Abstract. While groundwater recharge is one of the most prominently covered subjects in hydrogeology, the spatial distribution of recharge has been given relatively little attention, especially in semi-arid, karstic aquifers. Under conditions of highly diverse geology, relief, vegetation and land use, the complexity and variability of spatially distributed hydrological processes remains a challenge in many regions around the world. This is particularly true for hitherto ungauged basins, such as Wadi Natuf, a 103 km² large karstic Eastern Mediterranean watershed in the Palestinian upstream mountain and recharge area of the Western Aquifer Basin (WAB), which is shared with Israel in the coastal plain. In this first in a series of two papers, distributed recharge is estimated and represented, based on seven years of extensive field observations and measurements and based conceptually on observable physical landscape features such as geology, land use and land cover (LU/LC) and especially soil conditions. For the first time in the WAB, a forward calculated soil moisture and percolation model (SMSP) was set up with parameters, directly gained from field observations. The model was parameterized in a strictly parsimonious manner, as a one-dimensional model (aka ‘tank’ model, bucket or box model), based on dominant hydrological processes, in particular saturation excess in the soil column, and by identifying patterns of linkage between different landscape features. Average soil thickness was encountered at the range of decimetres, rarely above one metre. Both, soil thickness and LU/LC features, such as terraced olive groves or forests, grassland or barren rock outcrops were found to be highly formation-specific. This linkage allowed us to further simplify the model and its requirements in a realistic manner for eight soil moisture stations, chosen at six different geological formations with typical soil and LU/LC representations. The main result of the model was the determination of formation-specific recharge coefficients, spatially ranging between 0 % and almost 60 % of annual rainfall, or up to 300 mm/a in Wadi Natuf’s climate. The karstified main aquifers showed recharge coefficients (RC) above 40% and even the less prominent slightly aquitardal local aquifers reached RC-values above 30%. The model was separately tested on two conceptual levels – on the level of basin form (soil moisture) and basin response (signatures of peak recharge and local spring discharge events) under well controlled conditions in isolated sub-catchments. In principle, our approach is applicable in many of the scarcely gauged karstic groundwater basins around the world with a highly diverse landscape and geology.

Keywords. Distributed recharge, landscape features, basin signatures, soil moisture, reservoir model, parsimonious approach, PUB, recharge coefficients, saturation excess, deep percolation.

1 Introduction

35 Knowledge about distributed recharge is important for the exploration, sustainable management, protection and equitable allocation of water resources. Acquiring recharge information remains complex and challenging for hydrogeological research, especially in the many ungauged basins around the world and particularly in karstified aquifers, which supply

about one quarter of world population (Ford and Williams, 2007). One key issue of water negotiations in shared groundwater basins is the spatial distribution of water resources in the different zones, such as the recharge zones of an aquifer.

40 **1.1 Global and specific problems in distributed recharge assessment**

A general problem in recharge studies worldwide is that most basins remain poorly gauged or ungauged, particularly with respect to basin function, i.e. the description and drivers of hydrological processes that are usually variable, both spatially and temporally. Such lack of empirical and local knowledge from the field cannot readily be circumvented by ever more sophisticated modelling approaches and mathematical methods. A second general problem is encountered in karstified
45 aquifer formations with their non-Darcian, anisotropic flow fields, where data from the discharge area cannot be readily used to infer process or parameter information for the upstream recharge areas (Hartmann *et al.*, 2012a, 2012b; Dafny, 2009; Dafny *et al.*, 2010).

The study of groundwater recharge and its spatial variability in semi-arid to sub-humid karst regions can be approached
50 through three research venues – observations of surface water (where available), of the saturated and of the unsaturated zone (Scanlon *et al.*, 2002, 2006). In addition, Dörhöfer and Josopait (1997) subdivided the field into direct and indirect research approaches or methods, (Lerner *et al.*, 1990) – not to be confused with direct and indirect recharge (see also Bredekenkamp *et al.*, 1995; Simmers *et al.*, 1988; De Vries *et al.*, 2002). While direct approaches determine recharge governing parameters near the surface by observing runoff, interflow and soil moisture, indirect approaches model the basin behaviour balancing
55 integral measurements of discharge of springs or rivers at the catchment scale with abstraction rates and aquifer storage based on groundwater level measurements. In specific, for the Western Aquifer Basin (WAB, see section 1.3 below), such indirect approaches cannot be employed in the recharge area, where any groundwater access and thus observations in the saturated zone, like drilling monitoring boreholes, are prevented due to the political circumstances of a long standing water conflict and occupation. In addition, most WAB catchments carry no surface water, except for occasional storm runoff
60 events, particularly in the recharge zone, such as Wadi Natuf (Messerschmid *et al.*, 2018). The research is left only with direct approaches to determine deep percolation from the soil into the bedrock, which is equated with recharge in this study (see also: Schmidt, *et al.* 2014).

1.2 Dealing with spatial variability

Hartmann *et al.* (2013) emphasized the need to focus on process-based approaches; this is especially true for hydrological
65 predictions in ungauged basins (PUB). In the absence of field data describing the dominant hydrological processes and functioning of a basin, it was often recommended to make use of the more readily accessible and measurably physical basin form (Savenije, 2010) and then to differentiate landscape units according to a hydrologically meaningful landscape classification metric to translate form into function (subject to follow-up paper). For the link between physical features and basin response, Eder *et al.* (2003) and Hartmann *et al.* (2013) suggested the use of so-called hydrological system signatures
70 to describe emergent properties of a system – both, quantitatively or qualitatively – such as flow duration curves or spring hydrographs.

Most of the PUB literature, such as Sivakumar *et al.* (2013) and Hrachowitz *et al.* (2013), stressed the need for parsimony in hydrological modelling, especially under the presence of equifinality in calibrated parameters; see also Grayson and Blöschl
75 (2000); Woods (2002); Sivapalan *et al.* (2003b); McDonnell and Woods (2004); Sivakumar (2004, 2008); Wagener *et al.* (2007); Young and Ratto (2009) and Olden *et al.* (2012). Such parsimonious models stick to the description of simple local processes and the identification of a few but realistic and observable physical parameters and hydrological drivers governing these process (Franchini and Pacciani, 1991; Zomlot *et al.*, 2015). Sivapalan *et al.* (2003a) pointed out that despite the

80 heterogeneity of local parameters and processes the response at the catchment-scale is often characterized by surprising process simplicity. Hence a small number of field observations may describe the main characteristics of a process (Seibert and Beven, 2009), even in ungauged basins, and with short time series data only (Juston *et al.*, 2009; Seibert and Beven, 2009; Blume *et al.*, 2008; Nash, 1957; Dooge, 1959; Lambert, 1969).

85 So far, most studies have focused on runoff, rather than on recharge (Sivapalan *et al.*, 2003a; Batelaan and de Smedt, 2001; 2007), but with some notable exceptions: For example, Aish *et al.* (2010) determined recharge distribution in the Gaza Strip; however, here, local data on groundwater depth were available for the recharge zone. The bulk of recharge models worldwide have been using lumped or only partially distributed approaches, because they do not require detailed spatial information but transfer input into output by a set of equations on a basin-wide scale (Jeannin and Sauter, 1998; Hartmann *et al.*, 2013; Abusaada, 2011). This also applies to the Western Aquifer Basin (WAB).

90 1.3 Existing recharge studies in the Western Aquifer Basin (WAB)

The Western Aquifer Basin (WAB or Aujah-Tamaseeh in Arabic and Yarkon-Tanninim in Hebrew) is the largest, freshest and most productive groundwater basin in all of Israel and the occupied Palestinian territories (oPt), also known as West Bank and Gaza Strip, spanning from the sub-humid Mt. Carmel in the North into the Sinai in the South and from the West Bank mountains to the Mediterranean Sea with an area of 14,148 km² (SUSMAQ, 2003; ESCWA-BGR, 2013), see Fig. 1. 95 The WAB is a classical transboundary water basin, subject to negotiations over equitable allocations under international water law (UN-GA, 1997). The intensive use of the basin dates back to the early 1960s starting with deep well drilling in the Coastal Plain and in the adjacent foothills area. The basin rapidly became one of the single-largest sources of Israeli water supply, which also has the potential to become one of the largest future sources of Palestinian supply in the West Bank. On the other hand, the WAB's recharge and accumulation areas, which are located in the mountains, slopes and foothills of the 100 West Bank, remain relatively untouched, ungauged and unexplored, due in large part to the continued restrictions imposed on Palestinian water sector and infrastructure development (World Bank, 2009). Within this recharge zone lies Wadi Natuf, a 103 km² large surface watershed stretching from the crest of the West Bank Mountains, which is north of Ramallah, down to the Green Line (that separates Israel from the Palestinian West Bank) - see section 2.

105 Also in the Western Aquifer Basin (WAB) the preferred choice of most of the existing studies were fully lumped models. This was done primarily to avoid problems with spatial differentiation and over-parameterization (Goldschmidt and Jacobs, 1958, Guttman *et al.*, 1988; Guttman and Zukerman, 1995; Guttman, 2000; Berger, 1999; Abusaada, 2011; and Abusaada and Sauter, 2017). Some researchers created partially distributed models. Sheffer, 2009 and Sheffer *et al.* (2010) for example applied a distributed basin-wide recharge model to the WAB, which however only distinguished coarsely between two units 110 – permeable carbonatic formations and less permeable, chalky or marly rock outcrop. In addition, crucial model parameters, such as soil characteristics were taken from the literature (Dingman, 1994), not gained from in-situ findings in the field (see also: Dvory *et al.*, 2016; Weiss and Gvirtzman, 2007 and Schmidt *et al.*, 2014). Truly spatially distributed and field-based approaches so far are restricted to studies on the local scale of less than 1 km² (Frumkin, 1994; Lange *et al.*, 2003; Arbel *et al.*, 2010; Lange *et al.*, 2010; Steinmann, 2010 and Grodek *et al.*, 2011). However these studies mainly focussed on runoff 115 rather than recharge. Sprinkler tests on a plot scale (10 m x 18 m) by Lange *et al.* (2003) pointed to the importance of soil saturation excess for surface runoff and recharge. Similar observations were published by Ries *et al.* (2015, 2017) in the neighbouring Eastern Aquifer Basin (EAB) that drains towards the Jordan Rift Valley and the Dead Sea.

120 The so-called “object-oriented” recharge model of the WAB by Hughes and Mansour (2005) and Hughes *et al.* (2008) separated runoff, spring flow, soil infiltration and deep percolation (recharge) into individually calculated compartments. At

first, each compartment had a high spatial resolution but then was lumped into an integrated basin-wide model. Moreover the entire model input was based on a priori estimated parameters, not local field knowledge, which has been found to often result in little consistency (Kapangaziwiri *et al.*, 2012). Such simplified, lumped water budget approaches of course contribute little to the understanding of the spatial variability of distributed recharge, particularly on a local scale, where the hydrostratigraphy is more complex (as explained in section 2). Abusaada (2011) in his three-dimensional integrated flow model of both, plains and slopes called for refined data input on land use, soil, geology and structural characteristics in the WAB (see also: Martinez-Santos and Andreu, 2010).

1.4 PUB paradox and recommendations

These findings point to the so-called PUB paradox, according to which data-rich catchments are needed to test methods for data-poor environments as Seibert and Beven (2009) noted. Their 'hydrologically intelligent choice', focused on the correct interpretation of the dominant process features and on keeping observations at the necessary minimum, for reasons of practicality (e.g. measurement costs and field accessibility). Such an intelligent design remains a learning process starting with insufficient data and adding data as required by the application (Binley and Beven, 2003; Seibert and Beven, 2009). In order to improve the conceptual realism, Pomeroy (2011) summarized three principle aims: to demonstrate the value of observations, to reduce the reliance on calibration and to enhance the capability to predict based on process understanding. In addition, Beven and Kirkby (1979) suggested a three way compromise between a) the advantages of model simplicity, b) the complex spatial variability of basin hydrological response and c) the economic limitations on field parameter measurements.

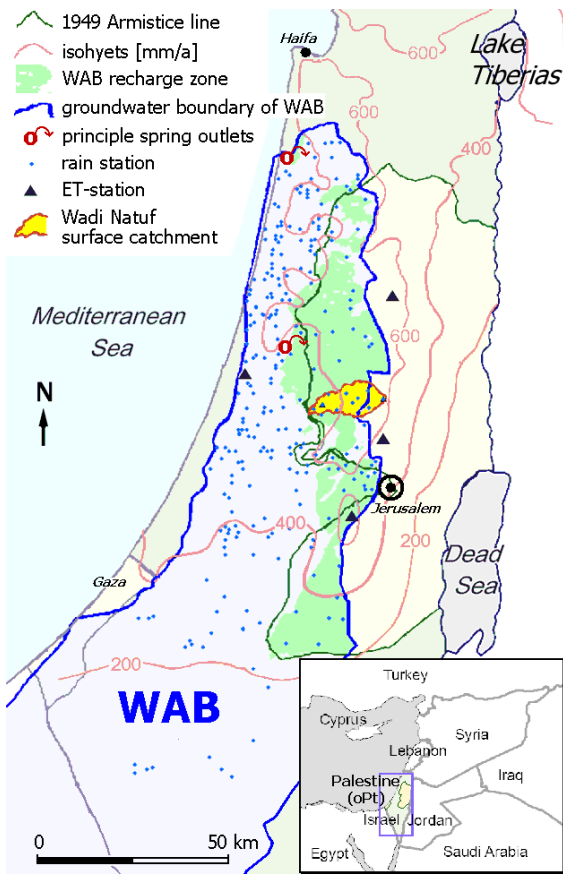

To summarize, firstly, only one of the three general venues to estimate recharge (Scanlon *et al.*, 2002) are applicable to Wadi Natuf – the saturated zone is inaccessible for field measurements and observations and surface water bodies are absent (see section 2). Secondly, the severe lack of primary empirical field data cannot be circumvented by ever more sophisticated advances in modelling. Therefore, thirdly, new surface- and process-based direct methods are called for that are firmly based in field observation and measurements of observable features and that find ways to conceptualize, describe, classify and measure the spatially variable and complex recharge processes, while simultaneously adhering to the goal of parsimony and avoiding exhaustive calibration associated with the problems of equifinality.

1.5 Aims, motivation and approach

The objective of this study is to investigate spatially distributed recharge in a largely ungauged karst aquifer catchment in order to develop formation-specific recharge coefficients (RC) in the central WAB for the first time. The process understanding and physical model parameters were based on specifically targeted measurements (McDonnell *et al.*, 2007) and firmly grounded on fundamental physical laws and theories, as well as local knowledge of the observable landscape and climate controls of hydrological processes as stressed by Sivapalan (2003) and Hrachowitz *et al.* (2013). A parsimonious soil/epikarst reservoir or "tank" model for laterally disconnected one-column elements (Schmidt *et al.*, 2014; Hrachowitz and Clark, 2017) was performed in daily steps and based on observable physical features and empirical field measurements for core parameters of the soil water budget – thus avoiding the need for retrofitting. The model was examined and tested in a novel combination of both, quantitative and semi-qualitative basin observations: On the one hand, at the level of basin form (physical soil parameters) the modelled soil moisture content was compared to the field measurements. On the other hand, on the level of basin response, the signatures of measured spring flow events (peak discharge periods) were compared to the modelled periods of deep percolation (DP). Finally, the model results of spatially distributed annual recharge coefficients were compared to literature results from former recharge studies in the WAB.

2 Study area

Wadi Natuf is a 103 km² catchment stretching from the mountain plateau at the crest of the West Bank at 816 m above sea level (asl) down to its foothills at 138 m asl (Fig. 1). In the Eastern mountain region, the topography is characterized by the rocky mountain crests and high plains with steep terraced slopes towards the Central Wadi Natuf further west. Here, in the midstream catchment, undulating hills with deeply incised ephemeral rivers (wadis) dominate, descending further down to the gentle slopes and plains in the lower Natuf region near the outlet of the main wadi bordering the Coastal plain. Within the Natuf catchment, all sub-aquifer formations of the WAB and some of the overlying cover series crop out (Fig. 2a, b) and are therefore exposed to direct infiltration. The climate is typically Eastern Mediterranean with precipitation occurring from November to April, monotonously rising from the semi-arid Western foothills (500 - 600 mm/a) to sub-humid conditions in the Eastern Mountains (above 600 mm/a). Wadi Natuf drains westwards towards the Mediterranean Sea and has a remarkably low overall runoff coefficient of approximately 0.11 %, mainly due to high percolation rates into the bedrock under shallow soils and due to considerable transmission losses (Messerschmid *et al.*, 2018) into the karstified carbonate materials underlying the wadis.

175 **Figure 1: Western Aquifer Basin (WAB) overview and Natuf location map.**

176 Wadi Natuf (in yellow) lies in the uphill recharge zone (shaded green) of the Western Aquifer groundwater basin, whereas the easternmost part of its surface catchment belongs to the (EAB) Basin. Isohyets indicate semi-arid to sub-humid climate in Wadi Natuf. The two former principle spring outlets of the WAB have all but dried up, due to excessive pumpage in Israel. Four evapotranspiration stations (ET) around Wadi Natuf were complemented by two automatic weather stations (AWS) in this study. Sources: modified after Sheffer *et al.* (2010), SUSMAQ (2001), Abusaada (2011) and ESCWA-BGR (2013).

180

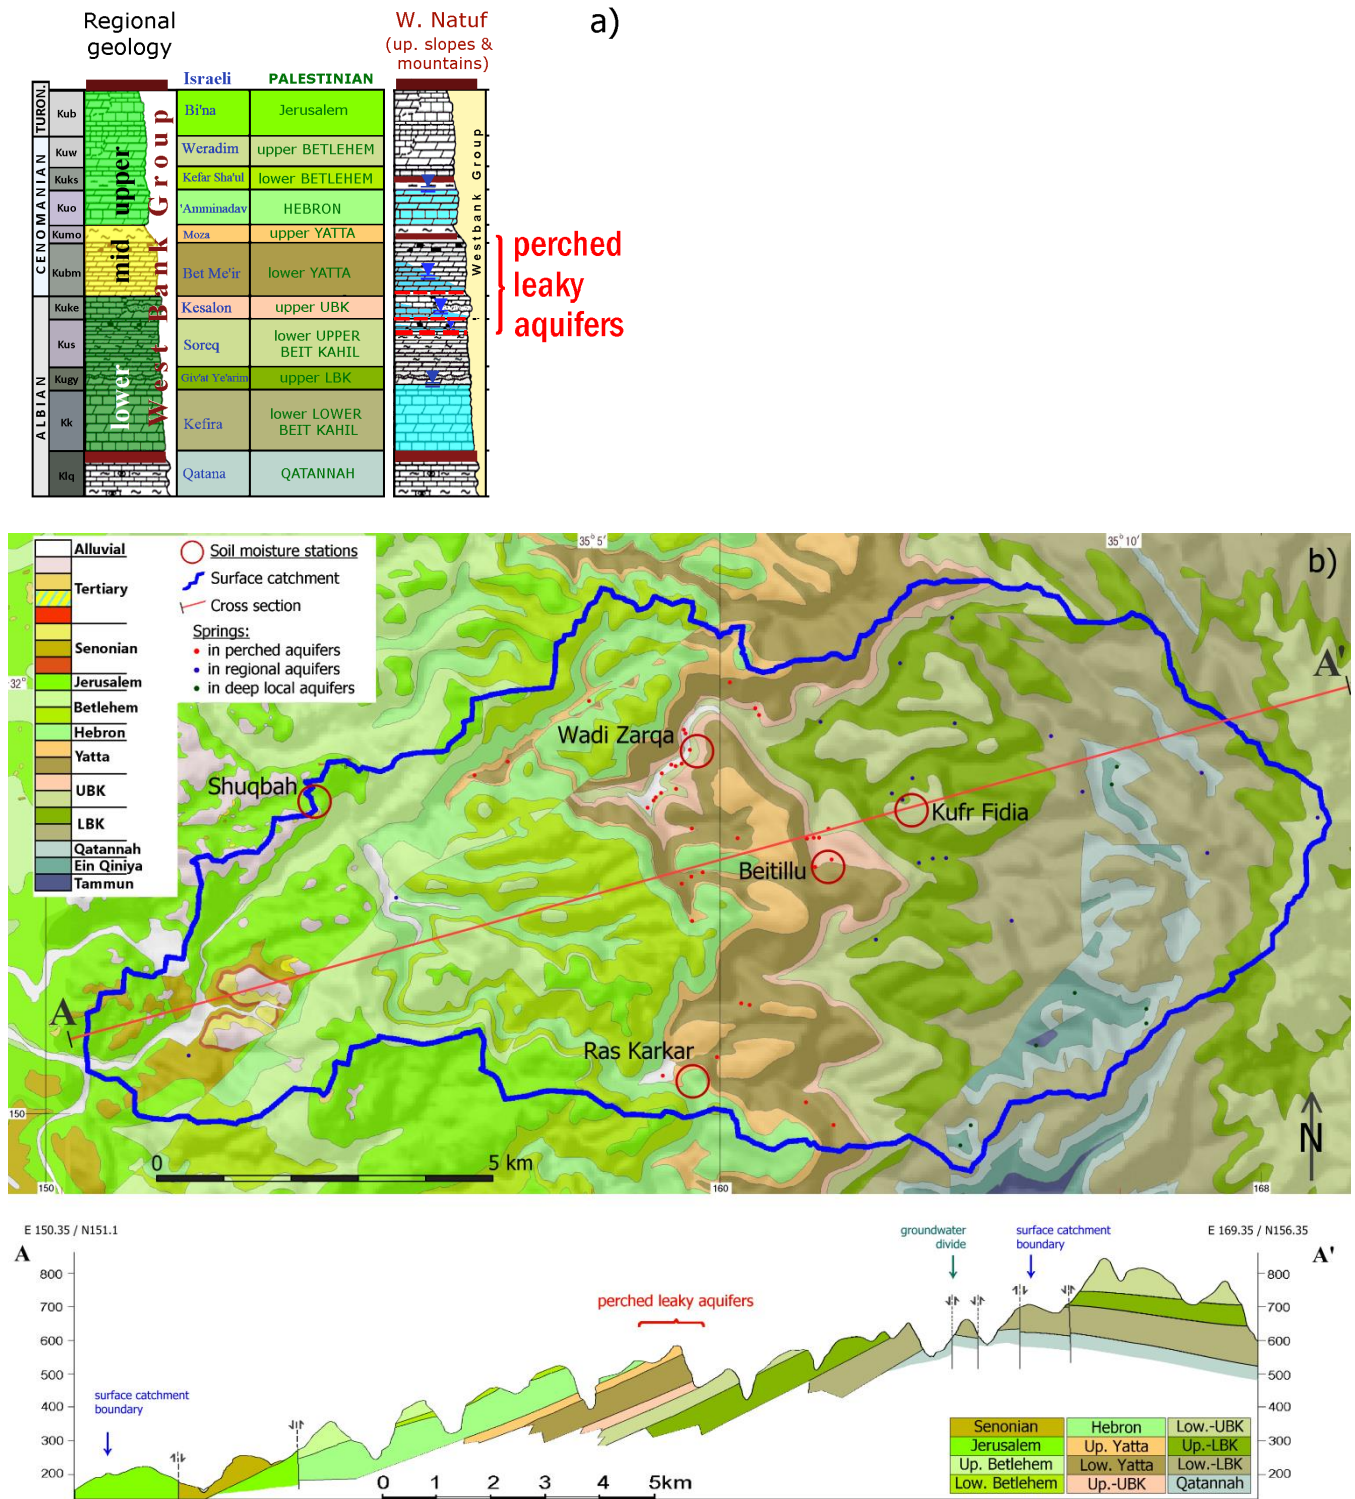

Figure 2: Stratigraphic column (2a) and geological relief map with cross section (2b).

2a: The stratigraphic column shows the regional hydrostratigraphy of the lower, middle and upper West Bank Group (in Israel: *Judea Group*) with only two aquifers (left side), such as the Lower Aquifer ('lower' group) and the Upper Aquifer ('upper' group), separated by the yellow 'mid' group (left side). On the local scale, they can be differentiated into several sub-units of aquifer and aquitardal series with three separate perched aquifers in the middle, e.g. the lower Yatta formation, upper UBK formation and the top of lower UBK formation (abbreviated to l-Yat, u-UBK & top of l-UBK). The middle columns show the Israeli and Palestinian formation names.

2b: The geological relief map indicates a selection of the many small local springs, mostly fed by the perched aquifers in central Wadi Natuf (red dots), partly also locally from within the regional aquifers (blue dots) or from the deep local aquifers (green dots). Red circles inside the map indicate the five areas of the eight soil moisture stations. The cross-section indicates the surface catchment of Wadi Natuf and, further to the west, the groundwater divide that separates the Western and Eastern Aquifer Basins at a stratigraphically low position where the Lower Aquifer is fully eroded and the deep aquifers crop out. Sources: stratigraphic column, modified after Dafny (2010); geological map, modified after GSI (2000 and 2008); cross section: this study.

Conventionally and on a regional scale, the WAB is subdivided into two main regional aquifer units of mostly karstified carbonates. The ‘Lower Aquifer’ is of Lower Albian age (ca. 113-106 million years) and the ‘Upper Aquifer’ of Upper Cenomanian to Turonian age (ca. 95-89 million years). Together they make up around two thirds (64.4 %) of the outcrops in Wadi Natuf (Fig. 2b). The remaining third of the catchment consists of aquitards from marl and chalk. According to this conventional view, the regional aquifers are divided by some 100 to 150 m thick marly, chalky and carbonatic series of the so-called ‘Middle Aquitard’ (Bartov *et al.*, 1981; SUSMAQ, 2002; ESCWA–BGR, 2013). However, closer scrutiny reveals that both, the regional aquifers can be further subdivided into more permeable and more impermeable sections (Fig. A3a, A3c). Also the regional ‘Middle Aquitard’ can be subdivided into an aquitard or even aquiclude section of yellow soft marl (upper Yatta formation or u-Yat) and a more carbonatic, partly karstified intermediate perched aquifer horizon (lower Yatta formation or l-Yat), see Fig. 2a (Messerschmid *et al.*, 2003a, 2003b). Lower Yatta is underlain by another perched aquifer (upper Upper Beit Kahil formation or u-UBK), which consists of a cliff-forming very permeable reefal limestone series (Fig. A3b). The third perched aquifer on a local scale is formed by the top of lower Upper Beit Kahil formation (l-UBK), a more chalky and marly limestone series that is underlain by an impermeable twin marl band (Fig. A3c). The three perched local aquifers can be found in central Wadi Natuf where they give rise to over 100 small local contact springs (Fetter, 1994), as shown in Fig. 2b. Together, their outcrops account for about 13 % of the catchment area. On a regional scale, the two perched aquifer series within Upper Beit Kahil formations are considered part of the Lower Aquifer. By contrast to the perched aquifers, most other parts of the regional Lower Aquifer as well as the entire Upper Aquifer within Wadi Natuf are void of springs.

The soil cover in Wadi Natuf consists of terra rossa, mostly with thicknesses in the decimetre range (Fig. A2, Appendix A). Although regional maps (Dan *et al.*, 1975) indicate small portions of rendzina in the central part (near Ras Karkar, Fig. 2b), no such types of soils were found during intensive field reconnaissance and measurement campaigns. The soils were found to have high silt and clay contents. In the dry season, the soils disintegrate into fist-size crumbs and form desiccation cracks. These cracks can act as preferential pathways for infiltration during the early half of the winter season (as also found by Gimbel, 2015). Soil thickness > 1m was only found at small agricultural plains overlying the aquitard series such as upper Yatta formation (u-Yat, see Fig. A1, Table 1).

An important and recurring observation during the field work was a pattern where soil thickness is associated to certain types of both, underlying bedrock lithology of formations and to the type of land use and land cover (LU/LC); carbonates show thin soils, while over argillaceous rock, thicker soil covers develop. Equally, soil cover over grassland and terraces were found thin, whereas agricultural cultivated fields and garden plots were located over thick soil stratum (see Fig. A2 and Table 1). In other words, typical land forms and soil depths can be identified for the different geological formations in Wadi Natuf, such as the perched aquifers (l-Yat, u-UBK and top l-UBK) and the Hebron (Heb) and Jerusalem formations (Jerus) of the Upper Cenomanian - Turonian main regional aquifer (‘Upper Aquifer’), see also Appendix D. This association of soil depths with other land features will be subject to a follow-up paper on regionalisation: Messerschmid *et al.*, (in preparation).

A prevailing feature in Wadi Natuf, as in most of the Mountain Aquifer (Schmidt *et al.*, 2013), was the finding of a thick unsaturated zone in the up to hundreds of metres thick karstified aquifers underlying thin soil cover; hence, all percolation from the soil into the underlying bedrock was considered as deep percolation.

3 Methodology

This study presents a distributed groundwater recharge model for a karst catchment based on extensive hydrological field measurements of three types, namely climatic drivers (like precipitation, radiation and temperature), hydrological processes

(such as soil moisture saturation and spring flow) and physical features (soil characteristics, geology and land use / land cover or LU/LC), as shown in Fig. 3. The forward-calculating model is parsimonious, i.e. based only on daily precipitation and evapotranspiration (as well as temporally stable location-specific soil parameters) in order to translate soil moisture saturation into deep percolation (DP), which here is equated with recharge (Schmidt *et al.*, 2014). The one-dimensional soil water balance model was designed as a soil tank with an upper boundary towards the atmosphere and a lower boundary towards the underlying karstified bedrock.

245

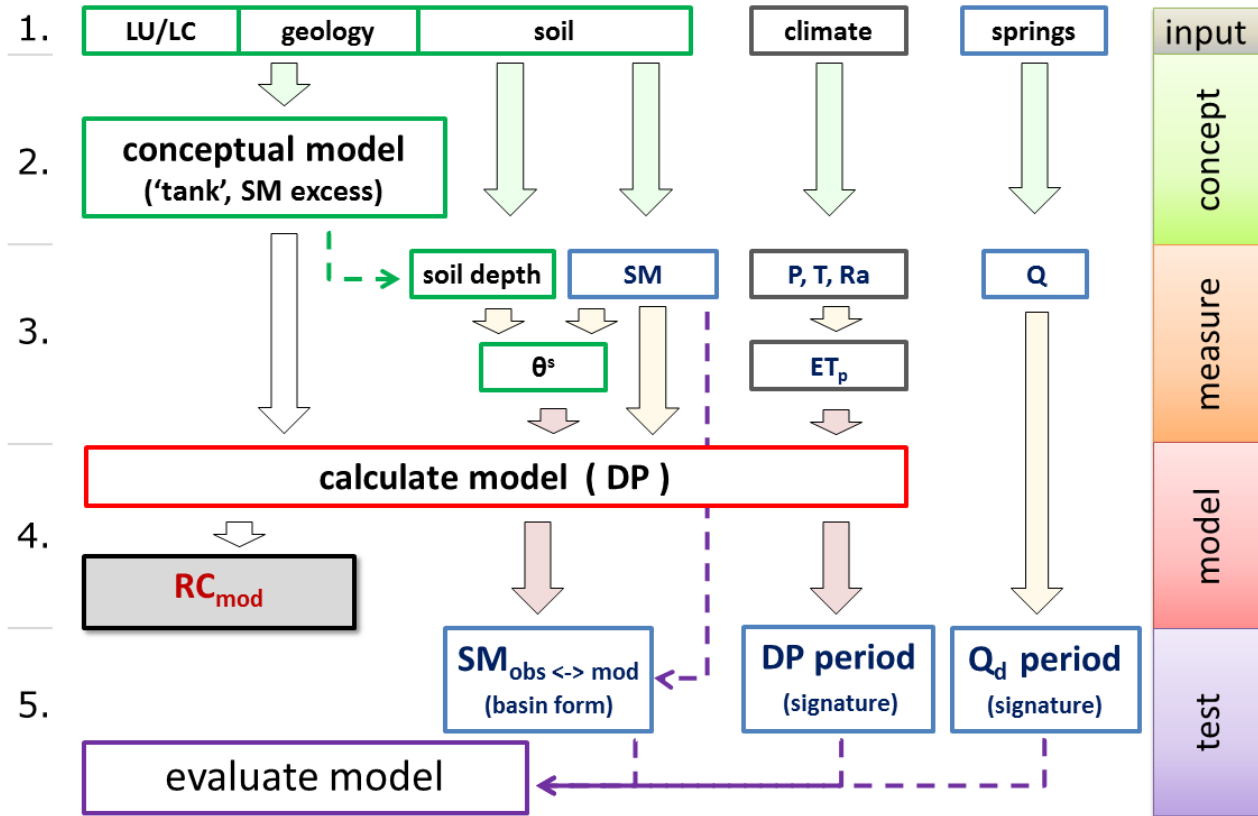

Figure 3: Conceptual flow chart of the work steps for the model. First row: measured and observed input such as climate, spring flow, land use and land cover (LU/LC), etc.; second row: conceptualisation of the one-reservoir ‘tank’ model; third row: actual measurements of daily values for soil moisture (SM), precipitation (P), temperature (T), solar radiation (Ra), spring flow (Q), etc.; fourth row: modelling deep percolation (DP) and transformation into annual recharge coefficients for each of the modelled formations (RC_{mod}); last row: model evaluation by different tests such as quantitative comparison between observed and modelled soil moisture contents (SM_{obs} and SM_{mod}), and semi-qualitative comparison between periods of percolation events (DP) and peak discharge at the daily measured springs (Q).

250

3.1 Climatic drivers – rainfall and evapotranspiration

255

The measurement period for precipitation and evaporation spanned over nine seasons, from 2003/04 until 2011/12. A complete set of weighted area rainfall data for the five sub-catchments (Fig. 4) was obtained from Messerschmid *et al.* (2018), originally measured in five minute steps at ten stations distributed evenly in upper, central and lower Wadi Natuf. The automated rain gauges (tipping buckets) with Eijkelkamp loggers were run in event mode. The model in this study used the weighted area rainfall precipitation at the five sub-catchments in daily steps (see Table 2 and Fig. 4).

260

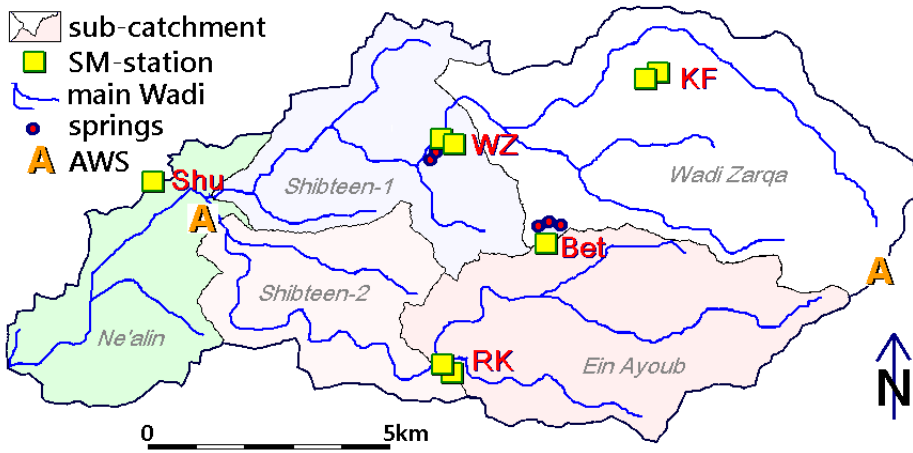

Figure 4: Drainage and measurement stations. Main branches of the northern and southern branches of Wadi Natuf: Soil moisture stations (SM) at Shuqbah (Shu), Wadi Zarqa (WZ), Beitillu (Bet), Kufri Fidiyah (KF) and Ras Karkar (RK); Daily measured springs at Beitillu and Wadi Zarqa; Automatic weather stations (AWS) in Shibteen (West) and Bir Zeit (East): Sub-catchments (in grey): Ne'alain (West), Shibteen-1 (midstream, North), Shibteen-2 (midstream, South), Ein Ayoub (South-East) and Wadi Zarqa (North-East).

Daily minimum and maximum temperature and solar radiation data were collected at two Automatic Weather Stations (AWS) for the calculation of potential evaporation (Fig. 4). The readings were taken with two Automatic Weather Stations (AWS) of the Type Campbell Scientific with a CR10X data logger and a HMP45D (Y3520067) Sensor. One station was installed upstream at Bir Zeit University at the mountain crest; the downstream station at Shibteen well No. 4, was located at the transition between the foothills and Coastal Plain to the West. Missing records were filled up with corrected temperature data from Jerusalem (IMS, 2017), which represented intermediate values between the relatively cool conditions in Bir Zeit and the relatively warm conditions downstream in Shibteen.

Potential evapotranspiration (ET_p) was calculated by the formula of Hargreaves *et al.* (1985). The Hargreaves approach was developed and applied for similar semi-arid conditions (e.g. Ryu *et al.*, 2008) and in comparable areas, such as the adjacent EAB (Schmidt *et al.*, 2014). ET_p is calculated by Equation (1):

$$ET_p = 0.0023 * Ra * (T_{mean} + 17.8) * (T_{max} - T_{min})^{0.5} * \lambda^{-1} \quad (1)$$

where Ra is the daily sum of extra-terrestrial solar radiation ($MJ d^{-1}$), T_{mean} is the daily mean air temperature (calculated as average of daily minimum and maximum temperature, in $^{\circ}C$), $T_{max} - T_{min}$ is the daily temperature range, and λ is the latent heat of vaporisation in order to obtain ET_p in units of $mm d^{-1}$.

3.2 Hydrological measurements – soil moisture and springs

Soil moisture content (SM) was monitored at eight different stations over a period of seven years (see Table 1). Due to budget limitations and reduced field accessibility (particularly during the height of the 2. Intifada), the measurements were kept at a minimum (as recommended by Beven, 2002 and by Seibert and Beven, 2009 – see sections 1.2, 1.4). It was therefore decided to increase the number of different SM -locations and to decrease the duration of measurement at each station (ranging between one and four years, see Table 1). All in all, 13 years of soil moisture measurements were carried out at the eight locations. The locations were chosen at places with minimum slope and without lateral water input from upslope overland runoff.

Target of the soil moisture (SM) measurements were daily time series data of overall available water content (θ). SM was measured at different depths by each sensor and then normalised to total water content of the respective soil column. Initially

two sets of frequency domain reflectometry soil moisture sensors (ML2-Theta probes, Delta-T Devices Ltd.) were used. Due to malfunction and vandalism they were replaced by two ECH2O loggers (EM50, Decagon Devices Inc.), each connected to two or three sensors (5TM, Decagon Devices, Inc.) that measured volumetric water content (%) based on the difference of dielectric permittivity between water and soil matrix. The loggers recorded in 30-minute intervals. The readings were averaged into daily values for the purpose of the model. The sensor installation depth varied between a minimum of 5 cm and a maximum of 75 cm at the thickest soils (Table 1). Technical problems with the equipment are discussed in Appendix B (Tables B1-B3).

In order to better relate the spatially discrete SM-stations to the overall catchment area, soil samples (150-550 g) were collected randomly at different depths and different times; the absolute water content of the samples was determined by oven-weighing at Bir Zeit laboratory. These results also served in reconfirming and calibrating the sensor readings.

Each of the sensor readings of volumetric water content (%) from different soil depths was multiplied with the thickness of the individual soil sections (m) and then combined to an overall water content of the soil column (as mm water column within the soil). The continuous soil moisture hydrographs were then analysed separately for each location, resulting in a typical and annually returning minimum (SM_{min}) and maximum water content (SM_{max}) as temporally stable but spatially distributed parameters. The representativeness of each SM station was further confirmed by the many hand collected SM samples from the same formations but at other locations. The maximum soil water storage capacity or storage capacity at saturation (θ^s) was then calculated for each SM station and according to the Equation (2):

$$\theta^s = (((SM_{max, 1} - SM_{min, 1}) * b_1) + ((SM_{max, 2} - SM_{min, 2}) * b_2) + ((SM_{max, 3} - SM_{min, 3}) * b_3)) * b_{\Sigma} \quad (2)$$

whereby SM_{max} and SM_{min} were used as measured water content per soil segment volume (m^3/m^3), $SM_{max, 1}$ indicates the maximum water content at the first surface-near soil section and deeper sections are indicated by successive numbers (2 and 3), and where b indicates the soil thickness (m) of the respective soil sections (1, 2, 3) or the overall soil thickness (b_{Σ}). θ^s represents the normalised effective maximum storage content in m (or mm) of the whole soil column (see Sheffer, 2009 and Sheffer *et al.*, 2010). It should be noted that θ^s was derived directly from the field-measured values of SM_{max} and SM_{min} , the range of which indicates the maximum amounts of soil water available for evapotranspiration before percolation sets in, see also sections 3.4 (Fig. 5) and 5.1.

The sensor readings included brief periods of water storage beyond field capacity, such as water in desiccation cracks (especially in heavy storm events during the late autumn and early winter season); these peak levels can be noticed as brief overshoots of SM-readings (here indicated as SM_{peak}) above the otherwise stable levels of annually recurring SM_{max} . It should however be emphasized here that the model in its daily budgets fully accounts for these additional water amounts (see section 4.1 and Appendix B).

Daily spring flow measurements were used as a model check. This high resolution spring flow record, for the first time in the WAB Mountains, enabled the detection of signatures, i.e. the temporal patterns of low and peak discharge for comparison with simulated recharge by the SMSP-model. From the large number of over 100 springs discharging from the perched aquifers, five springs from two spring groups (Fig. 4) were selected that can be considered representative for the total spring group discharge, due to their position and proximity to the soil moisture stations. At these springs, daily flow measurements were carried out continuously by metering (by hand) throughout almost the entire period (spring data coverage, s. Appendix C, Table C1). Three of these springs belong to the so-called 'Beitillu spring group'; the two other springs to the 'Wadi Zarqa spring group' (near Wadi Zarqa SM station, see Fig. 2b, 4). Their representativeness is discussed in Appendix F.

3.3 Model parameterization (soil thickness)

The soils in Wadi Natuf were found to consist only of one prevailing soil type, terra rossa (see section 2); field investigations, sampling and granulometric lab tests showed that the soil was mostly silty-clayey, with some samples also showing higher clay contents (Messerschmid *et al.*, 2018). This allowed for an important simplification for the soil moisture saturation and percolation model (SMSP), to only account for one uniform soil type throughout the study area. By contrast, soil thickness (b) plays an important role as a quantifiable parameter in the SMSP-model. Therefore it was necessary to determine the typical soil thicknesses at the different geological formations and LU/LC-types and to ensure that the selected soil moisture measurement plots were representative for the typical conditions of a given formation. The spatial distribution of soil thickness (b) was established by digging up the soil down to the soil-rock interface. The soil thickness differed between sampling locations, which led to variable sampling depths down to the respective horizon, where in-situ lithology prevailed. The results of the soil depth survey are shown in a soil thickness matrix for different LU/LC-types and lithostratigraphic units (see also Appendix D, Table D1 and Table 1).

3.4 Parsimonious soil moisture saturation and percolation modelling – design and processes

The SMSP-model implies a classical soil moisture balance approach; soils dry up to minimum water content during summer and then accumulate and store water with successive rainfall during autumn and winter. SM content above SM_{min} is subject to direct evaporation and plant transpiration and has to be deducted in daily steps from the SM content accumulated successively by precipitation. When soil conditions reach saturation (full effective storage capacity θ^s), deep percolation (DP) into the bedrock is triggered, here equated with groundwater recharge (Fig. 5). ET_a is limited downwards by available water content (θ_i) and upwards by ET_p :

$$ET_{a_{i+1}} = \begin{cases} ET_{p_{i+1}} & \text{if } (\theta_i + P_{i+1}) \geq ET_{p_{i+1}} \\ \theta_i + P_{i+1} & \text{if } (\theta_i + P_{i+1}) < ET_{p_{i+1}} \end{cases} \quad (3)$$

where θ_i is available soil moisture (mm), P daily rainfall (mm), ET_a daily actual evapotranspiration (mm) and ET_p daily potential evapotranspiration (mm).

Figure 5: Parsimonious SMSP-model of 'one reservoir saturation excess' (modified after Sheffer *et al.*, 2010). Parameters and drivers (top) were field-measured for every station and model. The available water content, shown as θ (between SM_{max} and SM_{min}), is seasonally variable but location-specific. Discounting runoff, soil water removal is accounted for in two ways: As SM saturation (red line) increases (above SM_{min}), evapotranspiration (ET) is triggered first; when θ^s reaches SM_{max} , deep percolation (DP) is initiated. Precipitation (P) was measured, potential evapotranspiration calculated from weather station data and transformed into actual ET -values (section 3.2).

All additional rainfall infiltrating from the surface and beyond the daily evapotranspiration losses can either be added to the available water storage, or, when limits of θ^s are exceeded, considered to percolate into the bedrock and represent recharge:

$$DP_{i+1} = \begin{cases} 0 & \text{if } (\theta_i + P_{i+1} - ETa_{i+1}) \leq \theta_{max} \\ \theta_i + P_{i+1} - ETa_{i+1} - \theta_{max} & \text{if } (\theta_i + P_{i+1} - ETa_{i+1}) > \theta_{max} \end{cases} \quad (4)$$

$$\theta_{i+1} = \theta_i + P_{i+1} - ETa_{i+1} - DP_{i+1} \quad (5)$$

where θ_{max} is the effective maximum soil water storage and DP is daily deep percolation, i.e. groundwater recharges (mm).

365 The testing of the model was reached in two independent ways, by a quantitative comparison of modelled and observed SM values, and by a semi-qualitative comparison of recharge periods (DP events) with times of observed spring discharge peaks; in other words, one examination was made on the reliability of the model to produce the observed physical feature of SM and the other by using the hydrologic response signature of spring flow responding to recharge.

3.5 Annual and mean recharge coefficients

370 First, the annual DP-rates (mm/a) divided by annual station rainfall delivered annual recharge coefficients (RC, in %) for each modelled SM station. Secondly, DP-rates from the model for the different stations representing different formations (Table 1) were referred to the outcrop sizes of the respective formations in Wadi Natuf to obtain annual recharge amounts (R, in m³/a). Then, thirdly, at each station (or for each formation) the seven different annual RC-values were transformed into an average recharge coefficient (RC_{avg}). This simplified approach assumes that our seven-year rain observation period
 375 fairly represented the long-term averages and inter-annual distribution patterns of precipitation (see 3.1 and Appendix E). In order to verify the representativeness of our seven-year observation period for long-term conditions (>30years) and since no long-term precipitation record for Wadi Natuf was available, the temporal precipitation patterns were compared on the level of the entire WAB and based on long-term records from HSI (2016). The comparison and its results are documented in Appendix E (Table E1 and Fig. E1).

380 4 Results

4.1 Seasonal soil moisture patterns

Table 1 presents the eight locations of soil measurements, used for the percolation models, with their respective bedrock formations and soil depths as well as the recurring maximum and minimum soil moisture levels, from which the maximum water storage capacity (θ^s) of each location was derived.

385

Table 1: Soil moisture measurement data by location (in mm and %).

land use	Shuqbah, grassland		Beitillu, gardens		Wadi Zarqa, fields		Kufr Fidiah, field		Ras Karkar, terraces	
Symbol	Shu	Bet	WZ-upT	WZ-gh	KF-W	KF-E	RK-W	RK-E	rocky & uncultivated	
Formation	Jerus	l-Yat	u-UBK		top	l-UBK			Heb	
soil depth (mm)	320	500	770	400	650	940	400	400		
sensor depth (mm)	110/190	110/110/430	420/660/750	170/360	130/180/390	50/75/175	50/140/320	100/200		
no. of yrs measured	1	1	1	1	2	1	4	2		
hydr. seasons measured	2003/4	2003/4	2005/6	2004/5	2005/6-06/7	2006/7	2005/6-08/9	2007/8-08/9		
SM_{max} (mm)	60	179	172	132	253	237	129	129		
SM_{min} (mm)	20	40	50.05	64.4	68.25	4.7	16.8	16.8		
SM_{min} (%)	10 %	8 %	6.5 %	16.1 %	10.5 %	0.5 %	4.2 %	4.2 %		
θ^s (mm)	40	139	121.5	67.5	185	232.5	112.5	112.5		
θ_{peak} (mm)	44	149	175	93	232	234	119	127		

θ_{peak} is a brief, episodically occurring available water storage above saturation storage capacity (θ^s); The soil moisture (SM) values SM_{max} and SM_{min} represent the highest and lowest recurring soil water contents measured in the field at different sensor depths (summed up in mm over the entire soil column or averaged in % as volumetric share of total soil volume).

The thin soils in Wadi Natuf showed a low water retention capacity (section 4.2, Fig. 6); in summer, soil usually dried up rapidly to an SM-content between 5 and 10 percent. Table 1 also shows two exceptions: In one case, the plot near the greenhouses in Wadi Zarqa (WZ-gh), some summer irrigation of crops cannot be excluded. However, it was assured that no irrigation took place during the crucial winter modelling period. In the second case, the extremely low moisture content (SM_{min} of 0.5%) at Kufr Fidiah (KF-E), was a result of vandalism (dug-up measurement pit with artificially reduced soil moisture at the then exposed deeper sections of the soil cover). In any case, such low soil moisture is not representative and the data of this station had to be taken with caution. In addition, the soil depth of almost one metre encountered at KF-E, an abandoned agricultural plot, overgrown with bushes, is a rare exception, and according to our soil depth survey not representative for usual conditions at the top of l-UBK formation (compare soil depth matrix, Appendix D, Table D1).

400

In contrast to minimum recorded SM-values, maximum moisture levels showed a more consistent pattern, which is important, because soil saturation is crucial for the SMSP-model. In line with our saturation excess model (section 3.4), it should be noted that once this maximum soil moisture level was reached, it remained stable for days and weeks and did not rise any further. Throughout the measured period and at almost all stations, it was found that maximum soil moisture is spatially highly variable and can be associated with the local soil depth, as apparent from Table 1 and discussed below. Another special case however is the occurrence of brief periods with extreme moisture (SM_{peak}) above saturation storage capacity (θ^s). They only occurred during extreme storms or during the early winter months, when desiccation cracks enabled preferential flow and rapid infiltration into deeper soil layers (see also Appendix B) and lasted usually less than one day.

410

Spatially, the distribution of seasonal soil saturation can be differentiated as follows: At locations with thinner soil cover, such as Ras Karkar (RK), Wadi Zarqa greenhouses (WZ-gh) and especially in Shuqbah (Shu), full saturation (θ^s) was usually reached by mid or late November. In the thicker soils, such as in Kufr Fidiah and Wadi Zarqa upper terrace (WZ-upT), saturation was usually reached later, by mid-December. In most years, full saturation conditions prevailed during January and February, on rare occasions until April. The season 2005/06 experienced the most intensive rain event of the entire measurement period and at the same time occurring very late in winter, between 1st and 5th April 2006 (Messerschmid *et al.*, 2018). Figure 6 gives an example for the time series of observed and modelled soil moisture (station RK-W). As can be seen, recharge (deep percolation, DP) only occurred when full saturation was reached and in form of relatively distinct events of a few days per year, depending on the high-resolution temporal rain distribution of a given season.

420

In each year the level of calculated soil moisture was the result of a unique set of different climatic drivers and of location-specific parameters and physical features (and thus a result of different overlapping processes). Yet, it could be observed that the levels of available soil moisture (i.e. the water content above SM_{min}), usually dropped to zero within one or two months after the last major rainfall event of a given season (effectively ending evapotranspiration during summer), see Fig. 6.

4.2 Quantitative examination of the model (by physical parameters)

425

Figure 6, which presents modelled and observed soil moisture contents, indicates the performance of the soil moisture percolation model. It should be stressed here that no calibration of the model was performed.

430

Some of the readings show a mismatch between observed and modelled SM values; these periods are indicated as dashed green line, where recorded soil moisture exceeded modelled SM-values. In some cases, recorded moisture levels even surpassed accumulated seasonal rain (which clearly hinted to equipment failure of the SM-sensors). Both issues are further discussed in section 5 and Appendix B. However, a comparison between observed and modelled soil moisture (Fig. 6)

showed a close performance, with an average Nash-Sutcliffe efficiency coefficient of 0.73 for all stations, except RK-E (which had a negative coefficient of -0.35 and was excluded from further analysis). In Shuqbah and Beitillu, NSE was found between 0.8 and 0.87, in Wadi Zarqa at 0.63, at KF-W and KF-E between 0.79 and 0.96 and at RK-W station at 0.7 (Appendix B, Table B3).

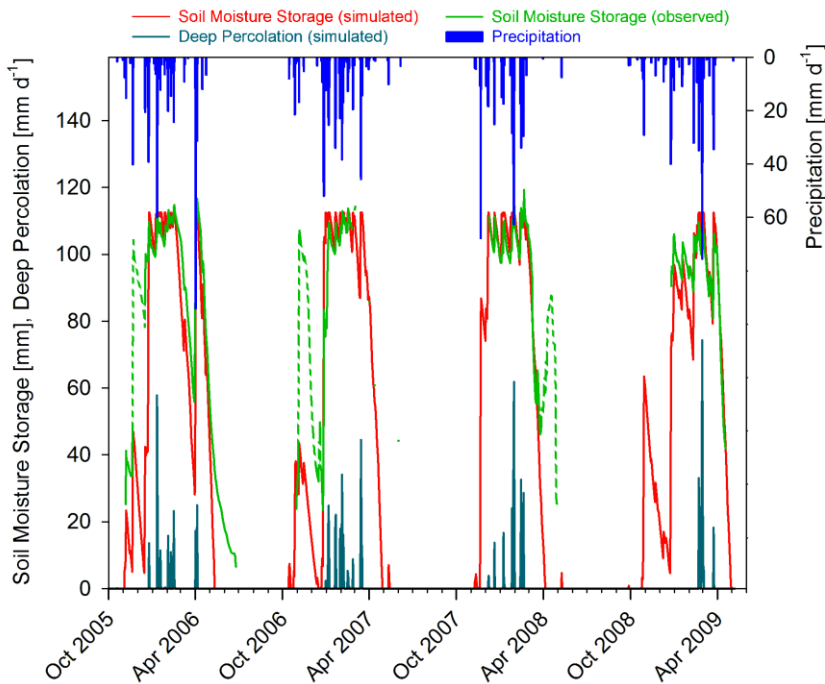

Figure 6: Comparison between observed and modelled available soil moisture at Ras Karkar West (RK-W), 2005/06-2008/09. Maximum water storage capacity (θ^s , at 112.5 mm) of the modelled moisture level (red) matched well with the observed maximum moisture (green). Brief periods of dashed green lines show questionable and erroneous soil moisture readings (see also section 5 and Appendix B). Deep percolation (DP, triggered above θ^s) is indicated as dark blue column (bottom of the graph), daily rainfall as blue columns (at the top).

4.3 Semi-qualitative examination of the model (by spring flow signatures)

For an additional check, we compared periods of deep percolation (DP) with the signature periods of peak spring discharge, as shown in Fig. 7. In most stations, recharge occurred during a period between 11 and 21 days per year. During very wet winters a maximum of up to 31 days per year (e.g. in WZ-gh); during very dry winters a minimum of only five days per year (e.g. KF-E) were recorded. Precipitation thresholds that triggered DP varied between different years and SM stations, e.g. from 74 mm of accumulated seasonal precipitation as a minimum (in Shu) to 470 mm as the highest threshold (in KF-E). For the different years, the gaps between average station thresholds ranged between 206 mm (in 2004/05) and 396 mm (in 2008/09), with a multi-annual mean of 290 mm.

Figure 7 shows a very close match of temporal patterns: Observed spring flow in the local perched aquifers responded with almost no delay, usually within one day after the first modelled recharge event. This demonstrates both, the karstic nature of the aquifers with rapid flow connections and the very local recharge conditions on the isolated hillsides.

The two most productive springs of the respective groups were Salem (Wadi Zarqa spring group) and Al-Qos (Beitillu spring group). Average spring flow was between 1.3 (Bibi) and 12.4 (Qos) m^3/d . The smallest spring (Bibi) had a maximum discharge of 9 m^3/d , the largest (Al-Qos) of 78 m^3/d . Both values were approximately six times larger than annual averages. Every slight rise of observed daily spring flow (by as low as 8 % of the amount of average discharge) was connected to simulated deep percolation or recharge (Fig. 7). Comparing the dates of peak spring flow with that of DP events, a complete

congruence of the respective dates was apparent. This analysis was performed for the period until September 2009, during which all springs had been measured reliably (see Appendix C, Table C1). All days with more than 1 m³/d of increase in discharge at Al-Qos spring were found to show simulated percolation; at Salem spring, the strongest spring in Wadi Zarqa spring group, this was true for all days with more than 0.7 m³/d rise and at Akkari spring for all days with an increase larger than 0.66 m³/d.

465

Figure 7: Signatures of peak spring flow and DP-events. Yellow shaded box: temporary pipe increase in spring discharge, caused by cleaning of the access pipe from plant roots at Al-Qos spring (July 2007). Daily measured spring flow at Beitillu spring group is shown in red, olive and green colours (bottom); at Wadi Zarqa group in blue and purple colours, daily deep percolation (DP) as grey columns (upper half) and precipitation as blue columns (top).

470

Finally, annual recharge coefficients were calculated and compared to literature values; see also Appendix H, Table H1. Table 2 shows annual DP-rates, annual recharge coefficients (RC) and the average of these annual RC-values (between 30% and 57%) for the entire period, according to the soil thickness at each station, ranging between 30 cm and 90 cm.

475

Table 2: Annual precipitation and recharge rates (DP), modelled at representative SM locations.

DP & P in (mm/a) year	Deep percolation (DP)								Precipitation (P)			
	Shuqbah	Bet	WZ-gh	WZ-upT	KF-W	KF-E	RK-W	RK-E	W	Centre	NE	SE

2008/09	258	180	251	197	165	<u>118</u>	204	204	594	570	561	528
2009/10	286	228	299	245	208	160	247	247	614	586	578	543
average DP	319	251	325	269	235	187	266	266	—	—	—	—
avg. P (*3/4-'9/10)	557	601	601	601	631	631	588	588	631	601	588	557
Soil depth (mm)	320	500	400	770	650	940	400	400	—	—	—	—
RC (DP _{avg} /P _{avg})	57 %	42 %	54 %	45 %	37 %	30 %	45 %	45 %	—	—	—	—

The table shows area precipitation of the respective sub-catchments of the SM stations (from Messerschmid *et al.*, 2018) as follows: West (W) uses average rain of Ne'alín and Shibteen-1 sub-catchments, Centre refers to the average between Shibteen-1 and Wadi Zarqa, North-East (NE) is the precipitation in Wadi Zarqa and South-East (SE) represents the average of Shibteen-2 and Ein Ayoub catchments, (Fig. 4). The daily rates of deep percolation (DP) were modelled with these area precipitation values. Minimum and maximum values of DP are underlined (WZ-gh in 2004/05; KF-E in 2008/09). All units are in mm/a, except for the soil depth (mm) and recharge coefficients (expressed as DP_{avg}/P_{avg}, in %).

480

4.4 Summary of model results on annual levels

485 The annual percolation rate did not only depend on the annual precipitation, but also on its seasonal distribution. For most years, a rise in annual recharge coincided with a rise in total annual rainfall, as shown in Fig. 8. The wettest winter (2004/05 with a rainfall of 742 mm/a) showed the highest recharge in each of the stations. However, the driest year (2007/08 with 496 mm/a) did not generate the lowest recharge, due to the seasonal distribution of very strong precipitation events that triggered high rates of percolation. This disconnection demonstrated the necessity to first calculate and model recharge in daily time steps in order to account for the event character of temporal rainfall distribution (Sheffer *et al.*, 2010, Cheng *et al.*, 2017), before these results can then be used for annual recharge calculations. It is also important to note the strictly reciprocal relationship between soil thicknesses and recharge coefficients. At all stations except for one (WZ-upT), the thinnest soils showed the highest recharge and the thickest soils the lowest recharge (see Fig. 8). This general pattern confirmed our conceptual approach that closely linked soil depth with recharge.

495

500 **Figure 8: Annual recharge coefficients, annual precipitation and soil depth (stations ordered by increasing RC).** The coloured lines present annual recharge coefficients by station (x-axis), increasing from left to right (in %). Average annual RC-values (red numbers) are reciprocal to the respective soil depths (as brown bars, with exception of WZ-upT as beige bar). The blue-shaded column at the right indicates annual precipitation - shown as P (Natuf) - as area average (in m/a).

500

Figure 8 plots different measurement stations with ascending soil depths on the x-axis against annual recharge rates on the y-axis with a marked and almost consistent linkage between the two (except for WZ-upT). This pattern of association forms the basis of our extrapolation and attribution approach for entire formations and their recharge coefficients (for the representativeness of the soil depths at our SM stations, see Appendix D, Table D1).

505

5 Discussion

5.1 General approach of process representation

Our results demonstrate that even in ungauged basins a realistic model of distributed groundwater recharge can be obtained through limited field observations of key parameters of the complex percolation process. Unlike previous studies in the WAB, direct and location-specific assessment of water storage capacity from long-term soil moisture readings was generated as robust and realistic ‘local knowledge’ to determine recharge, because the rate of modelled percolation (recharge) was a

510

direct function of SM storage, which was highly location-specific. Since distinct land forms of LU/LC and typical soil depths could be related to each geological formation (Table D1), the SM-plots and their RC-values were formation-specific. Existing literature often only provides values for permanent wilting points (pwp) and field capacities (Fc), which are similar but not identical with our measured maximum and minimum SM values. The θ^s -value is a direct measure of the mobile, available water inside the soil column, subject to accumulation, evapotranspiration, saturation and deep percolation (recharge). In reality, the processes of soil moisture accumulation, deficit and saturation are complex and depth-dependent. Indeed our sensors installed at different depths indicated slightly different temporal SM dynamics. Deeper soil segments reacted later in the season but arrived at a relatively stable maximum plateau value at about the same times as the shallower sensors, but on the other hand dried up at a slower pace in summer. This was in line with the generally known and expected dominant processes of accumulation, storage and loss through evaporation and transpiration from roots. It should be noted here that most of our soils were only about half a metre thick or less and that even the lowermost soil segments were within the reach of most plants (Mediterranean trees, bushes and shrubs), resulting in a low retention capacity. Our calculation method of adding up the measured water contents of all sections accounted for the different conditions and processes at varying soil depths and by this provided a simplified, yet realistic representation of total soil moisture throughout the soil column.

Adhering to the PUB-goal of parsimony, our SM saturation and percolation model only accounted for two climatic drivers (P & ET_p) and one spatially distributed physical parameter (θ^s), each set-up in daily time steps. The model is a simple one dimensional 'tank' or 'combined reservoir' model as already used by Sheffer *et al.* (2010) and Schmidt *et al.* (2014) – see Fig. 5. This parsimonious modelling approach is based on two conceptual but field-observed assumptions of dominant processes. Firstly, the model only accounts for direct recharge (as DP) from in-situ soil infiltration. Whereas, some local lateral water movement on and inside the soils and within the range of a few metres distance has to be expected, this nonetheless is conceptually included here under local processes and therefore quantitatively accounted for as direct recharge. This particularly applies to epikarst outcrops with soil pockets. Moreover, as discussed in section 2, no signs of indirect recharge processes were observed in the field (with the notable exception of transmission losses, discussed below). Ponding as a sign of lateral surface accumulation was restricted to small puddles of a few metres in diameter at maximum and within clearly discernible very small topographic depressions. Lange *et al.* (2003) in their runoff generation sprinkler and tracer tests close to Wadi Natuf also observed such near-surface runoff-runon processes and found them to occur in a radius of decimetres, at maximum metres (see also Ries *et al.*, 2015). This lead to surface runoff generation on hillslopes, which was largely lost by the aforementioned transmission losses through the gravel beds of the wadis. While this point and line infiltration along wadi beds could be considered as indirect recharge, previous studies by Messerschmid *et al.* (2018) had shown that overall runoff generation in Wadi Natuf was very low (< 1% of annual area precipitation). Hence, runoff, though important during single high intensity events (see also Ettinger, 1996), could be neglected as a significant part of the catchment's overall water budget, thus also adhering to the PUB goal of simplification and parsimony. Secondly, our model accounts for only one dominant recharge generation process – deep percolation from the soil into the bedrock under SM saturation excess. This is in line with the already discussed findings from other studies in the WAB and adjacent basins (Ries *et al.*, 2015, 2017; Sheffer, 2009; Messerschmid *et al.*, 2018; Lange *et al.*, 2003) that agreed that deep percolation or recharge, as much as surface runoff, must be described as a process of soil moisture saturation excess (see section 1.3). For further discussions on the applicability of soil moisture balance models in the WAB, see Hughes *et al.*, (2005 and 2008).

5.2 Spatial and temporal variability of precipitation and recharge

The main focus of our approach was the spatial differentiation of recharge, although our model also considered temporal patterns. Our annual recharge coefficients were based on a model, which was run in daily steps and therefore fully accounted

for the temporal distribution of rainfall, especially storm events. The model results of annual recharge coefficients suggested a relationship between spatial and temporal variability. When the standard deviations for annual recharge and annual precipitation were plotted against each other, we found that standard deviations for rainfall increased with annual rainfall (except for the year 2005/06), whereas spatial variability of recharge diminished (see Appendix G, Fig. G1).

Although seven years of modelling may not be enough to draw far-reaching conclusions, we can still conclude that the question of spatial variability of recharge deserves greater attention than given in most recharge studies, particularly in the Western Aquifer Basin. Within this study, average RC values were calculated from the individually calculated annual values (section 3.5). This somewhat extrapolative approach does not fully reflect the temporal variability and seasonal distribution of rainfall, which may lead to different recharge rates even in years with identical annual rainfall amounts. However, since our study focussed on spatial rather than temporal recharge variability, this inaccuracy seems justified and is in line with the PUB recommendations for simplification (Seibert and Beven, 2009). While our long-term average RC-values thus remain somewhat of an approximation, it can already be stated here that it appears likely that a true reflection of seasonal rainfall distribution would lead to a slight but not significant change in the overall average of multi-annual recharge coefficients.

5.3 Annual recharge coefficients – comparison with other studies

As observed by Lerner *et al.* (1990), recharge is a temporally highly variable process that is most adequately investigated on the event level (in WAB a time span of half a day to five days). While the model with its daily steps fully reflects the event character during the measurement period, generalisation of annual recharge coefficients always carries some range of uncertainty. However, as already presented, the individual recharge coefficients calculated for the different formations cropping out in Wadi Natuf ranged between a minimum of 0% (for non-recharging aquitards like upper Yatta formation) and a maximum of 57% for highly permeable and intensively karstified limestone aquifers such as Jerusalem formation (see Table 1). These overall recharge values fall well within the range, usually quoted for the WAB. Table H1 in Appendix H lists the regional and other reported recharge coefficients, both, for annual and event-based calculations and together with the methods applied therein.

6 Conclusions

This study provided formation-specific distributed recharge coefficients in a Mediterranean karst area with a highly variable lithostratigraphy from a one-dimensional soil water balance model, relating percolation to SM saturation excess (SMSP-model), applicable in comparable basins all over the world. The parsimonious forward-calculating model was restricted to key factors driving recharge with observed spatially distributed formation-specific maximum water storage capacities. The analysis was solidly grounded in intensive field measurements, and no calibration of model parameters was performed. The observed formation-specific correlation with soil depth and land form ensured the representativeness of maximum water storage capacity over each formation and for long-term conditions of wet and dry years.

The model was based on the observed key process understanding, namely that groundwater recharge can be simplified and described as soil saturation process in a variety of local conditions with a wide range of land features. Hereby, daily modelling steps were found appropriate to respond to the typically Mediterranean variability of meteorological events (storms) driving recharge. Equally, it was found that our seven years of observation covered the entire range and variability of long-term climatic conditions (30 year maxima and minima). The model was tested by a comparison between modelled and observed soil moisture and by a temporal overlay of peak spring discharge and deep percolation events.

A follow-up study will regionalise the here presented formation-specific recharge coefficients to all formations in the entire Natuf catchment (Messerschmid *et al.*, in preparation). The gained recharge coefficients can also be used for a basin-wide distributed recharge model of the entire WAB. The methodology presented here can be applied in many of the still ungauged groundwater basins worldwide.

Acknowledgements: The initial concept and design and the first two measurement seasons of this project were conducted by the Palestinian-British research and development project SUSMAQ, the Sustainable Use of West Bank and Gaza Aquifers, between the Palestinian Water Authority and University of Newcastle upon Tyne, funded by DFID. This work would not have been possible without the unselfish efforts and invaluable contributions by many, particularly the daily spring readings by Eng. Majdi Zaydah, Ahmad Bajes and Ahmad Falah. The authors would like to thank Sebastian Schmidt for his version of the spread sheet model and the ET_p input, as well as the reviewers and the editor Christian Siebert for their patience and their detailed and helpful comments. Gratitude is also owed to Ivonne Mansbach for many field trips and unwavering support throughout. This article is dedicated to Almut Hoffmann, my beloved partner who tragically was torn out of life in March 2015.

Appendix A

840 **Figure A1: Formation outcrops.** Rare outcrops of yellow marls, forming the main regional aquiclude (upper Yatta ftn.) near Ras Karkar (a), reefal limestone cliff at Wadi Zarqa (upper-UBK ftn.) with high primary porosity, development of karst and epikarst (b), karstic karren landscape (upper Betlehem ftn.), a relatively rare example of discontinuous soil cover (soil pockets) in Wadi Natuf (c).

845 **Figure A2: Soil cover.** Soil covering marly limestone (bottom Hebron/top Yatta ftn.), with some white caliche-type ‘Nari’ crust (a, b, c), Ras Karkar soil measurement station (RK-W, lower Hebron ftn.) on natural terraces of thin terra rossa soil (d).

850 **Figure A3. Lithostratigraphic formations:** Colourful, thinly plated limestone of lower Betlehem formation (l-Bet) with a more impermeable facies of fine marl intercalations (a) can act as a confining layer beneath upper Betlehem (u-Bet). Cliff-forming coral reef limestone of upper UBK formation (u-UBK) at Wadi Zarqa with high primary porosity but also signs of karstification; the inset photo shows a 1.5 cm thick remnant of coral branches (b). Twin band of soft yellow marls, located 2.5 km SE of Beitillu (c); it acts as confining layer beneath the local perched aquifer at the top of lower UBK formation (top l-UBK) and the main part of l-UBK beneath.

Some technical equipment and interpretation problems were encountered at three of the eight SM stations (RK-W, KF-W and WZ-upT), resulting in unreasonable measurement records or misreadings. ‘*Misreadings*’ here is understood as a general term for strong deviations between SM_{obs} and SM_{mod} or as unreasonable measurement values, either with alleged SM-contents above cumulative rain heights or apparent moisture increase during dry spells. The reasons for such deviations of SM_{obs} from SM_{mod} are manifold: first, the model could be inadequate, secondly, the interpretation of recorded field data could have been affected by additional factors, or thirdly, the measurement equipment could have malfunctioned. It seemed clear that at least when levels of SM_{obs} surpassed preceding seasonal precipitation, technical malfunctions occurred. This interpretation was strengthened by the following field observations: during summer and late autumn, before soil moisture slowly started to accumulate in the soil column, a lumpy to blocky, aggregate structure was encountered in the silty and clayey terra rossa soils, which had dried up and shrunk during summer. These soil aggregates then formed about fist-size lumps, separated by desiccation cracks. By this, preferential flow paths were formed along these cracks, which are known to enable increased rates of rapid infiltration and soil moisture accumulation, as observed by Gimbel (2015), further North in the West Bank. The temporary presence of free water within the desiccation cracks may have caused unrealistic moisture levels, if a sensor happened to cross such a crack. However, it is difficult to assess such a possibility in hindsight since the desiccation cracks are a transient soil pattern and their temporary position during measurements remained unknown. It is however important to note that such unreasonable SM-readings did not occur in winter during the recharge events, when the swelling soil had already closed the temporary desiccation cracks. In addition, hand collected soil samples during the peak rainy season with independent control readings in the laboratory confirmed the validity of field readings at the automatic SM gauges. In only one instance, unrealistic SM readings were also encountered during the end of the rainy season (April 2008) at station RK-W. Equipment failure is the most probable explanation here. However, this isolated late event happened long after the period of SM saturation and recharge and did not affect the results of the model calculations (Appendix B).

In addition to these conceptual interpretations, the overall reliability of SM readings was also assessed and analysed statistically. Table B1 lists the days with erroneous and questionable readings (together 147 days in four stations).

Table B1: Days with misreadings.

soil station	periods	no. of misread days	sum [days]
WZ-upT	31.10. - 5.11.2005	6	6
	9.11. - 20.11.2005	12	
KF-W	17.12. - 25.12.2005	+9	42
	29.10. - 13.11.2006	+16	
	18.11. - 22.11.2006	+5	
RK-W	6.11. - 15.11.2005	10	55
	22.11. - 25.12.2005	+24	
	4.11. - 24.11.2006	+21	
		sub-total	103
RK-W (Apr-2008)	17.3. - 29.4.2008	44	44
all stations		total sum	147

Table B2 compares the days with such “misreadings” to the total number of days measured and modelled, and indicates their respective shares.

Together, the 147 days of questionable measurement records in three stations represent 8.09% of all days recorded (147 days out of 1,818 days of total SM readings), and 0.72% of the total model period (20,456 days for the eight stations, over a seven-year period); these results are highlighted in bold font and marked grey within Table B2.

- 890
- In WZ-upT, only 6 days of failure occurred (Nov-2005), equivalent to 2.90% of recording days.
 - In KF-W, 42 days (or 14.95%) occurred over the entire read-out period.
 - In RK-W, 55 days occurred in early winter 2005 and 2006 (with $SM_{obs} > P_{cumulative}$), equivalent to 8.91% of recorded days, in addition to 44 days (7.13%) in April 2008 (together 16.05% failed readings).

895 **Table B2: periods and shares of days with misreadings.**

soil station	reference period	no. of days days misread	days misread in 7-year period (2,557 d) – [%]	misread days as share of recorded days – [days, (%)]
WZ-upT	w/o Apr-'08	6	0.23%	207 (2.90%)
KF-W	w/o Apr-'08	42	1.64%	281 (14.95%)
RK-W	w/o Apr-'08	55	2.15%	617 (8.91%)
RK-W	incl. Apr-'08	99	3.87%	617 (16.05%)*

soil station	reference period	no. of days with $SM > P$	days misread over total period of 7 years & 8 stations (20,456 d) – [%]	no. of all days read [-] and share of misread days [(%)]
all stations	incl. Apr-'08	147	0.72%	1818 (8.09%)
all stations	w/o Apr-'08	103	0.50%	1818 (5.67%)
RK-W	only Apr-'08	44	0.22%	617 (7.13%)

* Percentages rounded to the second digit after the comma

900 Table B3 presents the Nash-Sutcliffe efficiency coefficients for the eight SM stations. All stations (except one, RK-E) show NSE between 0.40 and 0.96. The one station with a bad match, RK-E (with an NSE of -0.35) was excluded from further calculations; its results were not used for the analysis of annual recharge coefficients (RC). As a result, we can state that such periods of malfunctioning soil moisture probes are extremely short and rare; therefore, modelled SM can be considered a valid representation of actual SM developments over time and for different spatial units. In addition, the quantities of additional soil water above the maximum storage capacity are fully accounted for by the daily budgets of the percolation model.

905 **Table B3: NSE statistics of SM_{obs} versus SM_{mod} .**

station	NSE
BET	0.87
Shu	0.80
WZ-upT	0.63
WZ-gh	0.40
KF-W	0.79
KF-E	0.96
RK-W	0.70
RK-E	-0.35
avg. all (w/o RK-E)	0.73
avg. all (incl. RK-E)	0.60

Appendix C

910

Table C1: Five spring data coverage.

Year	Abu Sa'efan	Bibi	Qos	Salem	'Akkari	∑ Coverage
2003/04	57 %	35 %	54 %	58 %	58 %	35–58 %
2004/05	2 %	2 %	2 %	2 %	2 %	2 %
2005/06	5 %	5 %	5 %	79 %	79 %	5 % & 79 %
2006/07	100 %	100 %	100 %	100 %	100 %	full
2007/08	100 %	100 %	100 %	100 %	100 %	full
2008/09	100 %	100 %	100 %	100 %	100 %	full
2009/10	42 %	42 %	42 %	68 %	68 %	42 % + 68 %

915

Daily spring readings were carried out by hand (with stop watch and bucket) and by different personnel in the respective spring groups. Beitillu spring group was fully covered for three years. In the first season (2003/04), measurements started late in the season, then were read most of the days in winter and scarcely in summer. In season 2009/10, continuous reading continued until February 2010. The two springs at Wadi Zarqa spring group (Salem & 'Akkari) had the same coverage as Beitillu group in 2003/04 and were almost uninterruptedly read from December 2005 (season 2005/06) until February 2010. Hence, high coverage was achieved during almost six seasons in Wadi Zarqa and during nearly five seasons in Beitillu.

920

Appendix D

Table D1: Soil depth matrix.

Hydrostratigraphy	Upper Aquifer	Yatta	Lower Aquifer
Geological formation	Heb., Bet., Jerus.	up UBK, Yatta	LBK, l-UBK
A) Terraces			
1. terraces with olives	<u>65, 40</u> cm	42, 25 cm	(49), 26 cm
2. terraces with other types cultivation	NA	(25)	NA
3. formerly used but now uncultivated terraces	NA	12, 47	46, 51, 22
4. natural terracing with shrubs and grass cover	<u>(26) 40</u>	10	22, 29
B) Plains			
1. arable plains with olive orchards	63, 67	94	26
2. arable plains with other types of cultivation	36	(56), 50, 65, 77	40
3. arable plains without cultivation	(58)	56	NA
4. rock plastered plains (karstification)	<u>32</u>	NA	(5), 15
5. dry plains with shrubs and grass cover	19	NA	19
C) Slopes			
1. non-terraced slopes with olives	NA	56	49
2. non-terraced slopes with other types of cultivation	58	<u>50</u>	NA
3. slopes with shrubs and grass cover	11, 26, 32	<u>40</u>	18
4. rock plastered slopes	<u>32</u>	NA	11
D) Pure rock cover and cliffs			

The soil thickness survey was carried out at representative locations of every outcropping formation, such as different types of vegetation, relief, land use and natural land cover. The table simplifies the results for an overview over different typical soil depths for the regional units of Upper and Lower Aquifers and the regional Middle Aquitard (with the individual formations indicated in line 2). Values that were also encountered at the SM stations are shown underlined. Main land form types are shown in the dashed boxes. The values for l-UBK formation are representative for the main body of the formation but not for the top of l-UBK (see second row, right column). Cells marked NA, represent untypical vegetation and land form types for the respective formations.

925

930

Appendix E

If the seven years covered in this study (2003/04-2009/10) are to be used for calculations of multi-annual averages, they must reflect the range of long-term climatic conditions in the basin. Since no long-term climatic records are available for Wadi Natuf, the representativeness of the seven years modelled was compared on the level of the entire WAB area. The Hydrological Service of Israel (HSI, 2016) presents records of annual area precipitation for six different sub-basins (cell groups) within the Western Aquifer Basin from North to South (Fig. E1). Wadi Natuf lies at the border between the Northern and Central cell group of the WAB and nearby the Jerusalem cell group and was found to be best represented by a mixture of the central, northern and Jerusalem cells of WAB.

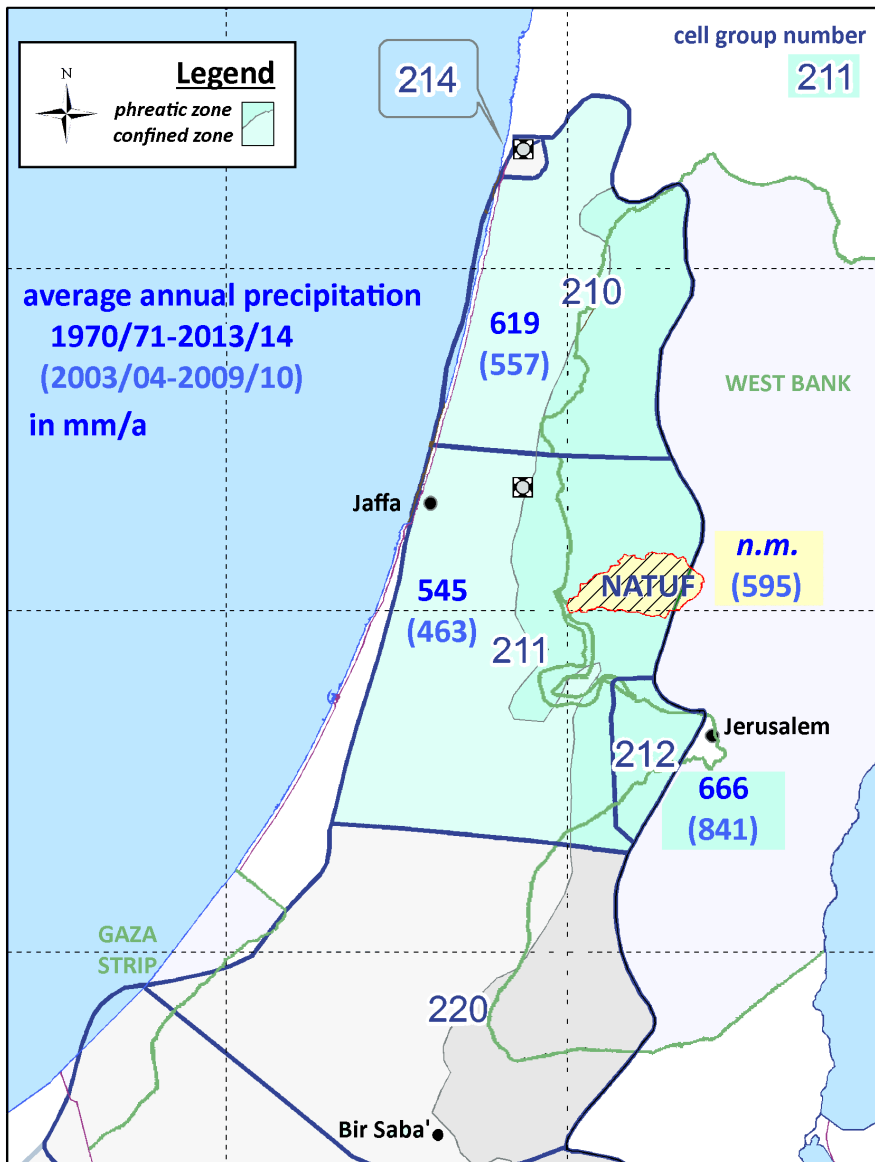

Figure E1: WAB cells of area precipitation (modified after: HSI, 2016). The map indicates area precipitation for two periods, long-term (1970/71-2013/14) and for the seven years of this study. Long-term area rainfall data for Wadi Natuf are not available; the seven-year period was measured by tipping buckets. Precipitation data for the three cells groups, no. 210, 211 and 212 were taken from HSI (2016).

The period of documented precipitation records spans 44 years from 1970/71 to 2013/14. Only two of these years were drier and only 12 years were wetter than the seven years studied here. Out of these 12 wet years, only five years (or 11% of the 44 years) were wetter than the maximum in the range of the seven years by more than 20%. And if we allow for a 10% margin of rainfall deviation, 82% of all 44 years (36 of 44 years) lie within the total range.

For each cell group (North – 210, Centre – 211 and Jerusalem – 212) the arithmetic mean precipitation was calculated over 44 years and over the seven year period, respectively. Then the average of the three mean values for each cell group was formed, for both, the entire and the 7-year period. These value were 610 mm/a for the entire 44 years and 621 mm/a for the seven years studied here. In other words, the seven years were slightly wetter than the average of all 44 years (for the spatial averages of three cell groups), but only by 1.7% (101.7% of 44-year average, marked underlined in Table E1).

When the same analysis was done for the median instead of the arithmetic mean, long-term conditions resulted in 600 mm/a, the seven-year period in 624 mm/a. The long-term and short-term median values were also compared in each cell group independently (their averages are indicated as underlined in Table E1). Table E1 shows the two different calculation methods and the end results of the analysis, together with the individual results for each cell group.

Table E1: Comparison of average rainfall in WAB cell groups, long-term and for the seven years 2003/04-2009/10.

cell item	type	period	# 210 North	# 211 Centre	# 212 Jerus.	avg. of all three cell groups	item
avg. of all years	long term	1970/71-2013/14	619	545	666	610	avg. of averages (all years)
average 7 years	7-year period	2003/04-2009/10	557	463	841	621	avg. of averages (7years)
ratio			90.0%	85.0%	126.3%	<u>101.7%</u>	<i>* ratio between averages</i>
median of all years	long term	1970/71-2013/14	597	504	698	600	avg. of medians (all years)
median of 7 years	7-year period	2003/04-2009/10	593	460	820	624	avg. of medians (7 years)
ratio			99.3%	91.3%	117.6%	<u>99.6%</u>	<i>* average of 3 groups</i>

* The above calculation uses the average between resulting means (610 mm and 621 mm per, respectively). The calculations below show the average of the ratios, formed in each cell group. WAB annual precipitation was based on data from the Hydrological Service (HSI, 2016). All rain heights are in mm/a, the ratios in percent.

Thus, it can be shown that the seven years of rainfall observation in Wadi Natuf cover almost the entire range of long-term annual rain distribution. Only one single year, the winter of 1991/92 with its century rainfall clearly lies outside the rainfall range covered by our measurement period.

Appendix F

When signatures of peak spring flow periods were compared with those of recharge (DP), it had to be assured that the discharge of the selected daily measured springs was representative for the entire spring groups draining the respective aquifers. This could be affirmed by the analysis shown below. In addition to the five springs that were daily measured, all springs in Wadi Natuf were measured during four key date campaigns. The tables below show that the ratios between the discharge at the combined daily measured springs and the entire spring group discharge were very stable; their relative shares deviated only slightly, as shown by the low standard deviation values in Table F1 and Table F2.

Table F1: Comparison of spring discharge (and standard deviation) between daily measured springs and entire Beitillu (Harat al-Wad) spring group during key date campaigns.

Spring flow (m ³ /d)	03 summer	03/04 winter	04 summer	07 summer	St. Dev.
Ein Abu Sa'efan	4.1	3.8	2.0	2.0	
Ein Al - Bibi	3.0	1.6	1.4	1.3	
Ein Al -Qos	12.4	16.7	9.6	13.2	
sum Beitillu spring group	98	110	61	73	
Relative share of group flow (%)					
Ein Abu Sa'efan	4%	3%	3%	3%	
Ein Al - Bibi	3%	1%	2%	2%	
Ein Al -Qos	13%	15%	16%	18%	
Sum (of 3 springs)	19.9%	20.2%	21.4%	22.4%	1.15%

At the four key date campaigns, total spring outflow at Beitillu spring group (Table F1) was lying between 61 and 110 m³/d. The three daily monitored springs combined made up 20-22% of total spring group flow with a standard deviation of 1.15%.

At the four key date campaigns, total spring outflow at Wadi Zarqa spring group (Table F2) was lying between 165 and 493 m³/d. The two daily monitored springs combined made up 6.8-8.5% of total spring group flow with a standard deviation of 0.72% (bottom right cell).

Table F2: Comparison of spring discharge (and standard deviation) between daily measured springs and entire Wadi Zarqa spring group during key date campaigns.

Spring flow (m ³ /d)	03 summer	03/04 winter	04 summer	07 summer	St. Dev.
Ein Al-'Akkari 1	13	17	14	7	
Ein Salem 1 (upper)	20	25	10	4	
sum Wadi Zarqa spring group	414	493	303	165	
Relative share of group flow (%)					
Ein Al-'Akkari 1	3.1%	3.5%	4.5%	4.3%	
Ein Salem 1 (upper)	4.8%	5.1%	3.2%	2.4%	
sum (of 2 springs)	7.8%	8.5%	7.7%	6.8%	0.72%

Appendix G

In most years, the variability of precipitation was reciprocal to the variability of recharge – in other words: the wetter the year, the higher the spatial variability of rainfall, but the lower the spatial variability of recharge. Variability here is expressed as the standard deviation (σ) for the values of the different stations. Although one year (2005/06) plotted far from the trend line, the otherwise quite pronounced pattern of the diagram shows that indeed spatial variability of recharge deserves more attention than given so far, since in the WAB, most studies focussed on temporal recharge variability. The trend is in line with general observations worldwide that basin responses in relatively dry climates are more variable than those in wet climates. A similar response pattern was observed for runoff in Messerschmid *et al.*, (2018), where strong precipitation events triggered runoff in all areas alike, whereas weaker rainfall events showed different responses in different areas.

Figure G1: Scaling - standard deviations (σ) of P & DP. Note: the linear trend line excludes the year 2005/06, which deviates from the trend of the other years. In this year, spatial variability of recharge was quite high but nonetheless, spatial variability of recharge was high as well. 2005/06 was a special year, because it had an exceptionally intensive storm event (and the strongest during the entire measurement period) very late in the season (early April 2006). The different stations were affected differently by the relatively long dry period before the event and the high precipitation during the event, depending on the soil thickness and therefore on the speed of drying up of the soils and consequent soil saturation during the event.

Appendix H

Recharge rates (in mm/a, or calculated as coefficients in %) have been reported in numerous studies within the WAB and adjacent basins of the Mountain Aquifer (such as the Eastern Aquifer Basin, EAB). Table H1 presents a collection of findings in the literature from both, the WAB as well as other regions of the world and from a large variety of different research methods (highly relevant studies marked in bold). The table shows that with an average area recharge coefficient between 41% and 47% (for the WAB portion of Wadi Natuf, see Messerschmid *et al.* (in preparation), and with RC-values between 30% and 57% for the individual aquiferous formations (not the aquitards), the findings of the model match very well with the ranges from the literature. While the lowest figures reported only 9-40% of RC, the highest figures reached over 50% and up to 60% of recharge coefficients (in Mt. Carmel basin with a very similar geology and climate as in Wadi Natuf). For a small groundwater catchment overlapping with Wadi Natuf surface catchment, Weiss and Gvirtzman (2007) found a long-term average of 47% (see note below Table H1). Both, the temporal and spatial variability of reported values are impressive (temporal variability can be detected by comparing average with maximum RC-values; spatial variability emerges from the differences between different basins and sub-basins, both, within and outside the WAB). In this respect, Wadi Natuf is highly representative for many basins with similar climatic, geological, soil type and landscape conditions.

Table H1: Recharge coefficients in the literature.

author (year)	average	max.	area	time	approach	how	method	miscellaneous
Sheffer <i>et al.</i> (2010)	9-40 %	(52 %)	Mt. Aquifer	annual	SM-model	calibrated numerical water budget model	daily soil saturation	non-empirically assumed field capacity (low) and soil thickness (high)
