18 **Abstract**

19 River systems that support high biodiversity profiles are conservation priorities world-wide.
20 Understanding river eco-system thresholds to low flow conditions is important for the
21 conservation of these systems. While climatic variations are likely to impact the streamflow
22 variability of many river courses into the future, understanding specific river flow dynamics
23 with regard to streamflow variability and aquifer baseflow contributions are central to the
24 implementation of protection strategies. While streamflow is a measurable quantity, baseflow

25 has to be estimated or calculated through the incorporation of hydrogeological variables. In
26 this study, the groundwater components within the J2000 rainfall/runoff model were distributed
27 to provide daily baseflow and streamflow estimates needed for reserve determination. The
28 modelling approach was applied to the RAMSAR-listed Verlorenvlei estuarine lake system on
29 the west coast of South Africa which is under threat due to agricultural expansion and climatic
30 fluctuations. The sub-catchment consists of four main tributaries, Krom Antonies, Hol,
31 Bergvallei and Kruismans. Of these, Krom Antonies was initially presumed the largest
32 baseflow contributor, but was shown to have significant streamflow variability, attributed to
33 the highly conductive nature of the Table Mountain Group sandstones and quaternary
34 sediments. Instead, Bergvallei was identified as the major contributor of baseflow. Hol was the
35 least susceptible to streamflow fluctuations due to the higher baseflow proportion (56 %), as
36 well as the dominance of less conductive Malmesbury shales that underlie it. The estimated
37 flow exceedance probabilities indicated that during the 2008-2017 wet cycle average lake
38 inflows exceeded the average evaporation demand, although yearly rainfall is twice as variable
39 in comparison to the first wet cycle between 1987-1996. During the 1997-2007 dry cycle,
40 average lake inflows are exceeded 85 % of the time by the evaporation demand. The
41 exceedance probabilities estimated here suggest that inflows from the four main tributaries are
42 not enough to support Verlorenvlei, with the evaporation demand of the entire lake being met
43 only 35 % of the time. This highlights the importance of low occurrence events for filling up
44 Verlorenvlei, allowing for regeneration of lake-supported ecosystems. As climate change
45 drives increased temperatures and rainfall variability, the length of dry cycles is likely to
46 increase into the future and result in the lake drying up more frequently. For this reason, it is
47 important to ensure that water resources are not overallocated during wet cycles, hindering
48 ecosystem regeneration and prolonging the length of these dry cycle conditions.

49 **1. Introduction**

50 Functioning river systems offer numerous economic and social benefits to society including
51 water supply, nutrient cycling and disturbance regulation amongst others (Costanza et al., 1997;
52 Nelson et al., 2009; Postel and Carpenter, 1997). As a result, many countries worldwide have
53 endeavoured to protect river ecosystems, although only after provision has been made for basic
54 human needs (Gleick, 2003; Richter et al., 2012; Ridoutt and Pfister, 2010). However, the
55 implementation of river protection has been problematic, because many river courses and flow
56 regimes have been severely altered due to socio-economic development (Gleeson and Richter,
57 2018; O’Keeffe, 2009; Richter, 2010). River health problems were thought to only result from
58 low-flow conditions and if minimum flows were kept above a critical level, the river’s
59 ecosystem would be protected (Poff et al., 1997; Tennant, 1976). It is now recognised that a
60 more natural flow regime, which includes floods as well as low and medium flow conditions,
61 is required for sufficient ecosystem functioning (Arthington et al., 2018; Bunn and Arthington,
62 2002; Olden and Naiman, 2010; Postel and Richter, 2012). For these reasons, before protection
63 strategies can be developed or implemented for a river system, a comprehensive understanding
64 of the river flow regime dynamics is necessary.

65 River flow regime dynamics include consideration of not just the surface water in the river but
66 also other water contributions including runoff, interflow and baseflow which are all essential
67 for the maintenance of the discharge requirements. Taken together these factors all contribute
68 to the hydrological components of what is called the ecological reserve, the minimum
69 environmental conditions needed to maintain the ecological health of a river system (Hughes,
70 2001; King and Louw, 1998; Richter et al., 2003). A variety of different methods have been
71 developed to incorporate various river health factors into ecological reserve determination
72 (Acreman and Dunbar, 2004; Bragg et al., 2005). One of the simplest and most widely applied,
73 is where compensation flows are set below reservoirs and weirs, using flow duration curves to

74 derive mean flow or flow exceedance probabilities (e.g. Harman and Stewardson, 2005). This
75 approach focusses purely on hydrological indices, which are rarely ecologically valid (e.g.
76 Barker and Kirmond, 1998; Lancaster and Downes, 2010).

77 More comprehensive ecological reserve estimates such as functional analysis are focused on
78 the whole ecosystem, including both hydraulic and ecological data (e.g. ELOHA: Poff et al.,
79 2010; Building Block Methodology: King and Louw, 1998). While these methods consider that
80 a variety of low, medium and high flow events are important for maintaining ecosystem
81 diversity, they require specific data regarding the hydrology and ecology of a river system,
82 which in many cases does not exist, has not been recorded continuously or for sufficient
83 duration (Acreman and Dunbar, 2004; Richter et al., 2012). To speed up ecological reserve
84 determination, river flow records have been used to analyse natural seasonality and variability
85 of flows (e.g. Hughes and Hannart, 2003). However, this approach requires long-term
86 streamflow and baseflow timeseries. Whilst streamflow is a measurable quantity subject to a
87 gauging station being in place, baseflow has to be modelled based on hydrological and
88 hydrogeological variables.

89 Rainfall/runoff models can be used to calculate hydrological variables using distributive
90 surface water components (e.g. J2000: Krause, 2001; SWAT: Arnold et al., 1998) but the
91 groundwater components are generally lumped within conventional modelling frameworks. In
92 contrast, groundwater models, which distribute groundwater variables (e.g. MODFLOW:
93 Harbaugh et al., 2000; FEFLOW: Diersch, 2002) are frequently set up to lump climate
94 components. In order to accurately model daily baseflow, which is needed for reserve
95 determination, modelling systems need to be setup such that both groundwater and climate
96 variables are treated in a distributed manner (e.g. Bauer et al., 2006; Kim et al., 2008).
97 Rainfall/runoff models, which use Hydrological Response Units (HRUs) as an entity of
98 homogenous climate, rainfall, soil and landuse properties (Flügel, 1995; Leavesley and

99 Stannard, 1990), are able to reproduce hydrographs through model calibration (Wagener and
100 Wheater, 2006; Young, 2006). However, they are rarely able to correctly proportion runoff and
101 baseflow components (e.g. Willems, 2009; Hughes, 2004). To correctly determine
102 groundwater baseflow using rainfall/runoff models such as the J2000, aquifer components need
103 to be distributed. This can be achieved using net recharge and hydraulic conductivity collected
104 through aquifer testing or groundwater modelling.

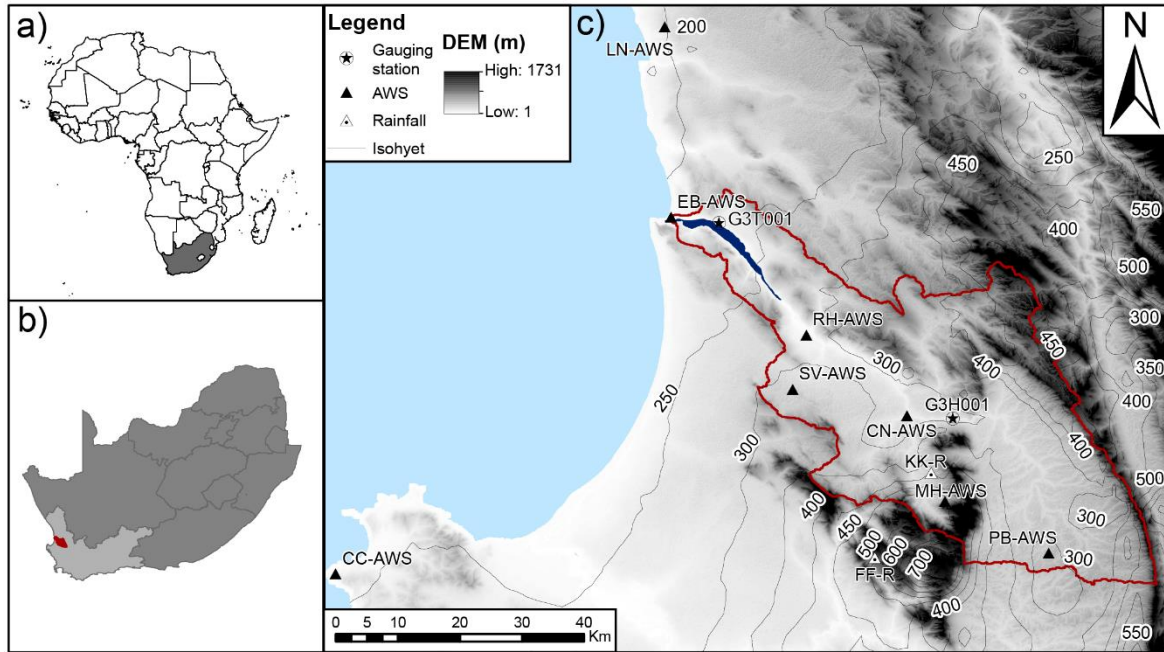

105 To better understand river flow variability, a rainfall/runoff model was distributed to
106 incorporate aquifer hydraulic conductivity within model HRUs using calibrated values from a
107 MODFLOW groundwater model (Watson, 2018). The model was setup for the RAMSAR
108 listed Verlorenvlei estuarine lake on the west coast of South Africa, which is under threat from
109 climate change, agricultural expansion and mining exploration. The rainfall/runoff model used
110 was J2000 as this model had previously been set up in the region and model variables were
111 well established (e.g Bagan, 2014; Schulz et al., 2013). While the estuarine lake's importance
112 is well documented (Martens et al., 1996; Wishart, 2000), the lake's reserve is not well
113 understood, due to the lack of streamflow and baseflow estimates for the main feeding
114 tributaries of the system. The modelling framework developed in this study aimed to
115 understand the flow variability of the lake's feeding tributaries, to provide the hydrological
116 components (baseflow and runoff proportioning) of the tributaries needed to understand the
117 lake reserve. The surface water and groundwater components of the model were calibrated for
118 two different tributaries which were believed to be the main source of runoff and baseflow for
119 the sub-catchment. The baseflow and runoff rates calculated from the model indicate not only
120 that the lake system cannot be sustained by baseflow during low flow periods but also that the
121 initial understanding of which tributaries are key to the sustainability of the lake system was
122 not correct. The results have important implications for how we understand water dynamics in

123 water stressed catchments and the sustainability of ecological systems in these types of
124 environments generally.

125 **2. Study site**

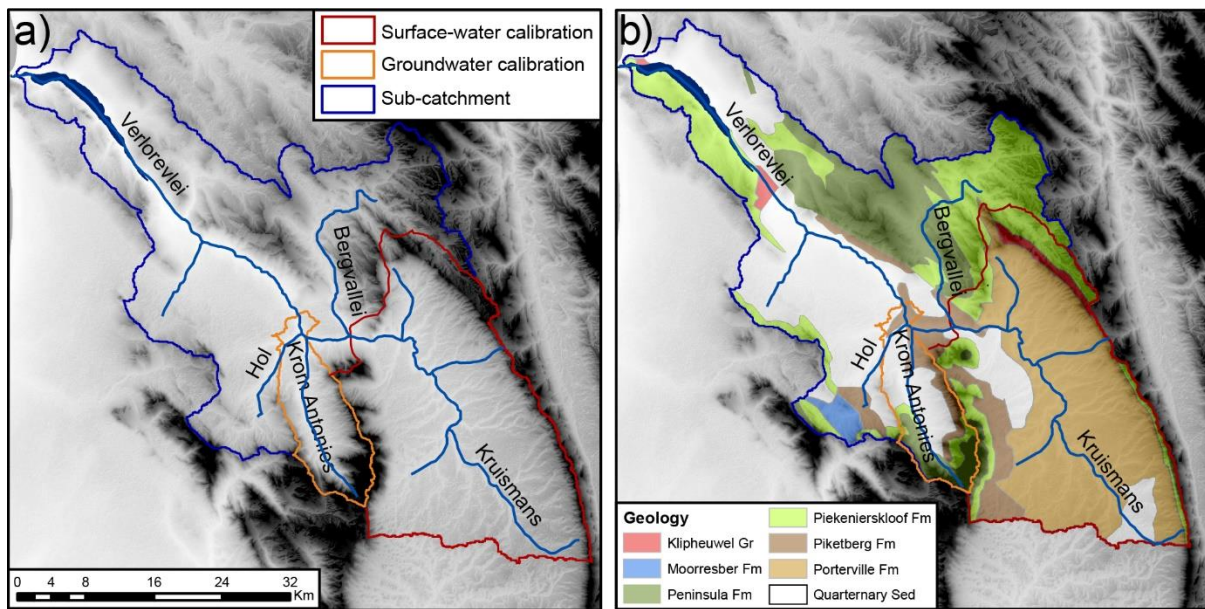

126 Verlorenvlei is an estuarine lake situated on the west coast of South Africa, approximately 150
127 km north of the metropolitan city of Cape Town (Fig. 1). The west coast, which is situated in
128 the Western Cape Province of South Africa, is subject to a Mediterranean climate where the
129 majority of rainfall is received between May to September. The Verlorenvlei lake, which is
130 approximately 15 km² in size draining a watershed of 1832 km², forms the southern sub-
131 catchment of the Olifants/Doorn water management area (WMA). The lake hosts both Karroid
132 and Fynbos biomes, with a variety of vegetation types (e.g Arid Estuarine Saltmarsh, Cape
133 Inland Salt pans) sensitive to reduced inflows of freshwater (Helme, 2007). A sandbar created
134 around a sandstone outcrop (Table Mountain Group; TMG) allows for an intermittent
135 connection between salt and fresh water. During storms or extremely high tides, water scours
136 the sand bar allowing for a tidal exchange, with a constant inflow of salt water continuing until
137 the inflow velocity decreases enough for a new sand bar to form (Sinclair et al., 1986).

138 The lake is supplied by four main tributaries which are Krom Antonies, Bergvallei, Hol and
139 Kruismans (Fig. 2). The main freshwater sources are presumed to be Krom Antonies and
140 Bergvallei, which drain the mountainous regions to the south (Piketberg) and north of the sub-
141 catchment respectfully. Hol and Kruismans tributaries are variably saline (Sigidi, 2018), due
142 to high evaporation rates in the valley. Average daily temperatures during summer within the
143 sub-catchment are between 20-30 °C, with estimated potential evaporation rates of 4 to 6 mm.d⁻¹
144 ¹ (Muche et al., 2018). In comparison, winter daily average temperatures are between 12-20 °C,
145 with estimated potential evaporation rates of 1 to 3 mm.d⁻¹ (Muche et al., 2018).

146

147 Figure 1: a) Location of South Africa, b) the location of the study catchment within the Western
 148 Cape and c) the extend of the Verlorenvlei sub-catchment with the climate stations, gauging
 149 station (G3H001), measured lake water level (G3T001) and rainfall isohyets

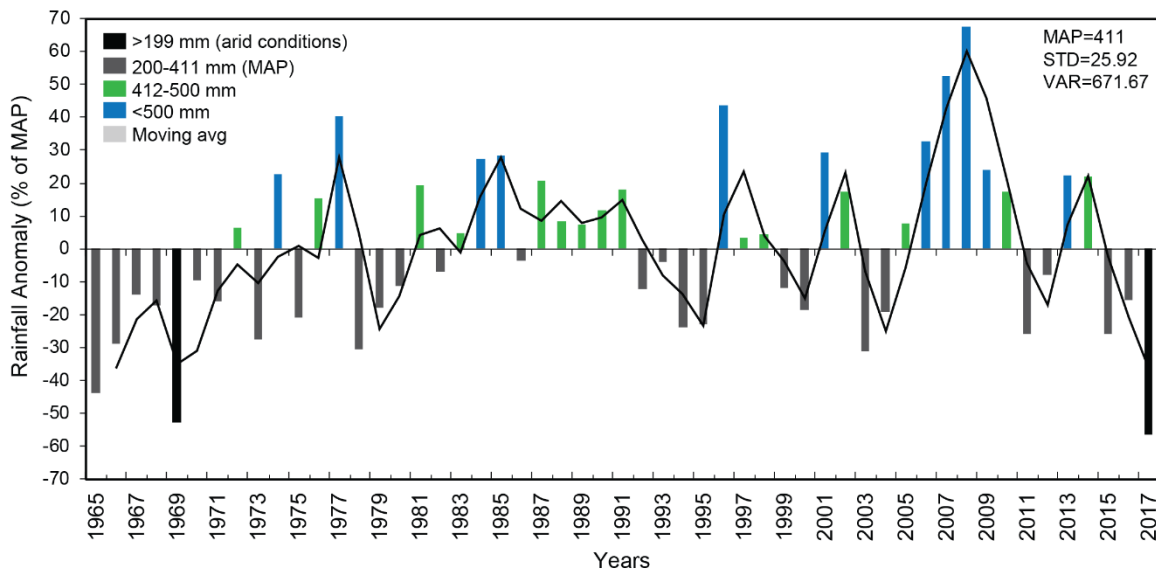

150

151 Figure 2: a) The Verlorenvlei sub-catchment with the surface water calibration tributary
 152 (Kruismans) and groundwater calibration tributary (Krom Antonies) and b) the hydrogeology
 153 of the sub-catchment with Malmesbury shale formations (MG; Klipheuwel, Mooresberg,

154 Porterville, Piketberg), Table Mountain Group formations (Peninsula, Piekenierskloof) and
155 quaternary sediments

156 Rainfall for the sub-catchment, recorded over the past 52 years by local farmers at KK-R (Fig.
157 1) shows large yearly variability (26 %) between the Mean Annual Precipitation (MAP) (411
158 mm) and measured rainfall (Fig. 3). Where rainfall was greater than 500 mm.yr⁻¹ (2006-2010),
159 it is presumed that the lake is supported by a constant influx of streamflow from the feeding
160 tributaries. Recently, where rainfall was less than 50 % of the MAP (2015-2017), concerns
161 over the amount of streamflow required to support the lake have been raised.

162
163 Figure 3: The difference between MAP and measured rainfall (plotted as rainfall anomaly) for
164 52 years (1965-2017) at location KK-R in the valley of Krom Antonies (after Watson *et al.*,
165 2018).

166 While rainfall varies greatly between years in the sub-catchment, it is also spatially impacted
167 by elevational differences. The catchment valley which receives the least MAP 100-350 mm.yr⁻¹
168 ¹ (Lynch, 2004), is between 0-350 masl and is comprised of quaternary sediments that vary in
169 texture, although the majority of the sediments in the sub-catchment are sandy in nature. The

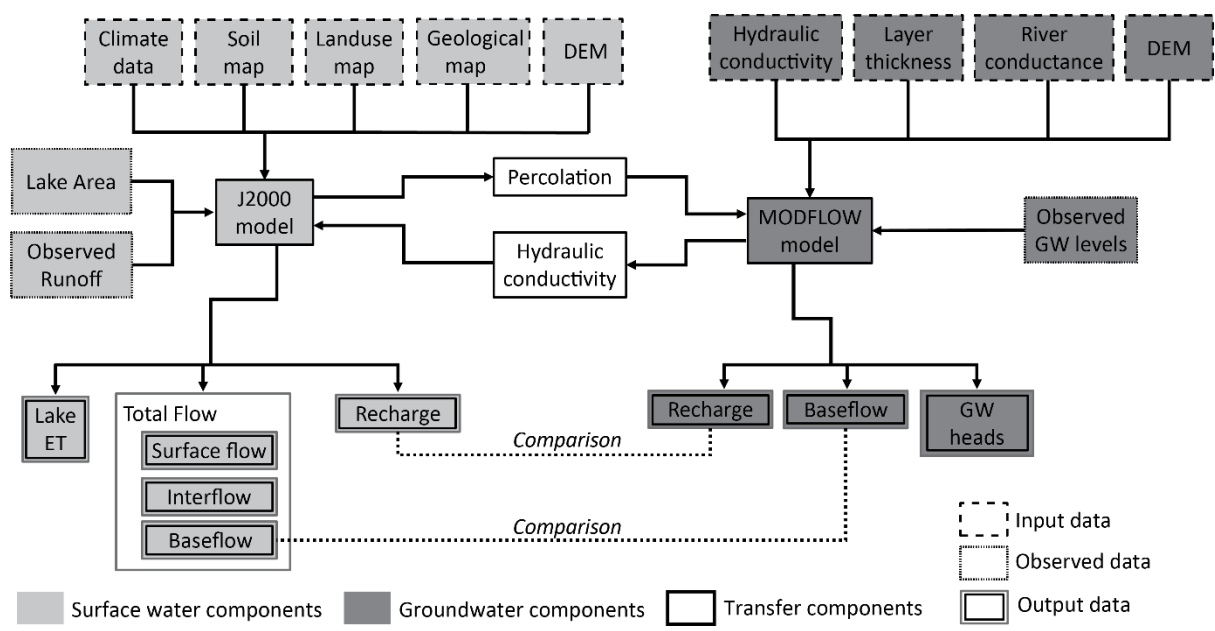

170 higher relief mountainous regions of the sub-catchment between 400-1300 masl receive the
171 highest MAP 400-800 mm.yr⁻¹ (Lynch, 2004), are mainly comprised of fractured TMG
172 sandstones, (youngest to oldest): Peninsula, Graafwater (not shown), and Piekernerskloof
173 formations (Fig. 2) (Johnson et al., 2006). Underlying the sandstones and quaternary sediments
174 are the MG shales, which are comprised of the Mooresberg, Piketberg and Klipheuvel
175 formations (Fig. 2) (Rozendaal and Gresse, 1994). Agriculture is the dominant water user in
176 the sub-catchment with an estimated usage of 20 % of the total recharge (Conrad et al., 2004;
177 DWAF, 2003), with the main food crop being potatoes. The MG shales and quaternary
178 sediments, which host the secondary and primary aquifer respectfully, are frequently used to
179 supplement irrigation during the summer months of the year. During winter, the majority of
180 the irrigation water needed for crop growth is supplied by the sub-catchment tributaries or the
181 lake itself. The impact of irrigation on the lake is still regarded as minimal (Meinhardt et al.,
182 2018) but further investigation is still required. For additional information regarding the study
183 site refer to Watson *et al.*, (2018) and Conrad *et al.*, (2004).

184 **3. Methodology**

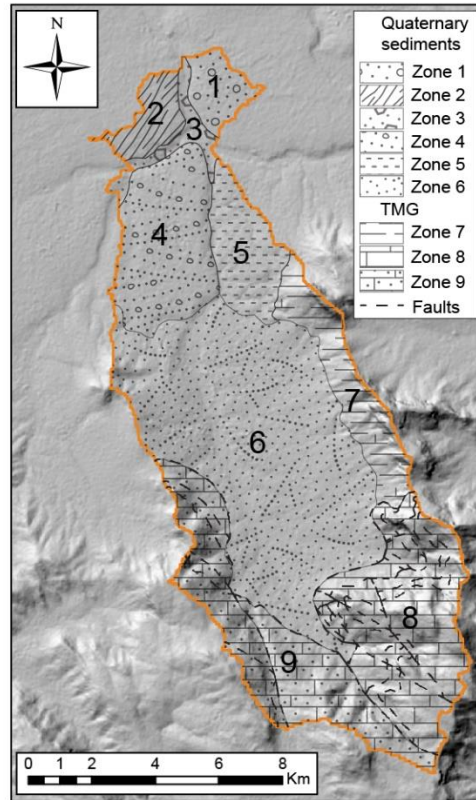

185 In this study, the J2000 coding was adapted to incorporate distributed groundwater components
186 for the model HRU's (Fig. 4). This was done by aligning the MODFLOW recharge estimates
187 and previous studies (Conrad et al., 2004; Miller et al., 2017; Vetger, 1995; Weaver and Talma,
188 2005; Wu, 2005) with those of the J2000, through adjustment of aquifer hydraulic conductivity
189 from the MODFLOW groundwater model of Krom Antonies (Watson, 2018) (Fig. 5). The
190 assigned hydraulic conductivity for each geological formation was thereafter transferred across
191 the entire J2000 model of the sub-catchment. The adaption applied to the groundwater
192 components influenced the proportioning of water routed to runoff and baseflow within the
193 J2000 model. To validate the outputs of the model, an empirical mode decomposition (EMD)

194 (Huang et al., 1998) was applied to compute the proportion of variation in discharge timeseries
 195 that attributed to a high and low water level change at the sub-catchment outlet. The streamflow
 196 estimates were thereafter compared with the lake evaporation demand, to understand the sub-
 197 catchment water balance.

198 The J2000 model incorporated distributed climate, soil, landuse and hydrogeological
 199 information, with aquifer hydraulic conductivity transferred from MODFLOW as described
 200 above (Fig. 4). The measured streamflow was used to both calibrate and validate the model,
 201 with the landuse dataset being selected according to the period of measured streamflow.
 202 Changes in the recorded lake level were used alongside remote sensing to estimate the lake
 203 evaporation rate. The impact of irrigation was not included in the model, as there is not enough
 204 information available regarding agricultural water use. This is currently one of the major
 205 limitations with the study approach presented here and will be the focus of future work. The
 206 HRU delineation, model regionalisation, water balance calculations, lateral and reach routing
 207 as well as the lake evaporation procedure are presented. Thereafter the input data for the model,
 208 the calibration and validation procedures as well as the EMD protocol used, is described.

210 Figure 4: Schematic of the model structure, showing the processors simulated by the J2000 and
211 MODFLOW and the components that were transferred from the MODFLOW model

212

213 Figure 5: The aquifer hydraulic zones used for the groundwater calibration of the J2000 (after
214 Watson, 2018)

215 3.1 Hydrological Response Unit Delineation

216 HRUs and stream segments (reaches) are used within the J2000 model for distributed
217 topographic and physiological modelling. In this study, the HRU delineation made use of a
218 digital elevation model, with slope, aspect, solar radiation index, mass balance index and
219 topographic wetness being derived. Before the delineation process, gaps within the digital
220 elevation model were filled using a standard fill algorithm from ArcInfo (Jenson and
221 Domingue, 1988). The AML (ArcMarkupLanguage) automated tool (Pfennig et al., 2009) was
222 used for the HRU delineation, with between 13 and 14 HRUs/km² being defined

223 (Pfannschmidt, 2008). After the delineation of HRUs, dominant soil, land use and geology
224 properties were assigned to each. The hydrological topology was defined for each HRU by
225 identifying the adjacent HRUs or stream segments that received water fluxes.

226 **3.2 Model regionalisation**

227 Rainfall and relative humidity are the two main parameters that are regionalised within the
228 J2000 model. While a direct regionalisation using an inverse-distance method (IDW) and the
229 elevation of each HRU can be applied to rainfall data, the regionalisation of relative humidity
230 requires the calculation of absolute humidity. The regionalisation of rainfall records was
231 applied by defining the number of weather station records available and estimating the
232 influence on the rainfall amount for each HRU. A weighting for each station using the distance
233 of each station to the area of interest was applied to each rainfall record, using an elevation
234 correction factor (Krause, 2001). The relative humidity and air temperature measured at set
235 weather stations was used to calculate the absolute humidity. Absolute humidity was thereafter
236 regionalised using the IDW method, station and HRU elevation. After the regionalisation had
237 been applied, the absolute humidity was converted back to relative humidity through
238 calculation of saturated vapor pressure and the maximum humidity.

239 **3.3 Water balance calculations**

240 The J2000 model is divided into calculations that impact surface water and groundwater
241 processors. The J2000 model distributes the regionalised precipitation (P) calculated for each
242 HRU using a water balance defined as:

$$P = R + Int_{max} + ETR + \Delta Soil_{sat} \quad (1)$$

243 where R is runoff (mm) (RD1 - surface runoff; RD2 - interflow), Int_{max} is vegetation canopy
244 interception (mm), ETR is 'real' evapotranspiration and $\Delta Soil_{sat}$ is change in soil saturation.
245 The surface water processes have an impact on the amount of modelled runoff and interflow,

246 while the groundwater processors influence the upper and lower groundwater flow
247 components.

248 **3.3.1 Surface water components**

249 Potential evaporation (ETP) within the J2000 model is calculated using the Penman Monteith
250 equation. Before evaporation was calculated for each HRU, interception was subtracted from
251 precipitation using the leaf area index and leaf storage capacity for vegetation (a_{rain})
252 (Supplementary: Table 1). Evaporation within the model considers several variables that
253 influence the overall modelled evaporation. Firstly, evaporation is influenced by a slope factor,
254 which was used to reduce ETP based on a linear function. Secondly, the model assumed that
255 vegetation transpires until a particular soil moisture content where ETP is reached, after which
256 modelled evaporation was reduced proportionally to the ETP, until it becomes zero at the
257 permanent wilting point.

258 The soil module in the J2000 model is divided up into processing and storage units. Processing
259 units in the soil module include soil-water infiltration and evapotranspiration, while storage
260 units include middle pore storage (MPS), large pore storage (LPS) and depression storage. The
261 infiltrated precipitation was calculated using the relative saturation of the soil, and its maximum
262 infiltration rate ($SoilMaxInfSummer$ and $SoilMaxInfWinter$) (Supplementary: Table 1).
263 Surface runoff was generated when the maximum infiltration threshold was exceeded. The
264 amount of water leaving LPS, which can contribute to recharge, was dependant on soil
265 saturation and the filling of LPS via infiltrated precipitation. Net recharge (R_{net}) was estimated
266 using the hydraulic conductivity ($SoilMaxPerc$), the outflow from LPS (LPS_{out}) and the slope
267 ($slope$) of the HRU according to:

$$R_{net} = LPS_{out} \times (1 - \tan (slope) SoilMaxPerc) \quad (2)$$

268 The hydraulic conductivity, *SoilMaxPerc* and the adjusted LPS_{out} were thereafter used to
 269 calculate interflow (IT_f) according to:

$$IT_f = LPS_{out} \times (\tan(\text{slope}) \text{SoilMaxPerc}) \quad (3)$$

270 with the interflow calculated representing the sub-surface runoff component RD2 and is routed
 271 as runoff within the model.

272 3.3.2 Groundwater components

273 The J2000 model for the Verlorenvlei sub-catchment was set up with two different geological
 274 reservoirs: (1) the primary aquifer (upper groundwater reservoir - RG1), which consists of
 275 quaternary sediments with a high permeability; and (2) the secondary aquifer (lower
 276 groundwater reservoir- RG2), made up of MG shales and TMG sandstones (Table 1).

Aquifer	Formation	Type	RG1_max (mm)	RG2_max (mm)	RG1_k (d)	RG2_k (d)	RG1_active (n/a)	Kf_geo (mm/d)	depthRG1 (cm)
Primary	Quaternary Sediments	Sediments	50	700	100	431	1	500	1750
Secondary/MG	Moorresberg Formation	Shale Greywacke	0	580	0	350	0	950	1750
Secondary/MG	Porterville Formation	Shale Greywacke	0	560	0	335	0	2	1750
Secondary/MG	Piketberg Formation	Shale Greywacke	0	1000	0	600	0	950	1750
Secondary/MG	Klipheuwel Group	Shale Greywacke	0	500	0	300	0	950	1750
Secondary/TMG	Peninsula Formation	Sandstone	0	1000	0	600	0	950	1750
Secondary/TMG	Piekenierskloof Formation	Sandstone	0	600	0	400	0	1	1750

277
 278 Table 1: The J2000 hydrogeological parameters RG1_max, RG2_max, RG1_k, RG2_Kf_geo
 279 and depthRG1 assigned to the primary and secondary aquifer formations for the Verlorenvlei
 280 sub-catchment

281 The model therefore considered two baseflow components, a fast one from RG1 and a slower
 282 one from RG2. The filling of the groundwater reservoirs was done by net recharge, with
 283 emptying of the reservoirs possible by lateral subterranean runoff as well as capillary action in
 284 the unsaturated zone. Each groundwater reservoir was parameterised separately using the
 285 maximum storage capacity (maxRG1 and maxRG2) and the retention coefficients for each
 286 reservoir ($recRG1$ and $recRG2$). The outflow from the reservoirs was determined as a function
 287 of the actual filling ($actRG1$ and $actRG2$) of the reservoirs and a linear drain function.

288 Calibration parameters $recRG1$ and $recRG2$ are storage residence time parameters. The
289 outflow from each reservoir was defined as:

$$OutRG1 = \frac{1}{gwRG1Fact \times recRG1} \times actRG1 \quad (4)$$

$$OutRG2 = \frac{1}{gwRG2Fact \times recRG2} \times actRG2 \quad (5)$$

290 where $OutRG1$ is the outflow from the upper reservoir, $OutRG2$ is the outflow from the lower
291 reservoir and $gwRG1Fact/ gwRG2Fact$ are calibration parameters for the upper and lower
292 reservoir used to determine the outflow from each reservoir. To allocate the quantity of net
293 recharge between the upper (RG1) and lower (RG2) groundwater reservoirs, a calibration
294 coefficient $gwRG1RG2sdist$ was used to distribute the net recharge for each HRU using the
295 HRU slope. The influx of groundwater into the shallow reservoir ($inRG1$) was defined as:

$$inRG1 = R_{net} \times (1 - (1 - \tan(slope))) \times gwRG1RG2sdist \quad (6)$$

296 The influx of net recharge into the lower groundwater reservoir ($inRG2$) was defined as:

$$inRG2 = R_{net} \times (1 - \tan(slope)) \times gwRG1RG2sdist \quad (7)$$

297 with the combination of $OutRG1$ and $OutRG2$ representing the baseflow component that is
298 routed as an outflow from the model.

299 **3.4 Lateral and reach routing**

300 Lateral routing was responsible for water transfer within the model and included HRU influxes
301 and discharge through routing of cascading HRUs from the upper catchment to the exit stream.
302 HRUs were either able to drain into multiple receiving HRUs or into reach segments, where
303 the topographic ID within the HRU dataset determined the drain order. The reach routing
304 module was used to determine the flow within the channels of the river using the kinematic
305 wave equation and calculations of flow according to Manning and Strickler. The river

306 discharge was determined using the roughness coefficient of the stream (Manning roughness),
307 the slope and width of the river channel and calculations of flow velocity and hydraulic radius
308 calculated during model simulations.

309 **3.5 Calculations of lake evaporation rate**

310 The lake evaporation rate was based on the ETP calculated by the J2000 and an estimated lake
311 surface area. The lake was modelled as a unique HRU (water as the land-cover type), with a
312 variable area which was estimated using remote sensing data from Landsat 8 and Sentinel-2
313 and the measured lake water level at G3T001 (Fig. 1). To infill lake surface area when remote
314 sensing data was not available, a relationship was created between the estimated lake's surface
315 area and the measured water level between 2015-2017. Where lake water level data was not
316 available (before 1999), an average long-term monthly value was used for the lake evaporation
317 calculations.

318 **3.6 J2000 Input data**

319 ***3.6.1 Surface water parameters***

320 Climate and rainfall: Rainfall, windspeed, relative humidity, solar radiation and air temperature
321 were monitored by Automated Weather Stations (AWS) within and outside of the study
322 catchment (Fig. 1). Of the climate and rainfall data used during the surface water modelling
323 (Watson et al., 2018), data was sourced from seven AWS's of which four stations were owned
324 by the South African Weather Service (SAWS) and three by the Agricultural Research Council
325 (ARC). Two stations that were installed for the surface water modelling, namely Moutonshoek
326 (M-AWS) and Confluence (CN-AWS) were used for climate and rainfall validation due to their
327 short record length. Additional rainfall data collected by farmers at high elevation at location
328 FF-R and within the middle of the catchment at KK-R were used to improve the climate and
329 rainfall network density.

330 Landuse classification: The vegetation and landuse dataset that was used for the sub-catchment
331 (CSIR, 2009) included five different landuse classes: 1) wetlands and waterbodies, 2)
332 cultivated (temporary, commercial, dryland), 3) shrubland and low fynbos, 4) thicket,
333 bushveld, bush clumps and high fynbos and 5) cultivated (permanent, commercial, irrigated).
334 Each different landuse class was assigned an albedo, root depth and seal grade value based on
335 previous studies (Steudel et al., 2015)(Supplementary: Table 2). The Leaf Area Index (LAI)
336 and vegetation height varies by growing season with different values of each for the particular
337 growing season. While surface resistance of the landuse varied monthly within the model, the
338 values only vary significantly between growing seasons.

339 Soil dataset: The Harmonized World Soil Database (HWSD) v1.2 (Batjes et al., 2012) was the
340 input soil dataset, with nine different soil forms within the sub-catchment (Supplementary:
341 Table 3). Within the HWSD, soil depth, soil texture and granulometry were used to calculate
342 and assign soil parameters within the J2000 model. MPS and LPS which differ in terms of the
343 soil structure and pore size were determined in Watson et al. (2018), using pedotransfer
344 functions within the HYDRUS model (Supplementary: Table 3).

345 Streamflow and water levels: Streamflow, measured at the Department of Water Affairs
346 (DWA) gauging station G3H001 between 1970-2009, at the outlet of Kruismans tributary (Het
347 Kruis) (Fig 1 and 3), was used for surface water calibration. The G3H001 two-stage weir could
348 record a maximum flow rate of $3.68 \text{ m}^2 \cdot \text{s}^{-1}$ due to the capacity limitations of the structure. After
349 2009, the G3H001 structure was decommissioned due to structural damage, although repairs
350 are expected in the near future due to increasing concerns regarding the influx of freshwater
351 into the lake. Water levels measured at the sub-catchment outlet at DWA station G3T001 (Fig
352 1) between 1994 to 2018 were used for EMD filtering.

353 **3.6.2 Groundwater parameters**

354 Net recharge and hydraulic conductivity: The hydraulic conductivity values used for the
355 groundwater component adaptation were collected from detailed MODFLOW modelling of
356 Krom Antonies tributary (Fig. 5) (Watson, 2018). The net recharge and aquifer hydraulic
357 conductivity for Krom Antonies tributary, was estimated through PEST autocalibration using
358 hydraulic conductivities from previous studies (SRK, 2009; UMVOTO-SRK, 2000) and
359 potential recharge estimates (Watson et al., 2018).

360 Hydrogeology: Within the hydrogeological dataset, parameters assigned include maximum
361 storage capacity (RG1 and RG2), storage coefficients (RG1 and RG2), the minimum
362 permeability/maximum percolation (Kf_geo of RG1 and RG2) and depth of the upper
363 groundwater reservoir (depthRG1). The maximum storage capacity was determined using an
364 average thickness of each aquifer and the total number of voids and cavities, where the primary
365 aquifer thickness was assumed to be between 15-20 m (Conrad et al., 2004), and the secondary
366 aquifer between 80-200 m (SRK, 2009). The maximum percolation of the different geological
367 formations was assigned hydraulic conductivities using the groundwater model for Krom
368 Antonies sub-catchment (Watson, 2018). The J2000 geological formations were assigned
369 conductivities to modify the maximum percolation value to ensure internal consistency with
370 recharge values calculated using MODFLOW (Table 1).

371 **3.7 J2000 model calibration**

372 **3.7.1 Model sensitivity**

373 The J2000 sensitivity analysis for Verlorenvlei sub-catchment was presented in Watson *et al.*,
374 (2018) and therefore only a short summary is presented here. In this study, parameters that
375 were used to control the ratio of interflow to percolation were adjusted, which in the J2000
376 model include a slope (SoilLatVertDist) and max percolation value. The sensitivity analysis

377 conducted by Watson *et al.*, (2018) showed that for high flow conditions (E2) (Nash-Sutcliffe
 378 efficiency in its standard squared), model outputs are most sensitive to the slope factor, while
 379 for low flow conditions (E1) (modified Nash-Sutcliffe efficiency in a linear form) the model
 380 outputs were most sensitive to the maximum infiltration rate of the soil (ie. the parameter
 381 maxInfiltrationWet) (Supplementary: Figure 1). The max percolation was moderately sensitive
 382 during wet and dry conditions, and together with the slope factor, controlled the interflow to
 383 percolation proportioning that was calibrated in this study.

384 3.7.2 Surface water calibration

385 The surface water parameters of the model were calibrated for Kruismans tributary (688 km²)
 386 (Fig. 3) using the gauging data from G3H001 (Fig. 6 and Table 1). The streamflow data used
 387 for the calibration was between 1986-1993, with model validation between 1994 to 2007 (Fig.
 388 6). This specific calibration period was selected due to the wide range of different runoff
 389 conditions experienced at the station, with both low and high flow events being recorded. For
 390 the calibration, the modelled discharge was manipulated in the same fashion, with a DT limit
 391 (discharge table) of 3.68 m³/s, so that the tributary streamflow behaved as measured discharge.

392

393 Figure 6: The surface water calibration (1986-1993) and validation (1994-2006) of the J2000
 394 model using gauging data from the G3H001

395 An automated model calibration was performed using the “Nondominating Sorting Genetic
396 Algorithm II” (NSGA-II) multi-objective optimisation method (Deb et al., 2002) with 1024
397 model runs being performed. Narrow ranges of calibration parameters (FC_Adaptation,
398 AC_Adaptation, soilMAXDPS, gwRG1Fact and gwRG2Fact) were chosen to (1) ensure that
399 the modelled recharge from J2000 was within an order of magnitude of recharge from the
400 MODFLOW model and previous studies; (2) achieve a representative sub-catchment
401 hydrograph. As objective functions, Nash-Sutcliffe-Efficiency based on absolute differences
402 (E1) and squared differences (E2) as well as the average bias in % (Pbias) were utilized for
403 the calibration (Krause et al., 2005) (Table 2). The choice of the optimized parameter set was
404 made to ensure that E2 was better than 0.57 (best value was 0.57) and the Pbias better than 5
405 % (Table 1). From the automated calibration, 308 parameter sets were determined with the best
406 E1 being chosen to ensure that the model is representative of low flow conditions (Table 1).

407 ***3.7.3 Model validation***

408 Observed vs modelled streamflow: For the surface water model validation, the streamflow
409 records between 1994-2007 were used, where Nash-Sutcliffe-Efficiency (E1 and E2) were
410 reported. The Pbias was also used as an objective function to report the model performance by
411 comparison between measured and modelled streamflow (Table 2). Although gauging station
412 limitations resulted in good objective functions from the model, the performance of objective
413 functions E1, E2, Pbias reduced between the validation and calibration period (Table 2). During
414 the calibration period there was a good fit between modelled and measured streamflow (Pbias=-
415 1.82), with a significant difference between modelled and measured streamflow during the
416 validation period (Pbias=-19.2). The calibration was performed over a wet cycle (1986-1997),
417 which resulted in a more common occurrence of streamflow events that exceeded $3.68 \text{ m}^3 \cdot \text{s}^{-1}$,
418 thereby reducing the number of calibration points. In contrast the validation was performed

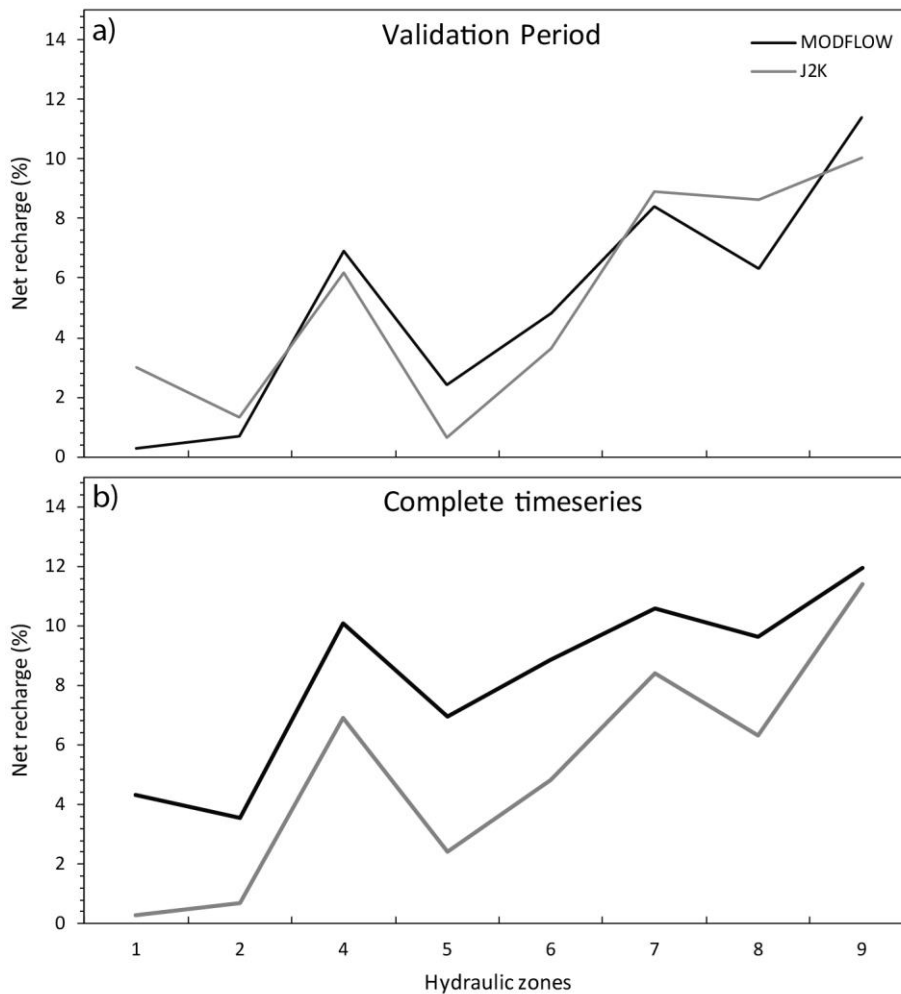

419 over a dry cycle (1997-2007), which resulted in more data points as few streamflow events
 420 exceeded $3.68 \text{ m}^3 \cdot \text{s}^{-1}$.

	Calibration 1987-1993	Validation 1994-2007
E1	0.55	0.53
E2	0.57	0.56
LogE1	0.28	0.10
LogE2	0.46	0.19
AVE	-19.24	-269.20
R ²	0.62	0.58
Pbias	-1.82	-19.23758
KGE	0.79	0.67417

421

422 Table 2: Value of the objective functions E1, E2, logarithmic versions of E1 and E2, absolute
 423 volume error (AVE), coefficient of determination (R²), Pbias and Kling Gupta Efficiency
 424 (KGE) (Gupta et al., 2009) for surface water calibration (1987-1993) and validation (1994-
 425 2007)

426 The J2000 and MODFLOW recharge estimates: With adjustment of hydraulic conductivities
 427 from MODFLOW to J2000 it was possible to converge the net recharge estimates between 1.3
 428 % with a range of recharge of 0.65-10.03 % for the J2000 and 0.3-11.40 % for MODFLOW.
 429 Recharge estimates from previous studies of the primary aquifer indicate recharge rates of 0.2-
 430 3.4 % (Conrad et al., 2004), and 8 % (Vetger, 1995), while for the TMG aquifer 13 % (Wu,
 431 2005), 27 % (Miller et al., 2017) and 17.4 % (Weaver and Talma, 2005) of MAP. J2000
 432 estimates had an average value of 5.30 % while MODFLOW was 5.20% for the eight hydraulic
 433 zones of Krom Antonies. The coefficient of determination (R²) between net recharge from the
 434 J2000 and MODFLOW was 0.81. Across the entire dataset J2000 overestimated groundwater
 435 recharge by 2.75 % relative to MODFLOW, although the coefficient of determination produced
 436 an R² of 0.92 which is better than during the validation period.

437

438 Figure 7: The groundwater calibration for each hydraulic zone with a) net recharge for the
 439 J2000 and MODFLOW during the model calibration (2016) and b) the net recharge deviation
 440 between MODFLOW and J2000 across the entire modelling timestep (1986-2017)

441 **3.8 EMD filtering**

442 To account for missing streamflow data between 2007-2017, an Empirical Mode
 443 Decomposition (EMD) (Huang et al., 1998) was applied to the measured water level data at
 444 the sub-catchment outlet (G3T001)(Fig. 1) between 1994 to 2018 (Fig 8a). EMD is a method
 445 for the decomposition of nonlinear and nonstationary signals into sub-signals of varying
 446 frequency, so-called intrinsic mode functions (IMF), and a residuum signal. By removing one
 447 or more IMF or the residuum signal, certain frequencies (e.g. noise) or an underlying trend can

448 be removed from the original time series data. This approach was successfully applied to the
449 analysis of river runoff data (Huang et al., 2009) and forecasting of hydrological time series
450 (Kisi et al., 2014). In this study, EMD filtering was used to remove high frequency sub-signals
451 from simulated runoff and measured water level data to compare the more general seasonal
452 variations of both signals (Fig. 8b).

453

454 Figure 8: a) The water level fluctuations at station G3T001 with modelled runoff and b) the

455 EMD filtering showing the variation in discharge timeseries attributed a water level change at

456 the station

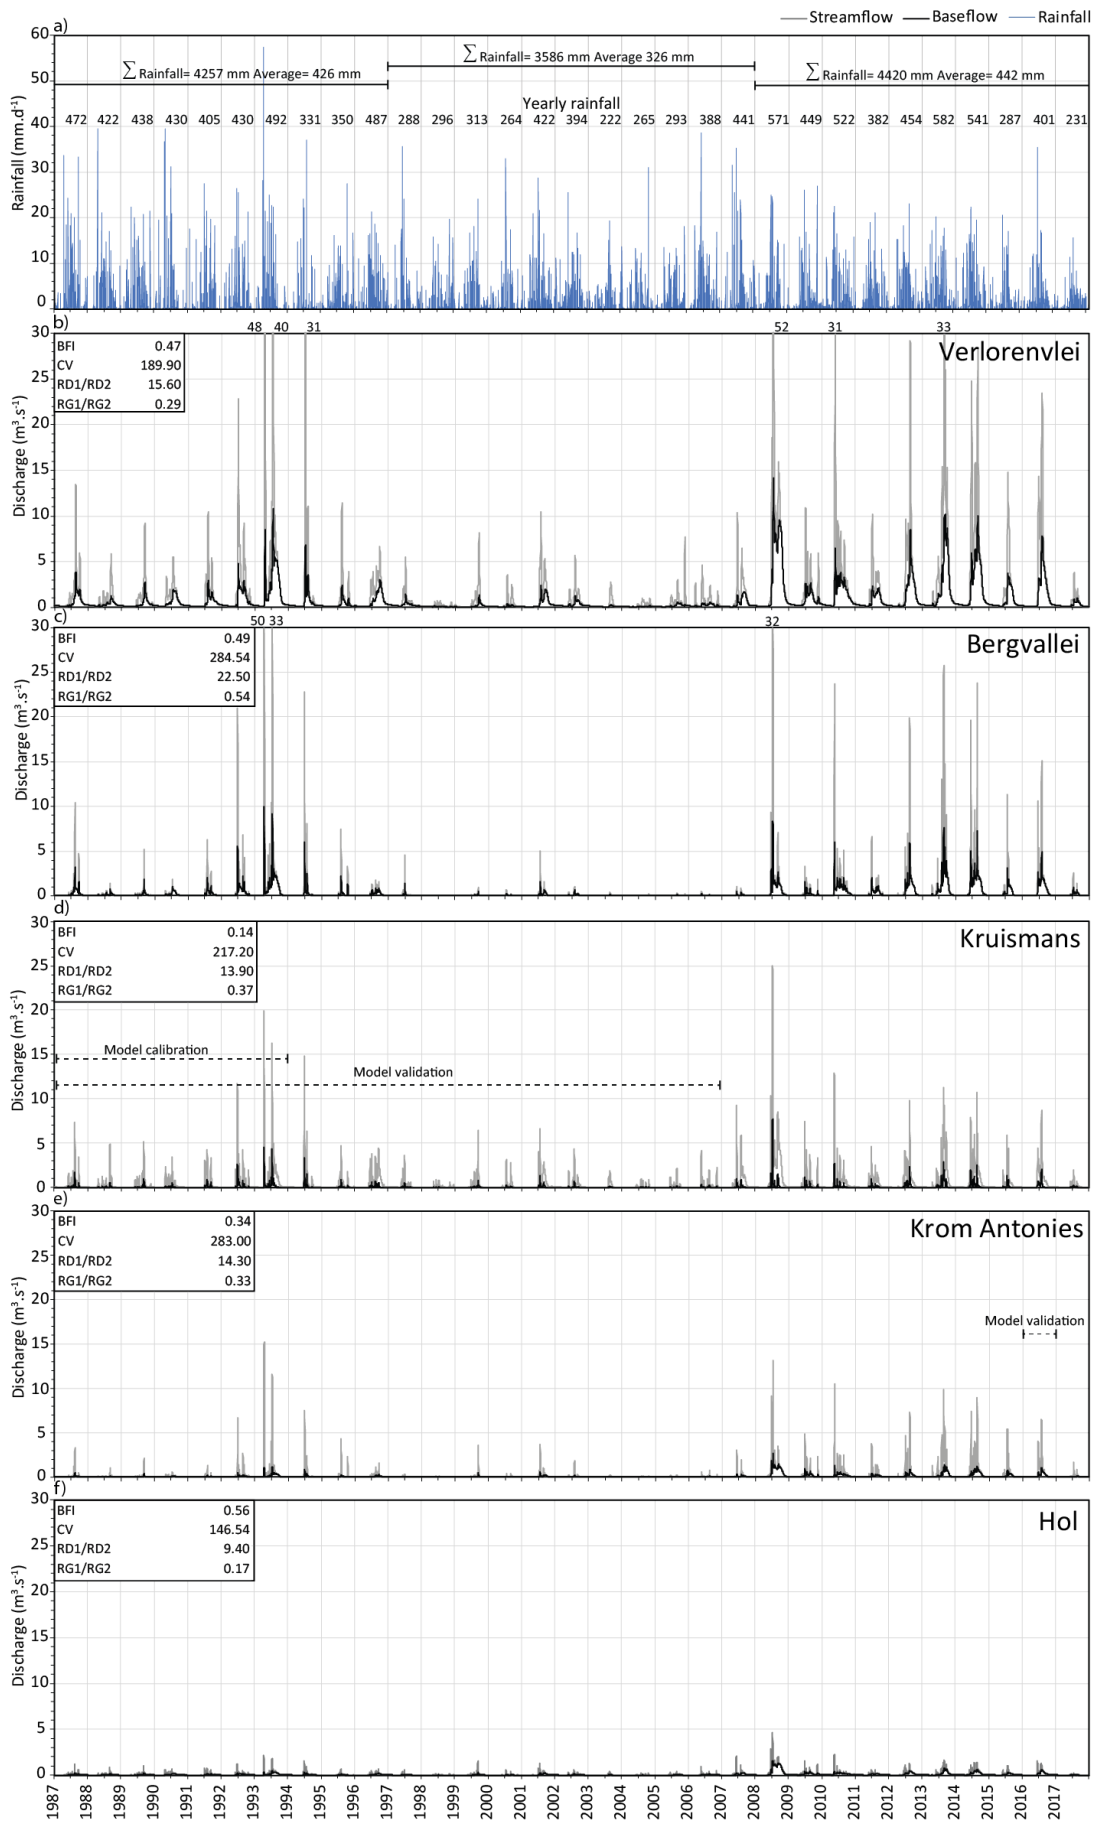

457 **4. Results**

458 The J2000 model was used to simulate both runoff and baseflow, with runoff being comprised
459 of direct surface runoff (RD1) and interflow (RD2) and baseflow simulated from the primary
460 (RG1) and secondary aquifer (RG2). Below, the results of the modelled streamflow and
461 baseflow are presented, along with the total flow contribution of each tributary, the runoff to
462 baseflow proportioning and stream exceedance probabilities. The coefficient of variation (CV)
463 was used to determine the streamflow variability of each tributary, while the baseflow index
464 (BFI) was used to determine the baseflow and runoff proportion.

465 **4.1 Streamflow and baseflow**

466 Streamflow for the sub-catchment shows two distinctively wet periods (1987-1996 and 2008-
467 2017), separated by a dry period (1997-2007) (Fig. 9). Yearly sub-catchment rainfall volumes
468 between 1987-1996 were between 288 and 492 mm/yr⁻¹, with an average of 426 mm.yr⁻¹ and
469 standard deviation (STD) of 51 mm.yr⁻¹. For this period, average yearly streamflow was 1.4
470 m³.s⁻¹, with an average baseflow contribution of 0.63 m³.s⁻¹. The modelled streamflow reached
471 a maximum of 48 m³.s⁻¹ in 1993, where 5 m³.s⁻¹ of baseflow was generated after 58 mm of
472 rainfall was received. Between 1997-2007 (dry period) sub-catchment yearly rainfall was
473 between 222 and 394 mm/yr⁻¹ with an average of 326 mm.yr⁻¹ and STD of 69 mm.yr⁻¹ (Fig.
474 9). For this same period, average yearly streamflow was 0.44 m³.s⁻¹, with an average baseflow
475 contribution of 0.18 m³.s⁻¹. The modelled streamflow reached a maximum of 11 m³.s⁻¹ in 2002,
476 with a baseflow contribution of 2.5 m³.s⁻¹ after 28 mm of rainfall was received. During the
477 second wet period between 2008-2017 sub-catchment yearly rainfall was between 231 and 582
478 mm.yr⁻¹ with an average of 442 mm.yr⁻¹ and STD of 112 mm.yr⁻¹ (Fig. 9). Over this same
479 period, average yearly streamflow was 2.5 m³.s⁻¹ with an average baseflow contribution of 1.3

480 $\text{m}^3.\text{s}^{-1}$. The modelled streamflow reached a maximum of $52 \text{ m}^3.\text{s}^{-1}$ in 2008, with $13 \text{ m}^3.\text{s}^{-1}$ of
481 baseflow generated after two consecutive rainfall events each of 25 mm.

483 Figure 9: a) Average sub-catchment rainfall between 1987-2017 showing wet cycles (1987-
484 1997 and 2008-2017) and dry cycle (1997-2007), Modelled streamflow and baseflow inflows
485 for the b) Verlorenvlei, c) Bergvallei, d) Kruismans, e) Krom Antonies and f) Hol tributaries
486 with estimated BFI, CV, RD1/RD2, RG1/RG2

487 **4.2 Tributary contributions**

488 The four main feeding tributaries (Bergvallei, Kruismans, Hol and Krom Antonies) together
489 contribute 81 % of streamflow for the Verlorenvlei, with the additional 19 % from small
490 tributaries near Redelinghuys (Fig. 10). Kruismans contributes most of the total streamflow at
491 32 %, but only 15 % of the area-weighted contribution as its sub-catchment is the largest of the
492 four tributaries at 688 km² (Fig. 10). Bergvallei with a sub-catchment of 320 km², contributes
493 29 % of the total flow with an area weighted contribution of 28 %. Krom Antonies has the
494 largest area weighted contribution of 30 % due to its small size (140 km²) in comparison to the
495 other tributaries, although Krom Antonies contributes only 13 % of the total flow (Fig. 10).
496 Hol sub-catchment at 126 km² makes up the smallest contribution to the total flow of only 7
497 %, but has a weighted contribution of 17 % (Fig. 10).

498

499 Figure 10: The Verlorenvlei reserve flow contributions (total flow and area weighted flow) of
 500 Kruismans, Bergvallei, Krom Antonies and Hol as well as flow component separation into
 501 surface runoff (RD1), interflow (RD2), primary aquifer flow (RG1) and secondary aquifer
 502 flow (RG2).

503 **4.3 Flow variability**

504 Streamflow that enters Verlorenvlei has a large daily variability with a coefficient of variation
505 (CV) of 189.90 (Fig. 9). This is mainly due to high streamflow variability from Kruismans (32
506 %) with a CV of 217.20, which is the major total flow contributor (Fig 10). Bergvallei and
507 Krom Antonies, which both have high streamflow variability with CV values of 284.54 and
508 283.00 respectfully (Fig. 9), further contribute to the high variability of streamflow that enters
509 the lake. While Hol reduces the overall streamflow variability with a CV of 146.54, it is a minor
510 total flow contributor (7 %) and therefore does not reduce the overall streamflow variability
511 significantly (Fig. 10).

512 Streamflow that enters Verlorenvlei is dominated by surface runoff which makes up 56 % of
513 total flow, with groundwater and interflow contributing 40 % and 4 % respectfully (Fig. 10).
514 The large surface runoff dominance in streamflow entering the lake, is due to a high surface
515 runoff contribution from Kruismans and Krom Antonies, which contribute 26 % of total flow
516 from surface runoff. However, for Bergvallei and Hol, surface runoff contributions are less
517 dominant with 16 % of the total, while the total groundwater contribution is 20 % from these
518 tributaries. Across all four tributaries, the secondary aquifer is the dominant baseflow
519 component with 28 % of total flow, with the primary aquifer contributing 12 %. Bergvallei and
520 Kruismans contribute the majority of primary aquifer baseflow with 8 % of the total. The
521 secondary aquifer baseflow is mainly contributed by Kruismans and Bergvallei, where together
522 18 % of the total is received. Interflow across the four tributaries is uniformly distributed with
523 0.3 – 1 % of the total flow being contributed from each tributary.

524 **4.4 Flow exceedance probabilities**

525 The flow exceedance probability, which is a measure of how often a given flow is equalled or
526 exceeded was calculated for each of the tributaries as well as the lake water body. The results

527 for the flow exceedance probabilities includes flow volumes which are exceeded 95 %, 75 %,
 528 50 %, 25 % and 5 % of the time. The 95 percentile corresponds to a lake inflow of $0.054 \text{ m}^3 \cdot \text{s}^{-1}$
 529 1 or $4,702 \text{ m}^3 \cdot \text{d}^{-1}$, with between $0.001\text{-}0.004 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries (Fig. 11 and
 530 Table 3). The 75-percentile flow, which is exceeded 3/4 of the time corresponds to an inflow
 531 of $0.119 \text{ m}^3 \cdot \text{s}^{-1}$ or $10,303 \text{ m}^3 \cdot \text{d}^{-1}$, with between $0.005\text{-}0.015 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries.
 532 Average (50 percentile) streamflow flowing into the Verlorenvlei is $0.237 \text{ m}^3 \cdot \text{s}^{-1}$ or $20,498$
 533 $\text{m}^3 \cdot \text{d}^{-1}$, with between $0.010\text{-}0.035 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries. The 25-percentile flow,
 534 which is exceeded $\frac{1}{4}$ of the time corresponds to a lake inflow of $1,067 \text{ m}^3 \cdot \text{s}^{-1}$ or $92,204 \text{ m}^3 \cdot \text{d}^{-1}$
 535 with between $0.044\text{-}0.291 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries. The lake inflows that are
 536 exceeded 5 % of the time correspond to $6.939 \text{ m}^3 \cdot \text{s}^{-1}$ or $599,535 \text{ m}^3 \cdot \text{d}^{-1}$ with between 0.224-
 537 $2.49 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries.

541

542 Table 3: The streamflow exceedance percentiles and lake evaporation demand for the
543 Verlorenvlei reserve, with the contributions from Kruismans, Bergvallei, Krom Antonies and
544 Hol (m³.s⁻¹ and m³.d⁻¹)

545 5. Discussion

546 The adaptation of the J2000 rainfall/runoff model was used to understand the flow
547 contributions of the main feeding tributaries, the proportioning of baseflow to surface runoff
548 as well as how often the inflows exceed the lake evaporation demand. Before a comparison
549 with previous baseflow estimates can be made and the impact of evaporation on the lake
550 reserve, the model limitations and catchment flow dynamics must also be assessed.

551 5.1 Model limitations and performance

552 A major limitation facing the development and construction of comprehensive modelling
553 systems in sub-Saharan Africa is the availability of appropriate climate and streamflow data.
554 For this study, while there was access to over 20 years of streamflow records, the station was

555 only able to measure a maximum of $3.68 \text{ m}^3\cdot\text{s}^{-1}$, which hindered calibration of the model for
556 high flow events. As such, the confidence in the model's ability to simulate high streamflow
557 events using climate records is limited. While the availability of measured data is a limitation
558 that could affect the modelled streamflow, discontinuous climate records also hindered the
559 estimations of long time series streamflow.

560 Over the course of the 31-year modelling period, a number of climate stations used for
561 regionalisation were decommissioned and were replaced by stations in different areas. This
562 required adaption of climate regionalisation for simulations over the entire 31-year period to
563 incorporate the measured streamflow from the gauging station. To account for missing
564 streamflow records since 2007, an EMD filtering protocol was applied to the runoff data (Fig.
565 6). The results from the EMD filtering showed that after removing the first nine IMFs, the local
566 maxima of both signals match the seasonal water level maxima during most of the years. While
567 considerable improvement can be made to the EMD filtering, the results show some agreement
568 which suggested that the simulated runoff was representative of inflows into the lake.

569 **5.2 Catchment dynamics**

570 Factors that impact streamflow variability are important for understanding river flow regime
571 dynamics. Previously, factors that affected streamflow variability such as CV and BFI values
572 were used to determine how susceptible particular river systems were to drought (e.g Hughes
573 and Hannart, 2003). While CV values have been used to account for climatic impacts such as
574 dry and wet cycles, BFI values are associated with runoff generation processes that impact the
575 catchment. For most river systems, BFI values are generally below 1 implying that runoff
576 exceeds baseflow. In comparison CV values can be in excess of 10 implying high variability
577 in streamflow volumes (Hughes and Hannart, 2003). In this study, these two measurements

578 have been applied to tributaries as opposed to quaternary river systems, to understand the
579 streamflow input variability into the Verlorenvlei.

580 The highest proportion of streamflow needed to sustain the Verlorenvlei lake water level is
581 received from the Bergvallei tributary, although the area weighted contribution from Krom
582 Antonies is more significant (Fig. 10). However, CV values for the Bergvallei indicate high
583 streamflow variability. This is partially due to the high surface runoff component in modelled
584 streamflow within the Bergvallei in comparison to the minor interflow contribution, suggesting
585 little sub-surface runoff. While streamflow from the Bergvallei tributary is 54 % groundwater,
586 which would suggest a more sustained streamflow, due to the TMG dominance as well as a
587 high primary aquifer contribution, baseflow from the Bergvallei is driven by highly conductive
588 rock and sediment materials. Similarly, CV values for Krom Antonies indicate high streamflow
589 variability due to the presence of a high baseflow contribution from the conductive TMG and
590 primary aquifers. Although Krom Antonies has a larger interflow component, which would
591 reduce streamflow variability, the dominant TMG presence within this tributary partially
592 compensates for the subsurface flow contributions.

593 In contrast, Hol has a much smaller daily streamflow variability in comparison to both
594 Bergvallei and Krom Antonies (Fig. 9). While streamflow from Hol tributary is mainly
595 comprised of baseflow (56 %), the dominance of low conductive shale rock formations as well
596 as a large interflow component results in reduced streamflow variability. While the larger shale
597 dominance in this tributary not only results in a more sustained baseflow from the secondary
598 aquifer, it also results in a large interflow component due to the limited conductivity of the
599 shale formations. Compounding the more sustained baseflow from Hol tributary, the reduced
600 extent of the primary aquifer results in a dominance in slow groundwater flow from this
601 tributary. Similarly, Kruismans is dominated by shale formations which result in a larger

602 interflow contribution, although due to the limited baseflow contribution (37 %) the streamflow
603 from this tributary is highly variable, which impacts on its susceptibility to drought.

604 The results from this study have shown that while Krom Antonies was initially believed to be
605 the major flow contributor, Bergvallei is in fact the most significant, although streamflow from
606 the four tributaries is highly variable, with baseflow from Hol tributary the only constant input
607 source. The presence of conductive TMG sandstones and quaternary sediments in both Krom
608 Antonies and Bergvallei, results in quick baseflow responses with little flow attenuation. The
609 potential implication of a constant source of groundwater being provided from Hol tributary,
610 is that if the groundwater is of poor quality this would result in a constant input of saline
611 groundwater, with Krom Antonies and Bergvallei providing freshwater only after sufficient
612 rainfall has been received.

613 **5.3 Baseflow comparison**

614 The groundwater components of the J2000 model were adjusted using aquifer hydraulic
615 conductivity from a MODFLOW model of one of the main feeding tributaries of the
616 Verlorenvlei. Krom Antonies was selected as it was previously believed to be the largest input
617 of groundwater to Verlorenvlei (Fig. 2). Baseflow for Krom Antonies tributary was previously
618 calculated using a MODFLOW model (Watson, 2018), by considering aquifer hydraulic
619 conductivity and average groundwater recharge. As average recharge was used, baseflow
620 estimates from MODFLOW are likely to fall on the upper end of daily baseflow values
621 estimated by the J2000 model. For Krom Antonies sub-catchment, Watson, (2018) estimated
622 baseflow between 14,000 to 19,000 m³.d⁻¹ for 2010-2016 using MODFLOW. Similar daily
623 baseflow estimates from the J2000 were only exceeded 10 % of the time, with average
624 estimates (50 %) of 1,036 m³.d⁻¹ over the course of the modelling period (Fig. 9).

625 The MODFLOW estimates were applied over the course of a wet cycle (2016). In comparison
626 to the MODFLOW estimates (14,000 to 19,000 m³.d⁻¹) average baseflow from J2000 for 2016
627 was 8, 214 m³.d⁻¹. The daily timestep nature of the J2000 is likely to result in far lower baseflow
628 estimates, as recharge is only received over a 6-month period as opposed to a yearly average
629 estimate. One possible implication of this is that while common groundwater abstraction
630 scenarios have been based on yearly recharge, abstraction is likely to exceed sustainable
631 volumes during dry months or dry cycles and this could hinder the ability of the aquifer to
632 supply baseflow. While the groundwater components of the J2000 have been distributed to
633 allow for improved baseflow estimates, the groundwater calibration was applied to Krom
634 Antonies. However, this study showed that Bergvallei has been identified as the largest water
635 contributor. In hindsight, the use of geochemistry to identify dominant tributaries could have
636 aided the groundwater model adaption. While it would have been beneficial to adapt the
637 groundwater components of the J2000 using the dominant baseflow contributor, considering
638 the geological heterogeneity between tributaries is more important for identifying how to adapt
639 the groundwater components of the J2000. While the distribution of aquifer components
640 improved modelled baseflow, including groundwater abstraction scenarios in baseflow
641 modelling in the sub-catchment is important for future water management for this ecologically
642 significant area.

643 **5.4 The Verlorenvlei reserve and the evaporative demand**

644 For this study, exceedance probabilities were estimated through rainfall/runoff modelling for
645 the previous 31 years within the Verlorenvlei sub-catchment. The exceedance probabilities
646 were determined for each tributary, as well as the total inflows into the lake. These exceedance
647 probabilities were compared with the evaporative demand of the lake, to understand whether
648 inflows are in surplus or whether the evaporation demand exceeds inflow.

649 From the exceedance probabilities generated in this study, the lake is predominately fed by less
650 frequent large discharge events, where on average the daily inflows to the lake do not sustain
651 the lake water level. This is particularly evident in the measured water level data from station
652 G3T001, where measured water levels have a large daily standard deviation (0.62) (Watson *et*
653 *al.*, 2018). The daily inflows of water into the Verlorenvlei has also been subject to significant
654 rainfall variability, with yearly rainfall between the second wet cycle (2007-2017) being twice
655 as variable in comparison to the first wet cycle (1987-1996). The change in rainfall variability
656 has had a significant impact on soil moisture conditions, resulting in not only larger peak
657 discharges but also lengthened low flow conditions. With climate change likely to impact the
658 length and severity of dry cycles, it is likely that the lake will dry up more frequently into the
659 future, which could have severe implications on the biodiversity that relies on the lake's habitat
660 for survival. Of importance to the lake's survival is the protection of river inflows during wet
661 cycles, where the lake requires these inflows for regeneration.

662 While the impact of irrigation could not be incorporated, over allocation of water resources
663 may potentially have a significant impact on the catchment water balance, especially during
664 wet cycles when ecosystems are recovering from dry conditions. The increased irrigation
665 during wet cycles as a result of agricultural development, could be a further impact on the
666 recovery of sensitive ecosystems. This type of issue is not limited to Verlorenvlei but applies
667 to many wetlands or estuarine lakes around the world, while they have been classified as
668 protected areas, water resources within the catchments are required for food security. As
669 climate change drives increased temperatures and variability in rainfall, the \pm 10-year cycles
670 of dry and wet conditions may no longer be valid anymore, where these conditions may shorten
671 or lengthen. With the routine breaking of weather records across the world (Bruce, 2018; Davis,
672 2018), it is becoming increasingly evident that conditions are changing and becoming more

673 variable, which could impact sensitive ecosystems around the world, highlighting the need for
674 effective water management protocols during times of limited rainfall.

675

676 **6. Conclusion**

677 Understanding river flow regime dynamics is important for the management of ecosystems that
678 are sensitive to streamflow fluctuations. While climatic factors impact rainfall volumes during
679 wet and dry cycles, factors that control catchment runoff and baseflow are key to the
680 implementation of river protection strategies. In this study, groundwater components within
681 the J2000 model were distributed to improve baseflow and runoff proportioning for the
682 Verlorenvlei sub-catchment. The J2000 was distributed using groundwater model values for
683 the dominant baseflow tributary, while calibration was applied to the dominant streamflow
684 tributary. The model calibration was hindered by the DT limit, which reduced the confidence
685 in modelling high flow events, although an EMD filtering protocol was applied to account for
686 the resolution limitations and missing streamflow records. The modelling approach would
687 likely be transferable to other partially gauged semi-arid catchments, provided that
688 groundwater recharge is well constrained. The daily timestep nature of the J2000 model
689 allowed for an in-depth understanding of tributary flow regime dynamics, showing that while
690 streamflow variability is influenced by the runoff to baseflow proportion, the host rock or
691 sediment in which groundwater is held is also a factor that must be considered. The modelling
692 results showed that on average the streamflow influxes were not able to meet the evaporation
693 demand of the lake, with yearly rainfall becoming more variable. High-flow events, although
694 they occur infrequently, are responsible for regeneration of the lake's water level and ecology,
695 which illustrates the importance of wet cycles in maintaining biodiversity levels in semi-arid
696 environments. With climate change likely to impact the length and occurrence of dry cycle
697 conditions, wet cycles become particularly important for ecosystem regeneration, especially
698 for semi-arid regions such as the Verlorenvlei.

699 **7. Acknowledgements**

700 The authors would like to thank the WRC and SASSCAL for project funding, the NRF and
701 Iphakade for bursary support and the Agricultural Research Council (ARC) and South African
702 Weather Service (SAWS) for granting access to climate and rainfall data. The research was
703 carried out in the framework of SASSCAL and was funded by the German Federal Ministry of
704 Education and Research (BMBF) under promotion number 01LG1201E. This contribution has
705 an Iphakade publication number of 227. The authors would like to thank Dimitrios Stampoulis,
706 two anonymous reviewers as well as Sara Andersson for useful ideas in improving the
707 manuscript.
