change the trend of the EO products.*

• **Page 16, Line 3.** The PF approach is designed explicitly to reduce closure residuals. So, it is questionable to use the reduction of closure residuals as evidence that that PF approach is "working" or that a closure constraint is necessary. Another possibility is that not all flux and stock terms are being accounted for him. That is, the flux/stock estimates utilized here are actually accurate but nevertheless should not close. Some discussion of this possibility is needed. The same issue comes up in Section 6, first paragraph. By design, the author's approach reduces residuals (that is a given). However, can this really be taken as objective evidence that flux or stock predictions have actually been improved?

- Yes, closure could happen for the wrong reasons, and we could correct fine EO products for compensating for missing components. The assumption is here that the missing components are random and that the merging will reduce their impact. The only way to make the closure constraint is beneficial is to evaluate the process using independent *in situ* data. This is done in our paper for precipitation and evapotranspiration, it was done also in: Combining data sets of satellite-retrieved products for basin-scale water balance study: 2. Evaluation on the Mississippi Basin and closure correction model, Munier, Aires, Schlaffer, Prigent, Papa, Maisongrande, and Pan, JGR Atmospheres, 2014. What we actually test in section 4.1 is that our methodology is doing what it was designed to do, close the water budget. This is now clearer in the text: *As a closure enforcing, the constraint approaches could yield to a closure of the water cycle, but in degrading fine EO estimate for compensating the imbalance. In order to evaluate the performance of the methodologies in improving the EO estimate, the constrained products will be compared with in situ measurements. The following Section is for assessing that the methodologies do close the water cycle as they suppose to do. The impact of hydrological constraint (PF) as well as the INTegration (INT) and CALibration (CAL) processes on the spatial averaging of the water component estimates and the WC budget residuals, over the several Mediterranean sub-basins, is summarized on Figure A.1 in the Apendix.*

• **Why are there so few rain gauge stations applied to the precipitation analysis in Figure 5? It's difficult to believe that only 7 rain gauges are available in the Mediterranean basin.**

- The rain gauge stations came from the FLUXNET database. In this way, precipitation and evapotranspiration evaluation are performed in the same

network (36 gauges for precipitation). However, precipitation is also evaluate using the *in situ* gridded dataset Eobs at the basin scale (Section 4.2).

• **Also, why is it that the best results (for INT) in Figure 5 occur OUTSIDE of the basin (where INT results are based on an approximate extrapolation)? This seems odd. If INT is performing an accurate downscaling, it seems like it would be more effective WITHIN the basin.**

- The fact that INT can have best results outside of the basin can be explained by the poor performance of the precipitation estimate over particularly complex topography (mountainous rainfall) or coastal pixels with land/sea contamination due to the coarse spatial resolution of satellite estimates. This have been added in the text: *The evaluation of EO estimate at 0.25° spatial resolution using tower sites should be taken with caution. The poor performance of satellite estimate over particularly complex topography (mountainous rainfall) or coastal pixels with land/sea contamination could explain the difference between the INT estimate and the FLUXNET measurement at this particular location.*

• **In Section 3.2 (on the "optimal selection" (OS) approach) necessary? The methodology section is already quite long and the OS results do not seem to make a significant contribution to the manuscript's results.**

- Thank you for this comment. Following your suggestion, we suppressed the OS section, the method is simply explained at the beginning of section 4.4 on SW: *A general approach to deal with EO datasets in the analysis of the WC is to chose the best individual dataset for each one of the water components. This is the approach developed, for example, in the GEWEX project. In Pellet et al. (2018) an Optimal Selection (OS) was based on the minimization of the water budget residuals to select the best combination of individual dataset. On the contrary, the SW approach relies on the merging of several EO datasets for each water component, in order to reduce their uncertainty.*

• **What is meant by "quasi-triangular balance" in Section 5.1? This terminology will likely be unfamiliar for some HESS readers (it was to me).**

- Sorry, the term "quasi-triangular balance" was really clumsy. We just wanted to mention that Mediterranean WC is mainly driven by the European sub-basins and that African coasts are not contributing so much.

We have replaced the title of section 5.1 by a straightforward description: "Analysis of the Mediterranean WC".

• **Figures 4 and 6. A better use of colour would be to differentiate between the INT and CAL cases (which are very difficult to distinguish). Also, the INT+/- and CAL+/- notation should be explained in the figure caption.**

- The reviewer might mean Figures 4 and 5. The colours are now changed and the caption explicits the notations.

• **Some discussion of the statistical significant of differences in Figure 3 would be useful**

- The correlation difference is statistically significant at the 70%-level based on the T-test. This has been added to the caption of Figure 3.

• **Overall the paper is quite well-written, but it does suffer from an excess of minor English usage errors. Superficial proof-reading in this regard would help.**

- The typos and English writing have been improved, we hope that the manuscript is now in a better shape.

# Integrating multiple satellite observations into a coherent dataset to monitor the full water cycle - Application to the Mediterranean region

**Abstract.** The Mediterranean region is one of the more complex environments and is a hot-spot for climate change. The HyMeX (Hydrometeorological Mediterranean eXperiment) aims at improving our understanding of the water cycle at the meteorological to the inter-annual scales. However, monitoring this water cycle with Earth Observations (EO) is still a true challenge: EO products are multiple, and their use still suffer from large uncertainties and incoherencies among the products. Over the Mediterranean region, these difficulties are exacerbated by the coastal/mountainous regions and the small size of the hydrological basins. Therefore, merging/integration techniques have been developed to solve these issues. We introduce here an improved methodology that closes not only the terrestrial but also the atmospheric and ocean budgets. The new scheme allows to impose a spatial and temporal multi-scaling budget closure constraint. A new approach is also proposed to downscale the results from the basin to the pixel scales. The provided Mediterranean WC budget is for the first time based mostly on observations such as GRACE water storage or the netflow at the Gibraltar strait. The integrated dataset is in better agreement with in situ measurements, and we are now able to estimate the Bosphorus strait annual mean netflow.

## 1 Introduction

The Mediterranean region is one of the main climate change hotspots (IPCC, 2014): its sensitivity to global change is high and its evolution remains uncertain. Its role in the evolution of the global ocean (i.e. mainly salinization and warming), as well as the socio-economics consequences it has for surrounding countries, stress the need of monitoring its water resource. Analyzing the Water Cycle (WC), the exchange among its terrestrial, atmospheric and oceanic branches are critical to estimate the availability of the water in the Mediterranean region. Most previous studies use model outputs or reanalysis (Mariotti et al., 2002; Sanchez-Gomez et al., 2011), and *in situ* data network is too sparse and irregular. A recent paper Jordà

et al. (2017) reviewed this literature on the analysis and quantification of the Mediterranean water budget. The WC components are estimated but their uncertainties remain high. Recommendations are made to increase our use of EO data, in a coordinated way. EO allow for the monitoring of the water cycle over long time-records, in particular in regions with low number of *in situ* stations. But the use of EO data for WC monitoring remains a challenge due to:

5 (1) the multiplicity of datasets for the same geophysical parameter, (2) the EO uncertainties (systematic and random errors), and (3) the inconsistency between datasets (for the same component or among the components of the WC). In Pellet et al. (2017), EO are used to monitor the WC over the Mediterranean region, it is shown that the WC budget is not closed and that some integration technique should be used to optimize them.

Several approaches have been considered in order to optimize EO dataset at the global scale, for the WC analysis.

10 The features of some “integration” methods presented in the following are synthesized in Table 1.

*The “Princeton” approach* - Pan and Wood (2006) presented first a work in which the authors aimed at closing the water balance using EO products. In this work, EO datasets such as precipitation was assimilated into a land surface model (the Variable Infiltration Capacity, VIC) using the combination of a Kalman filter and a closure constraint (see Table 1). The resulting “analysis” dataset is not a pure EO product since the VIC model is largely used. In fact, the authors show that the

15 Kalman filtering plus the closure constraint is equivalent to a traditional Kalman filtering, and then to the application of an independent post-filtering that constrains the closure (De Geeter et al., 1997; Simon and Tien Li Chia, 2002; Aires, 2014). This post-filtering acts by redistributing the budget residuals within each water component based on the uncertainties of each EO source. Several papers have been published based on this approach (Troy and Wood, 2009; McCabe et al., 2008; Sahoo et al., 2011; Troy et al., 2011; Pan et al., 2012). For instance, in Sheffield et al. (2009), two different precipitation datasets were used

20 over the Mississippi basin. Evapotranspiration was calculated using a revised Penman-Monteith formulation and changes in water storage were estimated from GRACE. For comparison, land surface model outputs, reanalyses data and *in situ* discharge measurements were used too. The authors concluded that a positive bias of the precipitation datasets leads to an overestimation of the discharge component when the estimation relies on EO data. Meanwhile, the land surface model shows a high degree of agreement with *in situ* data. The analysis also highlights the importance of error characterization in the individual WC

25 components. Yilmaz et al. (2011) relaxed the closure constraint during the assimilation. This is an important feature because strong closure constraint can result in high-frequency oscillations in the resulting combined dataset. A relaxed constraint is used in our approach (see Table 1).

*The NASA-NEWS project* - The project aims at a better characterization of the water cycle using EO data. The first step was to improve the coherency of the satellite retrievals; then to gather the EO dataset, and calibrate them. Some information about the uncertainties of the EO datasets was gathered from the data producers, but these information cannot be straightforwardly

30 used further in the integration process since their evaluation are not homogeneous but product-dependent. The water cycle budget can be closed using the satellite datasets (Rodell et al., 2015). However, this closure is obtained at the global and annual scale only, and residuals are still significant at regional and monthly scales (Rodell et al., 2015) uses then an interpolation for a monthly closure. Closing the budget at the global scale was a first step, and closure must now be obtained at thinner

35 spatial and temporal scales to monitor more precisely the distribution of the water components as the EO data are designed to.

In Rodell et al. (2015), the storage terms (e.g. ground water storage) had no significant change when considering annual and global means. This hypothesis was then straightforwardly used at the monthly scale with an optimized interpolation scheme to relax the storage change at the monthly scale. This translates into a quadratic quality criterion where storage and fluxes terms are minimized when using annual means, at the global scale (see Table 1). One interesting feature in this approach is that both the water (Rodell et al., 2015) and energy (L'Ecuyer et al., 2015) cycles were considered simultaneously in the assimilation taking into account the physical link between the two cycles through the Latent Heat flux.

*The ESA water cycle initiative* - In the context of the ESA WATCHFUL project on water budget closure, Aires (2014) developed several methodologies (Table 1) to integrate different hydrological datasets with a budget closure constraint. No surface or atmospheric model outputs were used in these integration methods, making the obtained product interesting for model calibration and validation. One of the proposed methods, the so-called Simple Weighting+Post Filtering (SW+PF), was applied by Munier et al. (2014) over the Mississippi basin, using satellite datasets for  $P$ ,  $E$  and  $\Delta S$  and gauge observations for  $R$ . The integrated components were compared to various *in situ* observations, showing good performances of the method. This integration approach can also be performed at the entire basin level however, one of the main limitations is the datasets availability, in particular for the *in situ* river discharges. Another concern was the downscaling of the basin closure constraint to the pixel-scale. A Closure Correction Model (CCM) was developed based on the integrated product (Munier et al., 2014), allowing to correct each dataset independently and to greatly reduce the budget residual. This calibration was applied over the basins where river discharges are available and extended to the global scale using an index characterizing the various surface types (Munier and Aires, 2017). This type of post-processing step is anchored in the combination approach, but it can be applied to long time records, at any time or spatial resolution.

**In this paper, we propose several improvements of this line of research. In particular, we propose to close the WC budget not only over land, but also over ocean and in the atmosphere. The budget closure constraint is used simultaneously at different spatial (basin and sub-basin) and temporal (monthly and annual) scales. A new spatial interpolation scheme is proposed to downscale the basin-scale closure constraint to the pixel scale. This new framework is applied to the Mediterranean basin to provide an updated WC budget.**

Section 2 presents the study domain and introduces the datasets used in the following. The integration approaches are described together with the other combination techniques in Section 3. Section 4 presents the evaluation metrics for the integrated product: its ability to close the WC and its validation with *in situ* data at the sub-basin or pixel scale. Section 5 presents the water cycle analysis for the period 2004-2009 using our resulting integrated dataset. Finally, Section ?? concludes the analysis and presents some perspectives. All notations used in the following are summarized in Table A1 in appendix.

## 2 Case study and datasets

This section presents the spatial domain and the datasets used in this study. Table B1 in appendix summarizes the main characteristics of these products and more details can be found in Pellet et al. (2017). All products have different temporal extents but share a common coverage period 2004-2009.

## 2.1 Mediterranean region

The study domain is represented in Fig. 1. It is the catchment basin of the whole Mediterranean Sea drainage area, computed from each coastal pixel, including all rivers that flows into the Sea. Basins have been computed using a hydrographic model (Wu et al., 2011) at a spatial resolution of  $0.25^\circ$ . The resolution of the hydrographic model used to compute land/Sea mask or catchment basin may have an impact on the spatial-average estimates and then on the WC budget residual. This area uncertainty is taken into account into the relaxation of the closure constrain at sub-basin scale (see Table 1). The Mediterranean Sea area with the Black Sea is 3.0 million  $\text{km}^2$ , and its drainage area is more than 5 million  $\text{km}^2$ .

Sub-basins have been introduced in Pellet et al. (2017). They facilitate the analysis of local climate and specific hydrological features. The Mediterranean Sea and the terrestrial sub-basins used in the following are defined as:

- The west Maghreb mainly based on the Atlas mountain discharge (**MA-DZ-TN**);
- The Nile Basin and Libyan coast characterizing Saharan and sub-Saharan climate (**LY-EG**);
- The Spanish coasts and Pyrenees (**ES-Pyr**);
- The French coast, Italy and Adriatic Sea, freshwater from the Alps and the Balkans mountains (**Alp-IT-ADR**);
- The eastern part of the Mediterranean Sea, Greece, Turkey and Israel (**GR-TR-IL**);
- The whole Black Sea drainage catchment, Bulgaria, Georgia, Romania, Russia, Turkey, Ukraine, Slovakia, Hungary, Austria, Slovenia, Bosnia and Serbia (**BLS**).

In the current study, even if the closure methods (PF) is applied over the LY-EG sub-basin, the high uncertainty of the Nile discharge and its particular climate (African monsoon) as well as anthropogenic conditions (most of its water is used for irrigation) make this sub-basin really different from the other sub-basins (Margat, 2004; Mariotti et al., 2002). In this study, the closure is ensured for the Nile sub-basin but no spatial extension will be extrapolated over the LY-EG and toward central Africa in the analysis (see Section 3).

## 2.2 Original EO datasets

The datasets presented in this section will be used in the integration process over the Mediterranean region. Most of them are satellite products and are commonly used for studying the water cycle. In order to integrate them, the datasets have been projected on a common  $0.25^\circ$  spatial resolution grid, and re-sampled at the monthly scale.

*Precipitation (P)*- Four satellite-based datasets have been selected. Two are gauge-calibrated products: the Tropical Rainfall Measuring Mission Multi-satellite Precipitation Analysis (TMPA, 3B42 V7) presented in Huffman et al. (2007) and the Global Precipitation Climatology Project (GPCP, v2) introduced by Adler et al. (2003). Two are uncalibrated products: Joyce et al. (2004) has unveiled the NOAA CPC Morphing Technique (CMORPH, v1) and Ashouri et al. (2015) developed the Precipitation Estimation from Remote Sensing Information using Artificial Neural Network (PERSIANN, v1). In this study, we use

a mix of gauged/ungauged-calibrated precipitation datasets. This choice is motivated by the will of preserving the original EO spatial pattern where limited gauge density in some areas may corrupt the signal during the gauge-calibration process (in TMPA and GPCP product).

5 *Evapotranspiration (E)*- Three satellite-based products were chosen to describe evapotranspiration (over land): the Global Land Evaporation Amsterdam Model (GLEAM-V3B, Martens et al., 2016; Miralles et al., 2011); the MODIS Global Evapotranspiration Project (MOD16, Mu et al., 2011); and the Numerical Terradynamic Simulation Group product (NSTG, Zhang et al., 2010).

Two products were chosen for the evaporation (over the Sea): the Objectively Analyzed air-Sea Fluxes for Global Oceans (OAflux, Sun et al., 2003); and The Global Energy and Water Cycle Exchanges Project product (GEWEX-Seaflux, Curry et al., 2004).

*Water storage change ( $\Delta S$ )*- The terrestrial and Sea water storage datasets are all derived from the GRACE mission. The estimates of water storage implicitly include the underground water. Four satellite datasets are based on the spherical decomposition of GRACE measurement: the Jet Propulsion Laboratory (JPL, Watkins and Yuan, 2014) product; the Centre for Space ReSearch (CSR, Bettadpur, 2012) product, the German ReSearch Centre for Geoscience (GFZ, Dahle et al., 2013) product; and the land-only product from the Groupe de Recherche de Géodésie Spatiale (GRGS, Biancale et al., 2005). One extra solution based on the JPL-MASCONS decomposition of GRACE measurement (Watkins et al., 2015) is also used in this work. In order to compute the monthly change in water storage, we applied a centred derivative smoothing filter:  $[5/24 \ 3/8 \ -3/8 \ -5/24]$  (Pellet et al., 2017). The filter is a slightly smoother version of the filter  $[1/8 \ 1/4 \ -1/4 \ -1/8]$  presented by Eicker et al. (2016). It has been compared with several other filters (results not shown). The chosen filter is a good compromise between its low smoothing (that suppress information) and its ability to de-noise the time series.

*Discharge ( $R_t$ )*- No satellite-based product is available for the discharge with sufficient temporal extent and few rivers are still monitored by public or private network for the Global Runoff Data Centre (GRDC) that collects discharge data at the global scale. The two discharge datasets used in the following are described in Pellet et al. (2017). Groundwater discharge is neglected and considered as uncertainty.

The CEFREM-V2 dataset of coastal annual discharge into the Mediterranean Sea (Ludwig et al., 2009) is based on *in situ* observations and some indirect estimates using the Pike formula (Pike, 1964). In addition, developed at the Laboratoire de Météorologie Dynamique (Polcher et al., 1998; Ducharne et al., 2003), the land surface model Organising Carbon and Hydrology In Dynamic Ecosystems (ORCHIDEE) is chosen here to describe the monthly dynamics of the discharge. Two coastal discharge outputs are available from its routing scheme with two different precipitation forcings: GPCC and Climatic ReSearch Unit (CRU) products. We therefore projected the monthly dynamical patterns from ORCHIDEE towards the CEFREM grid. We then scaled the monthly values of ORCHIDEE to match the CEFREM annual values. For comparison purpose, CEFREM total freshwater inflow into the Mediterranean, without the Black Sea is  $400 \text{ Km}^3 \text{ yr}^{-1}$ ; while ORCHIDEE is  $380 \text{ Km}^3 \text{ yr}^{-1}$ .

35 The scaling is then a simple way to take into account the anthropogenic impact that is not modelled at the annual and the  $0.5^\circ$

scales. The final product has then the spatial resolution and the annual cumulative value of CEFREM, but with the monthly dynamics of the ORCHIDEE model.

5 *Precipitable water change ( $\Delta W$ )-* We considered two datasets for the precipitable water: the ESA Globvapor dataset (Schneider et al., 2013) and the 6-hour reanalysis product from the ECMWF reanalyses (ERA-I, Dee et al., 2011). The ERA-I reanalysis has been considered here because precipitable water, although model-based, is largely constrained by satellite observations. In order to compute changes in precipitable water, we also applied the derivative filter:  $[5/24 \ 3/8 \ -3/8 \ -5/24]$ .

10 *Moisture divergence ( $Div$ )-* Due to the limited temporal extent of the satellite-based data, we use the 6-hour ERA-I reanalysis product (Dee et al., 2011). Among the various re-analyses, ERA-I was adopted for this study in view of previous results demonstrating advantages in the representation of long term wind variability in Stopa and Cheung (2014) which plays a key role in the representation of moisture divergence. Nevertheless, Seager and Henderson (2013) have shown the limitation of the reanalysis that do not catch moisture divergence events shorter than at the 6-hour temporal scale. This limitation must be taken into account when closing the water cycle.

15

*Gibraltar netflow ( $Gib$ )-* The only multiannual estimate of the Gibraltar netflow based on observations is the one presented in Jordà et al. (2016). We use there a monthly reconstruction of the net transport where the effects of the atmospheric pressure have been removed. This is done for consistency with the GRACE estimates of ocean water storage. The reconstruction technique used to generate that estimate has proven to be effective to simulate the variability but the uncertainties in the mean value are large. In Jordà et al. (2017) an expert-based assessment of the mean transport is presented. Therefore, in this work we substitute the 2004-2016 mean value of the Jordà et al. (2016) estimate by the estimate proposed in Jordà et al. (2017).

The Mediterranean Sea is also connected to the Red Sea with the Suez channel and to the Black Sea with the Strait of Bosphorus. The netflow at the Strait of Suez is neglected (Mariotti et al., 2002; Harzallah et al., 2016). Since no *in situ* reference is available on the Bosphorus netflow, the current work gathers the Mediterranean and the Black Seas into a single reservoir.

### 25 **2.3 Validation datasets**

*The ENSEMBLES observation dataset (EOBS) -* In order to validate the precipitation, an additional dataset is used: the EOBS dataset developed from the EU-FP6 project ENSEMBLES (Haylock et al., 2008). It is a regional, well documented and validated *in situ* gridded daily dataset at  $0.25^\circ$  spatial resolution, covering the period 1950-2007.

30 *FLUXNET -* Ground-based FLUXNET data (Falge et al., 2017) are used to validate the evapotranspiration and precipitation over several sites in Europe<sup>1</sup>. These flux measurements are based on eddy covariance technique. All stations available in Europe for the 2004-2009 period have been selected. In order to avoid coastal contamination, the three Seaside towers “IT-Ro2”,

---

<sup>1</sup>FLUXNET2015 datasets; <https://fluxnet.fluxdata.org>

“IT-Noe” and “ES-Amo” have been suppressed.

*Total and thermosteric Sea level datases*-To validate the Sea level output from the integration technique, we use and independent estimate of Mediterranean water content. The water content can be estimated (Fenoglio-Marc et al., 2006; Jordà and Gomis, 2006) as total Sea level minus the thermosteric variations (i.e. changes in Sea level due to thermal expansion/contraction). Total Sea level is obtained from the Ssalto/Duacs altimeter data produced and distributed by the Copernicus Marine and Environment Monitoring Service <sup>2</sup>. The thermosteric Sea level variations are estimated using two ocean regional reanalyses (MEDRYS, Hamon et al., 2016; Bahurel et al., 2012, MyOcean,) and two global products that include the Mediterranean (the Met Office Hadley Centre EN-v4 Good et al., 2013; Ishii et al., 2003, ISHII).

## 10 2.4 EO uncertainty assumptions

Some studies aimed at characterizing the uncertainty of satellite retrieved products : estimating relative uncertainty of numerous datasets by the distance to the average product (Pan et al., 2012; Zhang et al., 2016) or using non-satellite datasets (Sahoo et al., 2011). Nevertheless, such characterizations are generally product- and site-specific, and for some products used in this work, no uncertainty characterization can be found in the literature. For these reasons we considered the same uncertainty for all the datasets of a given parameter after de-biasing, following Aires (2014).

Table 2 summarizes the uncertainty used in the various integration techniques. The uncertainty is associated to a weight which is the ratio of the sum of all the uncertainty in the WC equation and the uncertainty of the considered variable (computed as  $\sigma_i^2 / \sum_i \sigma_i^2$  and expressed in percentage). Note that uncertainty in Table 2 stands for the merged product and not for particular satellite dataset (see Eq. (6)). Following Munier et al. (2014), the uncertainties are prescribed by the literature but slightly modified from Munier et al. (2014) to handle the special case of the Mediterranean region. Munier et al. (2014) used uncertainty values of 10 mm/month for each of the four  $P$  products and the three  $E$  products (leading to 5 and 5.8 mm/month for the merged P and E estimate), 5 mm/month for each of the three  $\Delta S$  products (leading to 2.9 mm/month for the merged product) and 1 mm/month for only one  $R$ . The choice of these values was motivated by results of the studies cited in Section 1. In order to be closer to Rodell et al. (2015), on the one hand, we decide to reduce  $P$  uncertainty to 4 mm/month. This is justified since the de-biasing was done toward the gauge-calibrated TMPA dataset (see Pellet et al. (2017) for details). On the other hand, we increased E uncertainty up to 6 mm/month. The uncertainty of the merged  $\Delta S$  is estimate to be broadly the same since it is mainly driven by the large pixel resolution of GRACE. Finally, the uncertainty of the discharge  $R$  has been increased since the product is partially based on model simulations and the groundwater discharge is not included in the analysis (see Section 2). For the atmospheric variables, we consider an uncertainty proportional to the range of variability for the precipitable water change: 1 mm/month. Following the suggestion from Seager and Henderson (2013), the reanalysis moisture divergence uncertainty has been set to 6 mm/month due to its large range of variability and time scale.

### 3 EO integration methodologies

This section presents the integration techniques used to optimize the EO datasets.

#### 3.1 Closing the water cycle budget

In this section, the notations are introduced but additional details can be found in Aires (2014).

5 **The WC can be described by the following time-varying budget equations:**

$$\begin{aligned}
 \frac{\delta S_l}{\delta t} &= P_l - E_l - R_l \quad (\text{Terrestrial}) \\
 \frac{\delta S_o}{\delta t} &= P_o - E_o + R_l^* - Gib \quad (\text{Oceanic}) \\
 \frac{\delta W}{\delta t} &= E_{l/o} - P_{l/o} - Div \quad (\text{Atmospheric})
 \end{aligned} \tag{1}$$

where  $l$  stands for land and  $o$  for ocean. If all the components in Eq. (1) are expressed in mm/month (area-normalized)

10 **then a fourth equality is defined:  $R_l^* = \frac{A_{land}}{A_{Sea}} \cdot R_l$  for total freshwater input/output with  $A_{land}$  is the total drainage area of the Mediterranean with the Black Sea, and  $A_{Sea}$  the total of the two Sea areas.**

We first consider the six terrestrial water components  $X_l^t = (P_l, E_l, R_l, \Delta S_l, \Delta W_l, Div_l)$  and the six oceanic water components  $X_o^t = (P_o, E_o, \Delta S_o, \Delta W_o, Div_o, Gib)$  ( $^t$  is the transpose symbol). We then define  $X_{lo}^t = [X_l, X_o]^t$ . The closure of the water budget can be relaxed using a centred Gaussian random variable  $r$  and  $X^t \cdot G_{lo}^t = r$ , with  $r \sim \mathcal{N}(O, \Sigma)$  where:

$$15 \quad G_{lo} = \begin{bmatrix} 1 & -1 & -1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & -1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{A_{land}}{A_{Sea}} & 0 & 0 & 0 & 1 & -1 & -1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & -1 & -1 & 0 \end{bmatrix} \tag{2}$$

which is equivalent to the water budget in Eq. (1) and

$$\Sigma = \begin{pmatrix} \sigma_l & \mathbf{0} \\ \mathbf{0} & \sigma_o \end{pmatrix}$$

with  $\sigma_l = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$  represents the standard deviation of the constrained terrestrial and atmospheric water budget residual over land; and  $\sigma_o = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$  represents the standard deviations of the constrained oceanic and atmospheric water

20 **budget residual over sea.  $\Sigma$  assumes no correlation in the imbalance of the 3 water cycles at monthly and annual scales, at sub-basin or entire basin scales.**

Let:

$$Y_l^t = \begin{pmatrix} P_1, \dots, P_p, E_1, \dots, E_q, R_1, \dots, R_r, \\ \Delta S_1, \dots, \Delta S_s, \Delta W_1, \dots, \Delta W_v, Div_1, \dots, Div_d \end{pmatrix} \tag{3}$$

be the vector of dimension  $n_l = p + q + m + s + v + d$  gathering the multiple observations available for each water component over land (similarly  $Y_o$  of dimension  $n_o$  is defined over Sea):

- $(P_1, P_2, \dots, P_p)$ , the  $p$  precipitation estimates;
- $(E_1, E_2, \dots, E_q)$ , the  $q$  sources of information for evapotranspiration;
- 5 -  $(R_1, R_2, \dots, R_m)$ , the  $m$  discharge estimates;
- $(\Delta S_1, \Delta S_2, \dots, \Delta S_s)$ , the  $s$  sources of information for the water storage change;
- $(\Delta W_1, \Delta W_2, \dots, \Delta W_v)$ , the  $v$  precipitable water change estimates;
- $(Div_1, Div_2, \dots, Div_d)$ , the  $d$  moisture divergence.

The aim of this approach is to obtain a linear filter  $K_{an}$  used to obtain an estimate  $X_{an}$  (“an” stands for analysis) of  $X_{lo}$  based on the observations  $Y_{lo}$ :

$$X_{an} = K_{an} \cdot Y_{lo} \text{ with } Y_{lo} = [Y_l, Y_o] \quad (4)$$

where  $K_{an}$  is a  $12 \times (n_l + n_o)$  matrix.

### 3.2 Simple Weighing (SW)

**A general approach to deal with EO datasets in the analysis of the WC is to choose the best individual dataset for each one of the water components. This is the approach developed, for example, in the GEWEX project. In (Pellet et al., 2017), an Optimal Selection (OS) was based on the minimization of the water budget residuals to select the best combination of individual dataset. Using the OS principle facilitates finding datasets coherent to each other and with independent errors (Rodell et al., 2015). But this kind of strategy limits the use of several source of information to reduce the uncertainties.**

**On the other hand, SW approach benefits from the multiplicity of the observations.** EO products and more generally any estimation of a variable via observations, presents two types of errors. (1) Systematic errors related, for instance, to the absolute calibration of the sensor. These can be represented by a bias and/or a scaling factor. (2) Random errors related to retrieval algorithm uncertainties or to missing or inaccurate auxiliary information (e.g cloud mask) or to the sensor itself. These are often characterized by a standard deviation using a Gaussian hypothesis. From a statistical point-of-view, using the average of several estimates reduces the random errors of the estimation if no bias errors are present in the estimates. The merging process such as in Eq. (4) requires then un-biased estimates (Aires, 2014). The difficulty is that, as for uncertainties (Section 2.2.4), it is rather difficult to obtain bias estimates from the literature for every dataset used in this approach. A pragmatic strategy is to set the reference as the mean state for each component. Then, all the sources of information for this component are bias-corrected toward this reference (Munier and Aires, 2017). A slightly modified version of the bias correction is to choose one reference among the datasets and apply the bias-correction. The author opted for the modified version and de-biased the EO using the

TMPA Season (Pellet et al., 2017). Therefore, the SW methodology, presented for instance in Aires (2014), is first based on a Seasonal bias correction to reduce the systematic biases and is then followed by a weighted average of the corrected estimates to reduce the random errors. **After the seasonal de-biasing, all the precipitation products will have a similar season, but their long-term trend, inter-annual or monthly variations will still be different. In particular, the seasonal de-biasing**

5 **will not change the trend of the EO products.**

The SW methodology uses the diversity of WC component estimations to reduce the random errors. **let us consider the  $p$  precipitation observations  $P_i$  associated with Gaussian errors  $\epsilon_i \sim \mathcal{N}(O, \sigma_i)$ .** The  $\sigma_i$  is the standard deviation of the estimate  $i^{th}$ . The SW precipitation estimate  $P_{SW}$  is given by the weighted average:

$$P_{SW} = \frac{1}{p-1} \sum_{i=1}^p \frac{\sum_{k \neq i} (\sigma_k)^2}{\sum_k (\sigma_k)^2} P_i. \quad (5)$$

10 This equation is valid when there is no bias error in the  $P_i$ s (thanks to the preliminary bias correction) and is optimal when the errors  $\epsilon_i$  are statistically independent from each other. This expression is valid for the other WC components. The variance of the  $P_{SW}$  estimate is then given by:

$$var(P_{SW}) = \frac{1}{(p-1)^2} \sum_{i=1}^p \left( \frac{\sum_{k \neq i} (\sigma_k)^2}{\sum_k (\sigma_k)^2} \right)^2 \sigma_i^2. \quad (6)$$

This is an important information because it gives the uncertainty of the estimate of Eq. (5). It shows that the  $P_{SW}$  errors can be significantly reduced by increasing the number  $p$  of observations.

Following Eq. (5) the state vector estimate via SW method  $X_{SW}$  can be defined as:

$$X_{SW} = K_{SW} \cdot Y_{lo}, \quad (7)$$

where  $K_{SW}$  is a  $12 \times (n_l + n_o)$  matrix in which each line represent Eq. (5) for one of the 12 water components (the first one for the precipitation estimate, the second for the evapotranspiration, *ect.*) and based on the  $(n_l + n_o)$  observations. **Since no specific uncertainty estimates were available in the literature for the Mediterranean basin, the uncertainties are assumed to have a same standard deviation  $\sigma_i$  in the following.**

### 3.3 Post-Filtering (PF)

In the SW approach, each water component is weighted (see Eqs. (6-7)) based on its *a priori* uncertainties (Section 2) but no closure constraint is imposed on the solution  $X_{SW}$ . Several methods were considered in Aires (2014) to introduce a WC budget closure constraint on the SW solution. However, Monte-Carlo simulations have shown that the SW solution associated to a so-called Post-Filtering (PF) provides results as good as more complex techniques such as variational assimilation.

The PF approach has been introduced (Pan and Wood, 2006) to impose the closure constraint on a previously obtained solution. Here we used  $X_{SW}$  as the first guess on the state vector  $X_{lo}$ . In Aires (2014), the PF was used and tested without any model, as a simple post-processing step after the SW. Following Yilmaz et al. (2011), the current study implements the PF filter with a relaxed closure constraint characterized by its uncertainty covariance  $\Sigma$ :

$$X_{PF} = (I - K_{PF} \cdot G_{lo} \Sigma^{-1} G_{lo}^t) \cdot X_{SW}, \quad (8)$$

where  $K_{PF} = (B_{lo}^{-1} + G_{lo} \sum^{-1} G_{lo}^t)^{-1}$  and  $B_{lo}$  is the error covariance matrix of the first estimate on  $X_{lo}$ .

In expressing  $X_{SW}$  with  $Y_{lo}$ , we can express explicitly the linear operator  $K_{an}$  of Eq. (4):

$$\begin{aligned} X_{an} = X_{PF} &= (I - K_{PF} \cdot G_{lo} \sum^{-1} G_{lo}^t) \cdot K_{SW} \cdot Y_{lo}, \\ X_{an} &= K_{an} \cdot Y_{lo}, \end{aligned} \quad (9)$$

- 5 Where  $K_{an} = (I - K_{PF} \cdot G_{lo} \sum^{-1} G_{lo}^t) \cdot K_{SW}$ . The PF step (budget closure) consists in partitioning the budget residual among the twelve components at each time step, independently. This technique allows obtaining a satisfactory WC budget closure for each basin. The residual term  $r$  could be reduced in SW+PF approach by decreasing the variance  $\sum$  in Eq. (8). If the relaxation term is too small, the closure is constrained but this is to the detriment of some hypotheses (such as unknown ground water and some uncertainties (e.g. size of the drainage area used to compute spatial average of the water components)).
- 10 Following (Aires, 2014; Munier et al., 2014) we enforced the budget closure by frequency range to avoid high-frequency errors to impact the low-frequency variables such as evapotranspiration (mainly driven by annual vegetation growth (Allen et al., 1998)). We first decomposed each parameter into a high and low-frequency components considering a cut-off frequency of 6 months (using a FFT decomposition). The budget is then applied independently on low and high frequencies. The high frequency component of  $E$  is then not included in the high budget closure. The linearity of PF and FFT ensures the budget
- 15 closure of the re-composed final product. In the following temporal multi-scaling, the annual constraint is applied only on the low-frequency budget closure.

*Spatial multi-scaling* - It is possible to impose a WC budget closure simultaneously over the six sub-basins, the full basin and over the ocean (i.e. Mediterranean and Black Seas). Let us consider the total WC state vector:

$$20 \quad X^t = [X_l^{(1)}, X_l^{(2)}, X_l^{(3)}, X_l^{(4)}, X_l^{(5)}, X_l^{(6)}, X_o]^t. \quad (10)$$

that includes the six water components  $X_l^i$  over each sub-basin  $i$  of area  $A_l^{(i)}$  and ocean. The ‘‘closure’’ matrix becomes:

$$G_{lo} = \begin{pmatrix} G_l^{(1)} & 0 & \dots & 0 & 0 \\ 0 & G_l^{(2)} & \dots & 0 & 0 \\ \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & G_l^{(6)} & 0 \\ L_{lo}^{(1)} & L_{lo}^{(2)} & \dots & L_{lo}^{(6)} & G_o \end{pmatrix} \quad (11)$$

with:

$$\begin{aligned}
 G_l^{(i)} &= \begin{bmatrix} 1 & -1 & -1 & -1 & 0 & 0 \\ -1 & 1 & 0 & 0 & -1 & -1 \end{bmatrix} \\
 L_{lo}^{(i)} &= \begin{bmatrix} 0 & 0 & \frac{A_l^{(i)}}{A_{Sea}} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \\
 G_o &= \begin{bmatrix} 1 & -1 & -1 & 0 & 0 & 1 \\ -1 & 1 & 0 & -1 & -1 & 0 \end{bmatrix}
 \end{aligned} \tag{12}$$

The last row of  $G_{lo}$  represents the overall budget closure, including all the sub-basins and the ocean. The dimension of the covariance matrices  $B_{lo}$  and  $\Sigma$  are increased following the new size of the state vector  $X_{lo}$ . No cross terms in  $B_{lo}$  and  $\Sigma$  are included, meaning that there is no dependency of the first guess and closure errors among the sub-basins.

- 10 *Temporal multi-scaling* - It is also possible to impose a WC budget closure simultaneously at monthly and annual scales. With monthly closure, the annual closure should automatically be obtained but due to the relaxation of the closure constrain, the annual closure would be relaxed too. We control here the yearly closure constrain with an uncertainty of 1 mm. Furthermore, we impose a yearly closure assuming no groundwater storage change at the annual scale over land (representing an additional constraint on  $\Delta S_l$  to ensure that no bias is introduced for this variable during the PF process). In this framework, monthly
- 15 closures are now interdependent in the given year and the new state vector is :

$$X_{year}^t = [X^{Jan}, \dots, X^{Dec}]^t, \tag{13}$$

with  $X^m$  is the total state vector  $X$  defined in Eq. (10), for month  $m$ . The closure is applied independently for the four years of the 2004-2009 period but the twelve months of each year are closed independently.

- The closure matrix  $GA_{lo}$  that includes closure for the twelve months of the year and the full year is derived from the monthly
- 20 constraint Eq. 11 and defined as:

$$GA_{lo} = \begin{pmatrix} G_{lo} & 0 & \dots & 0 \\ 0 & G_{lo} & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & G_{lo} \\ N_{lo} & N_{lo} & \dots & N_{lo} \end{pmatrix} \tag{14}$$

where  $N_{lo}$  is the modified closure matrix  $G_{lo}$  in which the matrix  $G_l^{(i)}$  is rewritten in  $N_l^{(i)}$  by imposing  $\Delta S_l = 0$  :

$$N_l^{(i)} = \begin{bmatrix} 1 & -1 & -1 & \mathbf{0} & 0 & 0 \\ -1 & 1 & 0 & 0 & -1 & -1 \end{bmatrix} \tag{15}$$

The last row of  $GA_{lo}$  represents the annual budget closure considering no storage change at the annual scale over land, including all the sub-basins and the ocean. The dimension of the covariance matrices  $B_{lo}$  and  $\Sigma$  are increased once again following the new size of the state vector  $X_{year}$ . No cross terms in  $B_{lo}$  and  $\Sigma$  are included, meaning that there is no dependency of the first guess and closure errors between the months.

5

This SW+PF technique is able to deal only with time series (the average on the considered sub-basins), not with maps (pixel) since the discharge is not available at this resolution. Therefore, in order to obtain a multi-component dataset that closes the WC budget and has spatial patterns at the pixel level, another technique needs to be used.

### 3.4 INTEgration (INT)

10 The INT methodology allows extrapolating the results obtained with the previous SW+PF, from the sub-basin to the pixel scale. To obtain a pixel-wise closure, Zhang et al. (2017) assimilate satellite data into the VIC model at the pixel scale ( $0.5^\circ$ ) using the VIC pixel water storage and runoff information. Munier and Aires (2017) extrapolated at the global scale the results of the WC closure of several large river basins around the globe, by using surface classes that intend to discriminate between EO error types, preserving as much as possible the hydrological coherency.

15 The INT approach proposed here uses the WC closure over the Mediterranean sub-basins to extrapolate the closure correction to the surrounding area. The methodology is presented in its various steps in Fig. 2 for precipitation and evaporation, for a particular month. In this analysis, we consider only the Mediterranean sub-basins and their close neighborhood, so a simple spatial interpolation of the closure correction is supposed to be sufficient.

The SW+PF method (Fig. 2, second row) provides a WC budget closure over the six sub-basins, for each month  $m =$   
20  $1, \dots, 72$  of the 2004-2009 period.

The INT method requires a scaling factor to go from the SW to the SW+PF solution at the sub-basin scale. We define  $\beta^{(i)}(m) = P_{PF}^{(i)}(m)/P_{SW}^{(i)}(m)$  (for precipitation here), the ratio between the SW and the SW+PF solution, for each sub-basin  $i$  and month  $m$ . This ratio can be used to scale the SW dataset towards the SW+PF solution at the basin scale, for a particular month  $m$ , in the following way:

$$25 \quad P_{INT}^{(i)}(m) = \beta^{(i)}(m) \cdot P_{SW}^{(i)}(m) \left( = P_{PF}^{(i)}(m) \right). \quad (16)$$

For water storage change or moisture divergence, this  $\beta$  could become negative. In this case, the bias-correction  $\gamma^{(i)}(m) = P_{PF}^{(i)}(m) - P_{SW}^{(i)}(m)$  is used instead:

$$\Delta S_{INT}^{(i)}(m) = \Delta S_{SW}^{(i)}(m) + \gamma^{(i)}(m) \left( = \Delta S_{PF}^{(i)}(m) \right). \quad (17)$$

The  $\beta$  scaling is defined at the sub-basin scale, but if interpolated spatially, it could be used at the pixel scale to obtain a truly  
30 spatialized solution.

Let us define a scaling map at the pixel level  $\alpha$  such that: for each pixel  $j$  in sub-basin  $i$ , for each month  $m$ :  $\alpha(j, m) = \beta^{(i)}(m)$  (or  $\gamma^{(i)}(m)$ ). When used as it is, the convolution of SW and  $\alpha$  maps allows for the spatialisation of the sub-basins closure

(Fig. 2, third row) with :

$$\iint_{j \in A_i^{(i)}} P_{SW}(j, m) \alpha(j, m) = \beta^{(i)}(m) \cdot P_{SW}^{(i)}(m) = P_{INT}^{(i)}(m) \quad (18)$$

However, this product presents not only a discontinuity across the sub-basins (where different scaling factors  $\beta$  are defined) but also no value can be provided outside of the sub-basins.

To solve these two issues, the  $\alpha$  scaling maps are interpolated/extrapolated:

- *Interpolation* - A region of 200 km on either side of the frontier between two sub-basins  $i_1$  and  $i_2$  is defined, and a smooth interpolation is performed between the two scaling factors  $\beta^{(i_1)}(m)$  and  $\beta^{(i_2)}(m)$  based on the distance to the frontier. This interpolation of the scaling factors  $\alpha$  between two sub-basins can introduce errors (closure residuals can slightly increase) but it will be shown that this effect is limited and that the bottom equations (in parenthesis) in Eqs. (16-17) stand overall.
- *Extrapolation* - An extrapolation of the  $\alpha$  maps is then performed to have a scaling factor  $\alpha$  outside of the sub-basins domain. This extrapolation is weighted according to the respective distances to the two closest sub-basins.

The INT product is the convolution between the SW EO dataset with the resulting scaling map  $\alpha$  that constrains the WC budget closure. INT is then an optimized version of SW in which the WC budget closure has been extended at the pixel scale. The fourth row of Fig. 2 shows the resulting INT product and its spatial coverage. The continuity issues between the sub-basins have been solved, and the extrapolation allows for a spatial coverage over the entire domain.

**The extrapolation of a closure constraint is interesting at the technical level because for other regions, or when working at the global scale, some form of inter/extrapolation between the monitored sub-basins is required (Munier and Aires, 2017). The extrapolation outside of the Mediterranean region will also allow for the use of more *in situ* observations for the evaluation, this will help the testing of the generalization ability of the extrapolation scheme. The justification of this inter/extrapolation is based on the assumption that most of the WC imbalance is due to satellite errors (this assumption is used for the CAL methodology too). The closure constrain is supposed to improve the satellite estimate by reducing the bias and random errors. If no other information is used (such as surface type, see (Munier and Aires, 2017)), the EO errors should have a spatial continuity and it then makes sense to extrapolate results based on this spatial continuity. We perform the main analysis over the Mediterranean basin and test the extrapolation scheme over well monitored locations.**

The difference between the SW and INT estimates, represented in the last row of Fig. 2, is then directly related to the pixel-wise interpolated scaling factor  $\alpha$ . Discontinuity between the sub-basins is smoothed. The north of Europe excluding France is mainly driven by the scaling factor on the BLS region. That is consistent with the updated köppen climate classification (Kottek et al., 2006). Since the SW+PF solution is available over the 2004-2009 period only, INT can be obtained only over this period.

### 3.5 CALibration (CAL)

To obtain the INT solution, many EO datasets were combined: multiple datasets for each water component (the SW part), and for the various WC components (the PF part). However, if one of the datasets is missing, the INT solution cannot be estimated and this will result in a gap in the time record, and shorter time series of the integrated database.

5 In Munier et al. (2014), a "Closure Correction Model" (CCM) was introduced to correct each dataset independently, based on the results of the SW+PF integration. The CCM is defined as a simple affine transformation with a scaling factor  $a$  and an offset  $b$ , such that  $X_{new} = a \cdot X + b$ . The CCM parameters  $a$  and  $b$  were calibrated by computing a linear regression between the original observation datasets and the SW+PF components.

A similar approach can be used, with the INT solution as a reference instead of the SW+PF. Instead of calibrating the  
10 original EO datasets using basin scale data, we propose here to calibrate the SW solution towards the INT solution at the pixel scale. This calibration of the SW allows obtaining a long-term dataset at the pixel scale like the SW solution, see Table 3, but with WC budget closure statistics closer to the INT solution. In our tests (not shown), the linear regression is quite satisfactory for the calibration, and it is not necessary to use a more complex statistical regression tool such as a neural network.

15 The merging/integration techniques used in this study are described in Table 3.

## 4 Evaluation of the integrated datasets

**In this section, the obtained integrated datasets are first evaluated in terms of WC budget closure. Our EO datasets integration technique is based on the closure of the WC budget. This is a physical constraint but in some cases (e.g. missing important water component), this constraint could result in a degraded estimation of the components. Therefore, available *in situ* data (precipitation, evapotranspiration and sea water level) are used to validate some of the water components of the integrated dataset. This evaluation is performed at two different spatial scales: the sub-basin scale and the pixel scale.**

### 4.1 Water cycle budget closure

The residuals of the surface and atmospheric WC budgets for the Mediterranean region are computed at the monthly scale,  
25 over the 2004-2009 period. The Root Mean Square (RMS) statistics of these residuals are summarized in Table 4 for the six considered products (ERA-I, OS, SW, SW+PF, INT and CAL). Percentage of improvement of the RMS of the residuals with respect to the SW solution are also shown for comparison purposes.

ERA-I stands for the reanalyses product for all variables except for the water storage and the discharge, to keep the comparison consistent. It should be noted that ERA-I does not have any water conservation constrain. The optimal selection is given  
30 by: TMPA precipitation; GLEAM evapotranspiration and OAFflux evaporation; GRGS water storage change over land and JPL water storage change over Sea; GPCC-forced ORCHIDEE-CEFREM discharge; and the derivate Globvapor for atmospheric

water vapour change. Only one dataset is available for the moisture divergence (Pellet et al., 2017). As shown in (Aires, 2014; Munier et al., 2014; Pellet et al., 2017), the SW merging procedure reduces the WC budget residuals at the sub-basin scale, by reducing the random errors of the EO data. The product outperforms the ERA-I reanalysis and the OS product. However, the full closure is generally not satisfactory with this technique. The SW+PF procedure closes the water budget over all the sub-basins, and over the surface and in the atmosphere, with a RMS of the residual of about 4 mm/month. The surface budget residuals are drastically reduced: from 72% over the GR-TR-IL sub-basin and up to 94% for the Mediterranean Sea. This shows the necessity to use a WC budget closure constraint that links the six water components.

The INT product provides satisfactory budget closure results (from 61% to 94%), even if they are slightly degraded compared to the SW+PF (due to the interpolation process between sub-basins). Since no interpolation has been applied over the Mediterranean Sea, the statistics are equal to the SW+PF.

The CAL product improves less the WC budget residuals compared to INT. Nevertheless, the RMS of the residuals for these products are reduced over all sub-basins compared to SW solution.

Fig. A1 gives, in Appendix, the 2004-2009 time series of all the water components estimate for the various methodologies (SW, SW+PF, INT and CAL) over the various sub-basin as well as the probability density function of the residual. This figure shows how the WC closure impact the time series.

## 4.2 Evaluation at the sub-basin scale

Since the WC budget closure constraint was imposed at the sub-basin scale (see Section 3), the evaluation of the integrated product is done at this scale too. Two metrics are used here, the RMS of the Difference (RMSD) with *in situ* measurements and the CORRelation (CORR). Only multiple-EO integrated datasets are compared in the two following sections.

*Terrestrial precipitation* - Table 5 provides the comparison of the EOBS gridded gauge precipitation dataset (section 2.2) with the SW, SW+PF, INT and CAL solutions, in terms of temporal correlation (at the monthly and sub-basins scales), and RMSD, for each sub-basin and for the “continental” scale (land included in Fig. 1). Since the SW+PF product is defined only on the Mediterranean drainage sub-basins, no statistic is shown for this approach over the continental region (last column). For the RMSD error statistics, results are also provided as improvements compared to the SW solution.

Over all the sub-basins, the SW+PF methodology improves results compared to the un-constrained SW method. Even if the correlation of SW with EOBS is already good, the closure constraint improves this correlation to 0.84 (0.81) over e.g. the MA-DZ-TN sub-basin. This is true even over the complex sub-basins Alp-IT-ADR. SW+PF also reduces the RMSD with EOBS (by up to 20%). These results show the merit of the closure constraint on precipitation. Without explicitly constraining satellite precipitation products towards the *in situ* data, SW+PF statistics are still improved.

The INT product shows similar CORR and RMSD statistics as SW+PF over the Mediterranean sub-basins, with a slight decrease of the CORR with EOBS over the ES-Pyr sub-basin. Over the continental region, INT improves the correlation compared to SW (from 0.78 to 0.80) while reducing by 17% the RMSD. Therefore, the interpolation process between the

sub-basins (see the spatialization in Section 3.3.4) does not degrade the solution inside the sub-basins, while the extrapolation outside of them allows to improve the un-constrained SW statistics over the whole continent. This is a true benefit since INT presents comparable performances to SW+PF in terms of closure capability and closeness to *in situ* measurements, with the advantage of the spatial variability at the pixel scale.

- 5 Finally, the CAL precipitation product shows results as good as SW (slightly better for the whole continental region) for the CORR, and smaller RMSD with EOBS. The CAL product does not close as well the WC budget as the INT solution, but it has the advantage of being available over a longer time-record (1980-2012) compared to the 2004-2009 INT period.

*Sea Water Level change* - The Seawater storage (related to the Sea water level) change over the Mediterranean Sea (excluding  
10 the Black Sea) is tested using altimetry and thermal datasets over the 2004-2009 period. First, the thermal content estimates of the four datasets presented in Section 2.2 are merged into one single estimate. The merge thermal content estimate is then subtracted from the AVISO Altimetry Sea water level. The monthly change is then computed using the same derivative filter as the one used for GRACE:[5/24 3/8 -3/8 -5/24].

Fig. 3 shows the altimetry estimate and the various methodologies estimates. Since the Mediterranean Sea is considered  
15 without the Black Sea for this evaluation, there is no SW+PF estimate (that added the Mediterranean Sea and the Black Sea). While the SW solution has a 0.52 CORR and a 12.2 mm/month RMSD with respect to Altimetry estimate, INT statistic are 0.58 for the CORR and 11.8 mm/month for the RMSD and CAL 0.56 for the CORR and 11.8 mm/month for the RMSD. Here again, the INT estimate outperforms the unconstrained SW methodology in both CORR and RMSD. CAL presents also better results than SW but the CORR with altimetry is slightly reduced compared to INT. **No inter/extrapolation have been used in**  
20 **INT for the "Mediterranean Sea plus the Black Sea" sub-basin and the improvement of INT versus SW is due only to the impact of the closure constraint. Nevertheless, the SW+PF approach closes the water cycle over the Mediterranean within the Black Sea (no information about the Bosphorus netflow) and the spatial downscaling in INT is needed to discriminate the closure correction above the two seas.** Using the closure of WC over the Mediterranean and Black Seas improves the water storage change estimates.

### 25 4.3 Evaluation at the pixel scale

The INT and CAL estimates are here evaluated at the pixel scale, for precipitation and evapotranspiration. Improvements of SW by INT and CAL are measured using *in situ* measurements of precipitation and evapotranspiration from the FLUXnet database, available over the Mediterranean region, for the 2004-2009 period (section 2.2).

Fig. 4 presents the scatter-plots of the RMSD between the SW estimate ( $E_{sw}$ ) and INT or CAL ( $E_{cor}$  for "corrected")  
30 datasets with the FLUXnet evapotranspiration data ( $E_{FLUX}$ ), for each station. The 1:1 line is also shown in scatter-plots. This line characterizes the (un)improvement due to the closure: each dots under the 1:1 line represents an improvement at the corresponding station from SW solution to INT or/and CAL. INT and CAL improve evapotranspiration estimates for more than 53% of the sites. The distribution of the differences in the encapsulated figure is slightly narrowed by the INT and CAL compared to the SW solution. Location of the station where the closure improves the RMSD with the flux measurement

is shown in green if INT and CAL both improves the estimate, blue when only CAL improves, and magenta when only INT improves. Red dots represent station where there is a degradation in both INT and CAL. *The evaluation of EO estimate at 0.25° spatial resolution using tower sites should be taken with caution. The poor performance of satellite estimate over particularly complex topography (mountainous rainfall) or coastal pixels with land/sea contamination could explain the difference between the INT estimate and the FLUXNET measurement at this particular location.*

Fig. 5 presents the scatter-plots of the RMSD between the SW estimate ( $P_{sw}$ ) and INT or CAL ( $P_{cor}$  for "corrected") datasets with the FLUXnet precipitation data ( $P_{FLUX}$ ), for each station. Over most of the stations (82%), the INT and CAL solutions improve precipitation estimate compared to SW. Location of improved sites are shown with the same color code as in Fig. 4. It can be seen in Fig. 5 that red dots are located mainly in mountainous or coastal region. These two type of landscape are really challenging for precipitation estimate due to snow precipitation on one side and coastal Sea/land contamination on the other.

## 5 A coherent multi-component dataset for the water cycle monitoring

**In this section, the integrated datasets are used to deliver updated estimate of the Mediterranean WC budget. The impact of hydrological constraint (PF) as well as the INTegration (INT) and CALibration (CAL) processes on the spatial averaging of the water component estimates and the WC budget residuals, over the several Mediterranean sub-basins, is summarized on Figure A.1 in the Appendix.**

### 5.1 Analysis of the Mediterranean WC

The mean fluxes of the Mediterranean water cycle and associated variability, over the 2004-2009 period are depicted in Fig. 6. **The water cycle is analyzed over its natural sub-basin's boundaries.** The variability is computed as the standard deviation of the annual values over the period. These value have been computed over the respective terrestrial or oceanic sub-basins; considering all the drainage area in Europe (within Turkish) or in Africa (without considering the Nile river basin for which just its discharge is represented), Black Sea or Mediterranean Sea. The large font numbers are the estimates resulting from the INT methodology while the little font is for SW. The two values for the netflow estimate at Bosphorus strait are estimated as the deficit term of the water budget equation, computed over the Mediterranean and Black Seas independently. Using INT estimate (i.e. closure of the two Seas at once) the two values are in better agreement to each other than to the two SW estimate. In the following, only the INT values are described.

Fig. 6 shows the uneven water contribution between the European ( $316 \pm 57 \text{ km}^3 \text{ yr}^{-1}$  for the total discharge) and the African ( $83 \pm 30 \text{ km}^3 \text{ yr}^{-1}$  within the Nile discharge) drainage area to the Mediterranean Sea budget. Furthermore, it shows the role of the Black Sea in the global Mediterranean WC. Most of the European freshwater flows to the BLS ( $398 \pm 70 \text{ km}^3 \text{ yr}^{-1}$ ; it represents more than 50% of the European discharge), where the E-P balance allows for an equal contribution to the Mediterranean Sea budget though the Bosphorus Strait input. Considering the Nile discharge, the closure optimization increase a lot the discharge value (from  $19 \pm 6$  to  $76 \pm 30 \text{ km}^3 \text{ yr}^{-1}$ ). The new value is higher to what has been monitored by GRDC near

the delta (El Ekhasse) in the final reported period ( $59 \pm 30 \text{ km}^3 \text{ yr}^{-1}$ ). Recent discussions on the Nile discharge can be found in Jordà et al. (2017). Our new discharge estimate includes the groundwater discharge passing through the aquifers.

After closure optimization, the annual precipitation, evapotranspiration and moisture divergence over European drainage area are estimated to be:  $2,760 \pm 103$ ,  $2,151 \pm 102$  and  $-540 \pm 103 \text{ km}^3 \text{ yr}^{-1}$  respectively. Europe accumulates most of the moisture coming from the Mediterranean Sea ( $1,787 \pm 200 \text{ km}^3 \text{ yr}^{-1}$ ) while the Black Sea poorly evacuates its moisture towards land ( $91 \pm 60 \text{ km}^3 \text{ yr}^{-1}$ ). Over land the contribution of the African part to the global moisture divergence is small ( $87 \pm 14 \text{ km}^3 \text{ yr}^{-1}$  mainly due to the presence of the mountain Atlas). The two netflow estimates at Bosphorus Strait are very close, with a difference lower than its associated uncertainty in Fig. 6. Freshwater inputs at the two Mediterranean Straits (Bosphorus and Gibraltar) compensate the very large evaporation loss ( $3,372 \pm 88 \text{ km}^3 \text{ yr}^{-1}$ ) occurring in the Mediterranean Sea. This process represents more than twice the precipitation ( $1,499 \pm 102 \text{ km}^3 \text{ yr}^{-1}$ ).

Fig. 6 represents the whole water cycle over the region of interest with its main feature: the role of the Mediterranean Sea as the moisture and energy reservoir for the surrounding land; the poor contribution of the African coast in term of water resource, and the role of the Black Sea as the buffer process for the freshwater input. This quasi-triangular process emphasizes the hydrological link between the surrounding land and the two Seas.

15

## 5.2 Comparison of the Mediterranean fluxes estimates with literature

Table 6 summarizes the comparison of the various estimates of the water fluxes in the current analysis with what can be found in the literature. The various annual mean estimates are based on different time periods and comparison must be taken with caution since some variability is likely to be due to the change in hydrologic regime. Sanchez-Gomez et al. (2011) focused on the Mediterranean Sea heat and water budget using an ensemble of ERA-40-driven high resolution Regional Climate Models (RCMs) from the FP6-EU ENSEMBLE database. The atmospheric budget was not considered in Sanchez-Gomez et al. (2011) and no moisture divergence estimate was provided. For comparison purposes, we decided to select the RCM ensemble-mean estimate and two particular models: the Danish HIRHAM (Hesselbjerg Christensen and Meteorologisk Institut, 1996) and the Canadian CRCM (Plummer et al., 2006). These two models have been selected since their  $E - P$  estimates are the extremes of the RCMs ensemble. In Sanchez-Gomez et al. (2011), the netflow at Gibraltar was estimated as the deficit term of the WC:  $Gib = E - P - R - Bos$ .

Mariotti et al. (2002) analyzed the WC over the Mediterranean region in the context of the NAO teleconnection over the 1979-1993 period using two reanalyses (ERA-40 and NCEP-NCAR) for precipitation, evaporation and moisture divergence. They used the discharge data from the monitored rivers through the Mediterranean Hydrological Cycle Observing System (MED-HYCOS) and GRDC. Their estimate includes a total Mediterranean input of  $100 \text{ mm} \cdot \text{yr}^{-1}$  from MED-HYCOS and the Bosphorus input of  $75 \text{ mm} \cdot \text{yr}^{-1}$  from the literature (Lacombe and Tchernia 1972). Mariotti et al. (2002) estimated the netflow at Gibraltar as the balance of the Mediterranean water deficit using the equation  $Gib = Div - R - Bos$  coming from the oceanic and atmospheric budgets and the null assumptions about the storage change. Mariotti et al. (2002) used old versions of the reanalyses and some remarks have already been raised on the precipitation and evapotranspiration estimates for these versions.

Nevertheless, from our knowledge, Mariotti et al. (2002) was the last effort to estimate the WC over the Mediterranean considering the atmosphere.

Jordà et al. (2017) reviewed the state-of-the-art in the quantification of the various water component estimates. Their estimates presented in Table 6 are the best consensual values among the scientific community. They are based on several studies and take into account the results of Mariotti et al. (2002) and Sanchez-Gomez et al. (2011) for example. In particular, the mean Gibraltar netflow estimate from (Jordà et al., 2016) has been commented and new mean is provided in Jordà et al. (2017).

Table 6 also shows the results from Rodell et al. (2015) before and after their satellite data optimization based on a variational assimilation at the annual scale. The constraint of the fluxes over the Mediterranean Sea and the Black Sea were made independently (considering no netflow at Bosphorus strait). The Mediterranean Sea was closed with no exchange to the Atlantic at Gibraltar (no netflow). Rodell et al. (2015) provided no explicit discharge for the Mediterranean Sea but only for the Eurasian continent.

For the four mentioned articles, only the Mediterranean Sea without the black Sea is considered. No estimate from SW+PF methodology is provided in Table 6. Our integrated dataset is the only one to use direct observations for the netflow at Gibraltar and to compute the Bosphorus's via a WC budget. For all estimates, Table 6 presents the associated variability. While the variability of real product is computed as the standard deviation of annual values, the variability associated with the RCM mean is the inter-model spread (i.e. closer to an uncertainty estimate).

*Evaporation* - The RCM ensemble mean for the annual evaporation is  $1,254 \text{ mm.yr}^{-1}$  with an inter-model spread of  $164 \text{ mm.yr}^{-1}$ . Some RCM evaluated higher annual evaporation as HIRHAM that estimated  $1,377 \pm 55 \text{ mm.yr}^{-1}$ . On the contrary, Mariotti et al. (2002) found comparatively low evaporation with the reanalyses ( $1,113$  and  $934 \text{ mm yr}^{-1}$  with respect to NCEP and ERA). Rodell et al. (2015) estimated much higher evaporation and higher annual variability with an mean annual value of  $1,391 \pm 157 \text{ mm.yr}^{-1}$  using only OAFlux and  $1,420 \pm 109 \text{ mm.yr}^{-1}$  after optimization. Our unconstrained SW solution gives an annual value of  $1,300 \pm 34 \text{ mm.yr}^{-1}$  and our constrained INT product gives  $1,295 \pm 33 \text{ mm.yr}^{-1}$ . The CAL estimate is close to INT.

*Precipitation* - The RCM ensemble mean for the annual precipitation was  $442 \pm 84 \text{ mm yr}^{-1}$  which is quite close to the NCEP reanalyses value in Mariotti et al. (2002). Satellite estimates in both Rodell et al. (2015) and the current study indicate higher precipitation: from  $576$  to  $571 \text{ mm.yr}^{-1}$  in (Rodell et al., 2015) after optimization and from  $573$  to  $577 \text{ mm.yr}^{-1}$  in this work after the closure constraint. SW, INT and CAL products present similar precipitation estimates at the annual scale due to the quite low uncertainty associated with the precipitation during the optimization. Even if the spread among the RCMs was lower than for the evaporation, some RCMs as CRCM did compute even larger precipitation than what have been retrieved from satellites ( $606 \pm 80 \text{ mm.yr}^{-1}$ ). Sanchez-Gomez et al. (2011) had already noted that gauges-calibrated satellite datasets such as GPCP and TMPA tend to give higher precipitation values than what was simulated in the RCMs. Precipitation over the Sea is a sensitive variable and its validation is difficult due to the lack of buoys for *in situ* measurements. The ERA reanalyses

value in Mariotti et al. (2002) was low compared with the NCEP estimate.

*Evaporation minus Precipitation* - Sanchez-Gomez et al. (2011) focused on the  $E - P$  budget to assess the physic consistency in the RCM. They assumed that a model having a high evaporation tends to have a high precipitation. The average  $E - P$  budget among the RCM was  $812 \pm 180 \text{ mm.yr}^{-1}$  and the range was between  $952 \pm 80$  (HIRHAM model) and  $602 \pm 107 \text{ mm.yr}^{-1}$  (CRCM model). The inter-model spread was high for the  $E - P$  budget stressing the difficulties to provide realistic water budget evaluation. Rodell et al. (2015) found similar  $E - P$  budget but the associated variability was high too due to the uncertainty in evaporation. Our  $E - P$  estimates are respectively  $726 \pm 57$  and  $719 \pm 60 \text{ mm.yr}^{-1}$  before and after the closure constraint. These values are lower but still in the RCM ensemble range. They are closer to what Mariotti et al. (2002) found with NCEP re-analyses. Jordà et al. (2017) consider the net surface flux to be  $900 \pm 200 \text{ mm yr}^{-1}$  which is in good agreement with the CRCM model estimate. Rodell et al. (2015) found similar  $E - P$  budget but with far higher evaporation estimate which seemed quite unrealistic. Furthermore, their closure constraint tends to increase the evaporation value and then the  $E - P$  budget.

*Discharge* - Only the RCMs providing the runoff have been used to compute the annual value of  $R$  ( $124 \pm 46 \text{ mm.yr}^{-1}$ ) in Sanchez-Gomez et al. (2011). Mariotti et al. (2002) found comparable values for the discharge, considering only the monitored rivers. Rodell et al. (2015) did not include explicit discharge into the Mediterranean Sea since the closure was done at the global scale (Eurasian continent) and no value was provided for Mediterranean freshwater input. Our discharge estimate is increased from  $144 \pm 21$  in SW to  $155 \pm 15 \text{ mm.yr}^{-1}$  in INT after the optimization. This increase is mainly driven by the re-evaluation of the Nile discharge that present larger discharge ( $76 \text{ km}^3.\text{yr}^{-1}$ ) after closure. All these discharge estimates are lower than the value prescribed in Jordà et al. (2017) ( $200 \pm 10 \text{ mm.yr}^{-1}$ ).

*Black Sea discharge* - The RCM ensemble-mean value for the freshwater input through the Bosphorus strait was  $87 \pm 60 \text{ mm.yr}^{-1}$  stressing the high discrepancies among the RCMs. Rodell et al. (2015) closed independently the Mediterranean and the Black Sea, with no exchange between the two oceanic basins (i.e. the netflow equals to zero). In the current approach, the Black Sea discharge is computed as the deficit in the water budget for the Mediterranean Sea, in considering the netflow at Gibraltar (Gib) corrected from Jordà et al. (2016):  $Bos = E - P - R - Gib$ . The SW product presents unrealistic value for the Black Sea discharge ( $2.0 \pm 615 \text{ mm.yr}^{-1}$ ), this is mainly due to the high uncertainty associated to the netflow at Gibraltar. On the other hand, the closure constraint improves the Bosphorus netflow estimate which equals  $129 \pm 60 \text{ mm.yr}^{-1}$  with INT, after optimization. The value is close to the deficit of the Black Sea water budget (computed after optimization):  $132 \pm 60 \text{ mm.yr}^{-1}$  (not shown in Table 6) stressing the consistency between the two Seas water budget. The value is still higher than the estimate of  $75 \text{ mm.yr}^{-1}$  in Mariotti et al. (2002).

*Gibraltar netflow* - Rodell et al. (2015) considered no flow at Gibraltar when closing the Mediterranean WC and then provided no estimate for this variable. Both Sanchez-Gomez et al. (2011) and Mariotti et al. (2002) evaluated the netflow by closing the WC over the Mediterranean region but they used different assumptions and equations. The estimate in Sanchez-

Gomez et al. (2011) is based on the oceanic closure while it is based on both the oceanic and atmospheric closure in Mariotti et al. (2002). The RCM ensemble mean was  $540 \pm 150 \text{ mm.yr}^{-1}$  in Sanchez-Gomez et al. (2011), while Mariotti et al. (2002) found lower value with the reanalyses ( $493$  and  $370 \text{ mm.yr}^{-1}$  with NCEP and ERA). Jordà et al. (2017) give two values for the netflow at Gibraltar: one from direct observations but suffering from large uncertainties ( $850 \pm 400 \text{ mm.yr}^{-1}$ ), and the other as the deficit of the water budget ( $600 \pm 200 \text{ mm.yr}^{-1}$ ). The value in INT and CAL estimate are impacted by the closure constraint. The netflow estimate after optimization ( $428 \pm 124 \text{ mm.yr}^{-1}$ ) is lower than what can be found in Jordà et al. (2017) but in the range of the RCM water budget deficit.

*Moisture divergence* - No moisture divergence was provided by the RCMs in Sanchez-Gomez et al. (2011). Mariotti et al. (2002) found moisture divergence to be  $659 \text{ mm yr}^{-1}$  in NCEP and  $488 \text{ mm.yr}^{-1}$  in ERA. Rodell et al. (2015) estimated the divergence to be  $848 \pm 105 \text{ mm.yr}^{-1}$  after optimization. The difference between Rodell et al. (2015) or Mariotti et al. (2002) estimates and what is found in the current study is mainly driven by the discrepancy between the three reanalyses: Modern-Era Retrospective Analysis for Research and Applications (MERRA) used by Rodell et al. (2015), NCEP and ERA-40 in Mariotti et al. (2002), and ERA-I used in the current analysis. Recent works focusing on atmospheric reanalyses comparisons have demonstrated the ERA-I quality. Stopa and Cheung (2014) have stressed the ERA-I performances in the representation of long term wind variability, critical for the representation of moisture divergence. Brown and Kummerow (2013) have pointed out that satellite derived  $E - P$  (SeaFlux- GPCP) correlates well with ERA-Interim atmospheric moisture divergence. Trenberth et al. (2011) have assess the performance of ERA-I reanalysis for atmospheric moisture budgets consideration.

## 6 Conclusions

The main goal of this work was to build a multi-component dataset describing the water cycle by constraining the WC closure. Various methodologies have been presented and particular attention has been put on the INTegration method. This approach full-fills the previous stated objectives: being a pixel-wise dataset but in which the WC closure is controlled. INT is an integrated dataset that shows several benefits compared with previous studies. The INT product allows to reduce the RMS of the WC budget residual down to  $3.55 \text{ mm/month}$  over land and  $5.27 \text{ mm/month}$  in the atmosphere. These reductions represent an improvement of respectively  $78\%$  and  $80\%$  compared with the best un-constrained satellite combination dataset. The temporal coverage of INT is limited by the common coverage period 2004-2009 of all the satellite estimates used in this study (see Table B1).

The INT dataset has been evaluated at various scales. Even if the evaluation is a difficult task and the presented work is not exhaustive, our results show that the consideration of the WC closure allows to reduce differences with the *in situ* measurements. At the sub-basin scale, the overall precipitation is closer to the *in situ* gridded EOBS dataset after being constrained. The Sea Water Level estimate is also improved compared to the altimetry estimate. At the pixel scale, the INT estimate shows a better agreement with *in situ* tower measurements from the FLUXnet2015 database.

The WC has been analyzed in terms of long-term means over the 2004-2009 period and compared with previous literature. The INT methodology has improved estimates of the Mediterranean water components. The INT product provides more realistic values for both Bosphorus and Gibraltar netflows by constraining it with the satellite observations. Note that the estimate of the Bosphorus is mainly driven by the Gibraltar estimate and can then be improved as the Gibraltar netflow evaluation would  
5 become more accurate.

This study conducted on the Mediterranean Sea is innovative from previous work. The Mediterranean WC has already been well investigated by Mariotti et al. (2002) and Sanchez-Gomez et al. (2011) relying on models and reanalyses. At global scale, Rodell et al. (2015) close independently the Mediterranean and Black Seas using satellite observation while Sanchez-Gomez et al. (2011) close the Mediterranean Sea WC in estimating the Gibraltar netflow as the WC budget deficit. This study aims at  
10 providing a full description of the WC, based on fewer hypothesis. It is the first effort to close the WC, at the surface and in the atmosphere over the whole Mediterranean region, using satellite observations and *in situ* measurement for Gibraltar netflow.

**There are still large uncertainties on the WC components but the INT methodology appears to be a valuable approach, in particular to include coherency among these components. The current work has introduced also the CAL product which is a calibration of the satellite products that can be used to extrapolate in time the closure constraint.**  
15 **The CAL product is less efficient to close the WC but presents the advantage to have longer temporal coverage. Several improvements will be considered in the future: (1) more accurate *in situ* observations (e.g. Bosphorus netflow estimate or coastal discharges) should lead to improved estimates. (2) New WC inputs could be considered (e.g. ground water exchange or horizontal exchange at oceanic sub-basin scale) to better characterize the flux and stock terms in the WC. (3) The use of other source of EO estimates should be considered. For example, the evapotranspiration estimate based on  
20 the closure of the energy cycle (Su, 2002; Chen et al., 2013) could be tested. This dataset could be an opportunity to (4) close simultaneously the water and the energy cycles and should lead to a better estimate of the evapotranspiration over land that is of major importance for the Mediterranean. The multiple-components dataset INT shows promising aspect for forcing, calibrating or constraining regional models with a water conservation constraint. Some developments and evaluations are still required before the production of a Climate Data Record (Su et al., 2018) can be started. The two  
25 databases (INT and CAL) can however be obtained under request to the corresponding author or via the HyMeX data server (<http://mistrals.sedoo.fr/HyMeX/>).**

*Acknowledgements.* We would like to thank the ESA (European Space Agency) and its Support To Science Element program for funding the "Water Cycle Observation Multi-mission Strategy For Mediterranean region" project (ESRIN Contract No. 4000114770/15/I-SBO; wac-  
30 mosmed.estellus.fr). We are grateful for the E-OBS dataset from the EU-FP6 project ENSEMBLES (<http://ensembles-eu.metoffice.com>), and the data providers of the ECA&D project (<http://www.ecad.eu>). We would like to thank the WACMOS-Med partners for the interesting related discussions and Phillipe Drobinsky and Véronique Ducrocq for their support to WACMOS-Med and his role in the HYMEX project.

**Figure 1.** Region of interest. Sub-basins have been computed using a hydrological model (Wu et al., 2011), and rivers are from HydroShed (<http://www.hydrosheds.org/>). See text for the definition of the sub-basins.

**Figure 2.** Steps of the spatialisation of the budget closure for the INT solution, from the SW to the INT solutions: Precipitation (left) and evapotranspiration (right), for July 2008. Units are in mm/month.

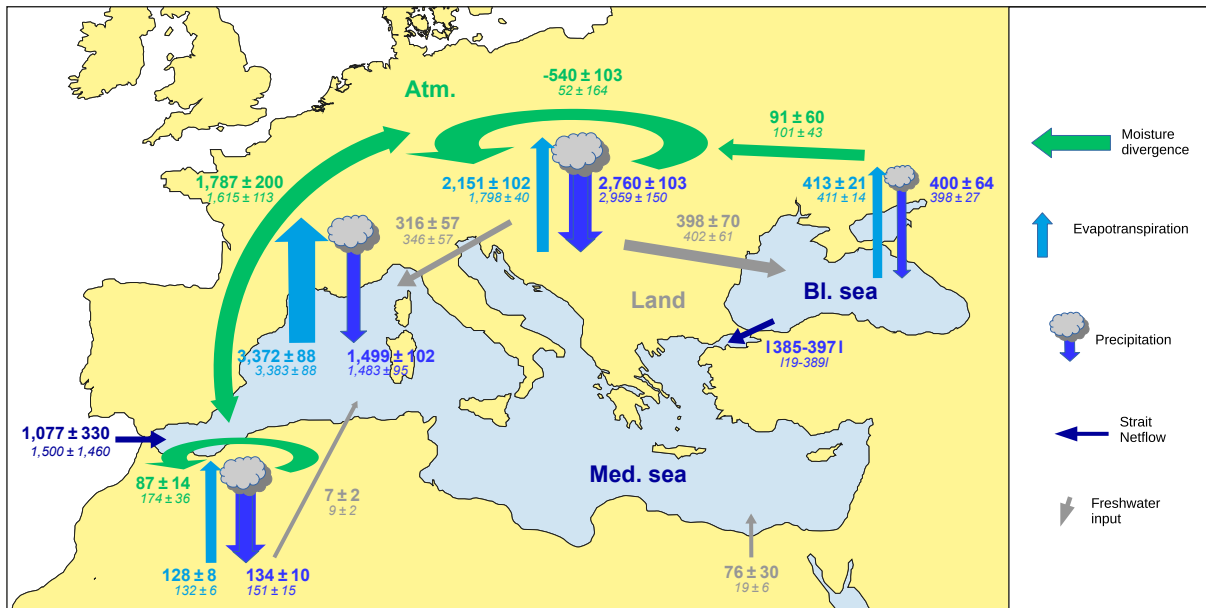

**Figure 3.** Sea water level evaluation of SW, INT and CAL estimates compared to altimetry minus thermal content. **The correlation difference is statistically significant at the 70%-level based on the T-test.**

**Figure 4.** Top panel: Scatterplot of the RMSD between FLUXnet station and the SW, INT and CAL products, for evapotranspiration. Dots under the 1:1 line (green) show improvement, and dots over the line (red) show degradation. **INT and CAL results are superposed for some locations, meaning that the linear approximation in CAL is enough to mimic the INT scaling factors at these location.** The encapsulated figure shows the distribution of the differences with the Fluxnet estimates. Bottom panel: **Location of the FLUXnet stations used for validation: green dots show an improvement for INT and CAL compared to SW (INT+& CAL+), blue dots show improvement only for CAL (INT-& CAL+), and magenta only for INT (INT+& CAL-). Red dots is where no improvement is observed (INT-& CAL-). Blue line limits the total basin area.**

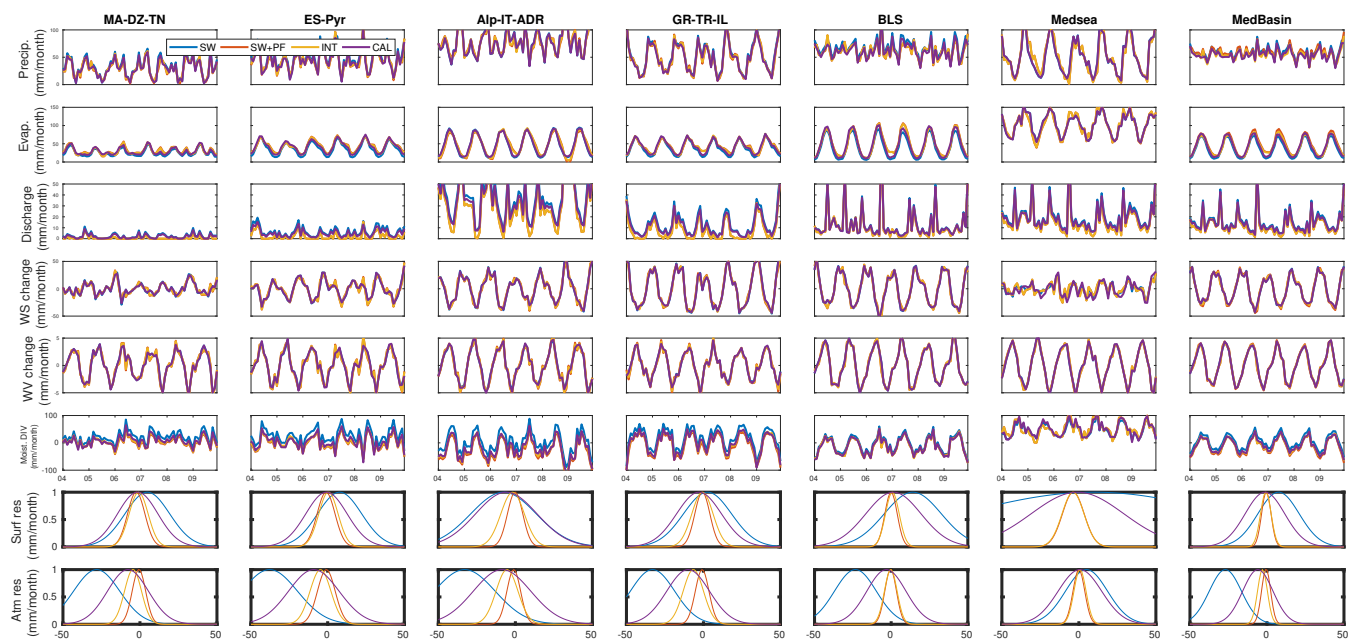

**Figure 5.** same as Fig. 4 but for precipitation.

**Figure 6.** Mean annual fluxes ( $\text{km}^3 \text{yr}^{-1}$ ) of the Mediterranean water cycle and associated uncertainties in SW (small font) and INT (large font) during the 2004-2009 period.

**Figure A1.** Comparison of the six water components estimates and the pdf of the two WC budget error (in row). The estimates are for the 6 terrestrial sub-basins, the oceanic part and the total land (in column) through the various methodologies presented in the study: SW, SW+PF, INT and CAL.

**Table 1.** The three main initiatives for budget closure constraint and their technical differences. [In the third column, bold font indicates the new features of the methodology presented in this article]. Subscript are:  $l$  for land,  $o$  for ocean, both include the atmosphere. All notations are summarized in Table A1. (1) Zhang et al. (2016) recently developed a WC-VIC assimilation scheme at the  $0.5^\circ$  pixel scale; (2) Rodell et al. (2015) used a two-step integration methods with annual closure simply downscaled at the monthly scale, plus a Lagrange interpolation for closure relaxation; (3) see Rodell et al. (2015) for details and hypothesizes.

	Zhang et al. (2017)	Sahoo et al. (2011)	Munier et al. (2014)	Rodell et al. (2015)	Our study
Area	Europe	Danube basin	Mississippi basin	Eurasia	Med. region
P	- 36%	- 47%	5 mm/month 37%	3 mm/month 24%	4 mm/month 25%
E	- 41%	- 32%	5.8 mm/month 49%	5 mm/month 65%	6 mm/month 55%
R	- 7%	- 3%	1 mm/month 1.5%	3 mm/month 11%	2 mm/month 6%
$\Delta S$	- 14%	- 18%	2.9 mm/month 12.5%	- -	3 mm/month 14%

**Table 2.** Comparison of the uncertainty specifications for terrestrial water components. The weights associated to a variable (computed as the ratio between the particular variable uncertainty with respect to the sum of all the uncertainties  $\sigma_i^2 / \sum_i \sigma^2$ ) are expressed in percentage.

	EO merging	Spatial resol.	Coverage period*	WC budget closure
OS	no	pixel	1993-2012	--
SW	yes	pixel	1980-2012	-
SW+PF	yes	basin scale	2004-2009	++
INT	yes	pixel	2004-2009	++
CAL	yes	pixel	1980-2012	+

**Table 3.** Main characteristics of the five merging methods in this study: EO stands for Earth Observation satellite datasets, and \* means not considering the GRACE period coverage. The last column shows the capability of the methodology to close the WC budget. '- -' means bad closure, '-' means quite bad closure, '+' means quite good closure and '+ +' means good closure.

**Table 6.** Comparison in the literature for the Mediterranean Sea (without the Black Sea) average annual mean fluxes and their associated variability (in  $\text{mm yr}^{-1}$ ). While the variability of real product is computed as the standard deviation of annual values, the uncertainty associated with the Regional Climate Models mean is the inter-model spread. The period of analysis for the various studies are recalled.

Mathematical symbols	
$M^t$	Transpose
$\Delta M$	Differenciation
$\frac{\delta M}{\delta t}$	Derivative
$N$	Normal distribution
$\sigma$	Standard deviation
RMS	Root Mean Square
RMSD	Root Mean Square of the Difference
Subscript	
$M_T$	Terrestrial
$M_l$	Over land (terrestrial plus atmospheric)
$M_l^i$	Over the $i^{th}$ sub-basin (terrestrial plus atmospheric)
$M_o$	Over ocean(oceanic plus atmospheric)
$M_{l_o}$	Global: land + ocean
$M_c$	Constrained
$M_{SW}$	Estimate through SW merging technique
$M_{PF}$	Estimate through SW+PF approach
$M_{INT}$	Estimate through INT approach
Water components	
$P$	Precipitation
$E$	Evapotranspiration
$S$	Water storage
$W$	Precipitable water
$Div$	Vertically integrated Moisture divergence
$Gib$	Gibraltar oceanic netflow
$Bos$	Bosporus oceanic netflow
WC State vector and associated uncertainty matrices	
$X_T, B_T$	Terrestrial state vector
$X_l$	Water cycle state vector over land (within the atmospheric aspect)
$X_l^{(i)}$	Water cycle state vector over the $i^{th}$ sub-basin (terrestrial plus atmospheric)
$X_o$	Water cycle state vector over Sea (within the atmospheric aspect)
$X_{l_o}, B_{l_o}$	Gobal water cycle state vector
$X_{l_o}^{Month}$	Gobal water cycle state vector for a particular month
$r, \Sigma$	Tolerated WC budget residuals
Closure matrices	
$G_T$	Terrestrial budget
$G_l$	WC closure over land (within the atmospheric closure)
$G_l^{(i)}$	Water cycle closure over the $i^{th}$ sub-basin (terrestrial plus atmospheric)
$G_o$	Water cycle closure over Sea (within the atmospheric aspect)
$G_{l_o}$	Gobal water cycle closure
$L_{l_o}$	Freshwater equality between land and Sea
$A_{land}$	Total drainage area of the Mediterranean Sea within the Black Sea
$A_l^{(i)}$	Drainage area of the $i^{th}$ sub-basin
$A_{Sea}$	Sea area
$L_{l_o}^{(i)}$	Freshwater equality between the $i^{th}$ sub-basin and Sea
$GA_{l_o}$	Global water cycle closure for all the month within the year
$N_{l_o}$	Modified version of $G_{l_o}$
$N_l^{(i)}$	Modified version of $G_l^{(i)}$
constraint filter	
$K_T$	Terrestrial constraint
$K_{merge}$	Merging matrix in SW methodology
$K_{PF}$	Global water cycle constraint via PF methodology
$K_{an}$	Theoretical analysis filter

**Table A1.** Notation used in this study

Dataset	Time coverage	Spatial res. (°)	Temporal res.	Description	Producer	Reference
<b>Precipitation</b>						
GPCP	1979-2015	2.5	daily	from multiple satellites and gauges	U. of Maryland	Adler et al. (2003)
CMORPH	1998-2015	0.25	30 min	from microwave and infrared	NOAA	Joyce et al. (2004)
TMPA	1998-2015	0.25	3h	from multiple satellites and gauges	NASA	Huffman et al. (2007)
PERSIANN	2000-2013	0.25	3h	from microwave and infrared	CHRS	Ashouri et al. (2015)
ERA-I Precipitation	1980-2015	0.25	12h	reanalysis	ECMWF	Dee et al. (2011)
EOBS Precipitation	1950-2006	0.25	daily	<i>in situ</i> gridded	project ENSEMBLES	Haylock et al. (2008)
FLUXnet precipitation	2002-2010	-	monthly	<i>in situ</i>	FLUXnet	Falge et al. (2017)
<b>Evapotranspiration</b>						
GLEAM	1980-2012	0.25	daily	satellite observation, gauges and reanalysis	U. of Amsterdam and U. of Ghent	Martens et al. (2016)
MOD16	2000-2012	0.25	8 days	satellite observation	NTSG	Mu et al. (2011)
NTSG	1983-2012	0.25	monthly	satellite observation and reanalysis	NSTG	Zhang et al. (2010)
ERA-I evapotranspiration	1980-2015	0.25	12h	reanalysis	ECMWF	Dee et al. (2011)
FLUXnet evapotranspiration	2002-2010	-	monthly	<i>in situ</i>	FLUXnet	Falge et al. (2017)
<b>Evaporation</b>						
Oaflux	1985-2015	1	daily	from satellite and reanalysis	WHOI	Sun et al. (2003)
Seaflux	1998-2015	0.25	3h	from satellite, reanalysis and <i>in situ</i>	GEWEX	Curry et al. (2004)
ERA-I Evaporation	1980-2015	0.25	6h	reanalysis	ECMWF	Dee et al. (2011)
<b>Water storage</b>						
CSR	2002-2012	0.25	monthly	GRACE	CSR	Bettadpur (2012)
GFZ	2002-2012	0.25	monthly	GRACE	GFZ	Dahle et al. (2013)
GRGS (land only)	2002-2012	0.25	monthly	GRACE	CNES	Biancale et al. (2005)
JPL	2002-2012	0.25	monthly	GRACE	JPL	Watkins and Yuan (2014)
MSC-JPL	2002-2015	0.25	monthly	GRACE	JPL	(Watkins et al., 2015)
<b>Precipitable water</b>						
Globalvapor	1996-2015	0.5	daily	merged estimates from satellite	DWD, GEWEX	Schneider et al. (2013)
ERA-I Water vapor	1979-2015	0.25	6h	reanalysis	ECMWF	Dee et al. (2011)
<b>Discharge</b>						
CEFREM	1980-2009	< 0.25	annual	<i>in situ</i>	Cefrem	Ludwig et al. (2009)
ORCHIDEE	1980-2009	0.5	monthly	model	LMD	Polcher et al. (1998)
<b>Moisture flux divergence</b>						
ERA-I Moisture divergence	1979-2015	0.25	6h	reanalysis	ECMWF	Dee et al. (2011)
<b>Gibraltar netflow</b>						
IMEDEA- netflow	2004-2010	-	monthly	<i>in situ</i> & model	IMEDEA	Jordà et al. (2016)

**Table B1.** Overview of the various datasets used in this study. Their common coverage period, on which the WC budget is estimated, is 2004-2009.
