## Abstract

Reliable estimates of daily, monthly and seasonal soil moisture are useful in a variety of disciplines. The availability of continuous in situ soil moisture observations in southern Africa barely exists hence, process-based simulation model outputs are a valuable source of climate information, needed for guiding farming practises and policy interventions at various Spatio-temporal scales. The aim of this study is to evaluate soil moisture outputs from simulation and satellite-based soil moisture products and to study how models compare in parting soil moisture organisation for different landscapes. The simulation model consists of a global circulation model known as the conformal-cubic atmospheric model (CCAM), coupled with the CSIRO Atmosphere Biosphere Land Exchange model (CABLE). The satellite-based soil moisture data products include satellite observations from the European Space Agency (ESA) and satellite observation-based model estimates from the Global Land Evaporation Amsterdam Model (GLEAM). The evaluation is done for both the surface (0-10 cm) and root zone (10-100 cm) using in situ soil moisture measurements collected from two study sites. The results indicate that both the simulation and satellite data derived models produce outputs that are higher in range compared to in situ soil moisture observations at the two study sites, especially at the surface. The coefficient of determination ranges between 0.4 to 0.75 (at the root zone) and 0.5 to 0.8 (at the surface), suggesting that models are able to explain more than 40 and 50% of the variability in the observed soil moisture states at the respective levels. An analysis evaluating phase agreement using the cross-wavelet analysis has shown that the models are generally in phase, occasionally with a time lag not exceeding 20 days on average. An analysis of soil moisture mutual (MI) information between CCAM-CABLE and each of the GLEAM models reveals that the residual soil moisture distribution from the process-based model and satellite observation-based model

estimates have more coincidence at the root zone relative to the surface. The high MI (between 1 and 2) among the respective models is reflected for most of landscapes albeit high lying ones.

**Keywords:** atmospheric model, cross wavelet, flux tower, land surface model, soil moisture

## 1 Introduction

Accurate estimates<sup>1</sup> of daily, monthly and seasonal soil moisture is important in a number of fields including agriculture (McNally et al., 2016), water resources planning (Decker, 2015), weather forecasting (van den Hurk et al., 2012) and the quantification of the impacts of extreme weather events such as droughts (Sheffield and Wood, 2008), heat waves (Fischer et al., 2007; Lorenz et al., 2010) and floods (Brocca et al., 2011). Soil moisture has been identified as one of the 50 essential climate variables (ECVs) by the Global Climate Observing System (GCOS) and the European Space Agency climate change initiative (ESA-CCI) (McNally et al., 2016). Available soil moisture affects the fluxes of heat and water at the surface and directly impacts local and regional weather patterns (Dorigo et al., 2015; Raoult et al., 2018; Yuan and Quiring, 2017).

Soil moisture is a key parameter to consider in the partitioning of precipitation and net radiation. The temporal and spatial variation in soil moisture is controlled by vegetation, topography, soil properties and climate variability (Xia et al., 2015). Root zone soil moisture plays a vital role in the transpiration process of evapotranspiration (ET) especially in arid and semi-arid regions, where most of the water loss is accounted for by transpiration during the dry period (Jovanovic et al., 2015; Palmer et al., 2015). The dry period, which is constituted by months when the sites experience minimum rainfall, occurs during the austral winter season May to October. Regions where soil moisture strongly influences the atmosphere is at the transition between wet and dry climates. This is associated with the strong coupling between ET and soil moisture which is a characteristic of these regions (van den Hurk et al., 2012; Lorenz et al., 2010).

The model evaluation in this study is achieved through a qualitative and quantitative comparison of modelled and in situ soil moisture products. Modelled and Satellite data derived soil moisture fields can be derived at different temporal and spatial resolutions while in site observations are mainly point-based (Fang et al., 2016). Despite the in situ data being limited in coverage, they are very useful for the calibration and validation of modelled and satellite-derived soil moisture estimates (Xia et al., 2015). Point-based in situ soil moisture data that are used as a reference in this study consist of surface and root zone measurements. The fact that the in situ data are point-based, poses significant challenges in the understanding of spatial patterns in soil moisture (Yuan and Quiring, 2017). Direct satellite observations, on the other hand, are presently only available for the surface. To obtain root zone estimates of soil moisture satellite-based surface soil moisture data are used in conjunction with ground-based observations and model estimates. The modelled soil moisture data are largely dependent on accurate surface forcing data (e.g. air temperature, precipitation and radiation) and the parameterisation of the land surface schemes (Xia et al., 2015). This is done in the framework of physically-based models whose accuracy may vary depending on the response of the models to the forcing data.

The study is inspired by the notion that an understanding of soil moisture characteristic patterns, for the study region can be reliably obtained by looking at independent datasets from simulation

---

<sup>1</sup> *Estimate* here refers to both process-based model simulation and satellite-derived data products thereafter, the term *simulation* will be used for process-based model outputs while *estimates* will be reserved for satellite-derived data.

80 experiments, theoretical or analytical models and in situ observations. In Africa, the evaluations of the  
soil moisture data products, from these various estimation approaches, are sparse mainly due to the  
lack of publicly available in situ observations (Sinclair and Pegram, 2010). The lack of publicly  
available long term and complete in situ soil moisture measurements in most parts of the world leads  
to a reliance on global climate models (GCMs) to estimate the land surface states (Dirmeyer et al.,  
2013). The data produced by land surface models, hydrological models and GCMs have been widely  
85 evaluated for many continents and regions (Albergel et al., 2012; An et al., 2016; Dorigo et al., 2015;  
McNally et al., 2016; Yuan and Quiring, 2017). The available studies include those conducted by  
McNally et al. (2016) and Dorigo et al. (2015) evaluating ESA-CCI satellite soil moisture products  
over East and West Africa respectively.

90 The aims of this study are twofold. Firstly, it is to evaluate the ability of the process-based simulation  
and satellite-derived soil moisture products to capture the observed variability in soil moisture at  
specific flux tower locations. Secondly, to understand how a coupled land-atmosphere model  
simulated results of soil moisture compare against satellite-based estimates on broad landscape classes  
that belong to homogenous elevation and soil types. The evaluation is undertaken at two soil depths  
namely; surface (SSM, i.e., 0-10 cm) and root zone (RZSM, i.e. 10-100 cm), using long term in situ  
95 measurements with the objective of establishing if the respective soil moisture data products are  
representative of local conditions This is done for two study sites whose data records are publicly  
available, namely the Skukuza and Malopeni flux tower sites located in the Kruger National Park in  
South Africa. Of these two sites, only the Skukuza site forms part of the global flux data network  
(FLUXNET). Other international flux observation networks, such as the International Soil Moisture  
100 Network (ISMN) have no affiliated data sites on the study region.

An investigation of how the CCAM-CABLE process-based simulation, satellite-derived and GLEAM  
model estimates compare with the in situ observations, we look at Spatio-temporal variations in  
simulated soil moisture data from a coupled land-atmosphere model i.e., the conformal cubic  
atmospheric model (CCAM) of the Commonwealth Scientific and Industrial Research Organisation  
105 (CSIRO) coupled to the CSIRO Atmosphere Biosphere Land Exchange (CABLE) model against the  
three versions of the European Space Agency (ESA) satellite observations (i.e., active, passive and  
combined), and estimates from three versions of the global land evaporation Amsterdam Model  
(GLEAM). The central idea is to understand how processed based models and satellite-based models  
spatial patterns compare at a regional level with a focus on grid points that belong to specific  
110 landscapes classes. This is done for landscapes where the availability of in situ observations over  
space and time presents a major challenge for climate model evaluation studies. We focus on the  
periodic patterns of soil moisture at a point. In particular, we investigate, both quantitatively and  
qualitatively, the agreement in phase and magnitude between the respective soil moisture data  
products with a view of establishing if they are representative of local conditions.

115 An understanding of the extent to which the climate model simulations and GLEAM model estimates  
have similar patterns at a regional level within inter-annual time scales is achieved by looking at a  
measure of their mutual information (MI). Model correspondence in capturing dominating processes  
is investigated by looking at the modelled soil moisture signal mutual information (MI). This is done  
for different landscapes organised by dominating soil and vegetation types, as well as altitude ranges  
120 across the study region. The study seeks not only to uncover interesting patterns in the observed data,  
for the study region but also to highlight the strengths as well as aspects of the climate model  
simulation and GLEAM estimates which may benefit from continuous testing and improvement.

125 The ability of models to capture seasonal cycles of terrestrial processes such as soil moisture is  
indicative of how well the physical processes that underlie the variability of soil moisture over space  
and time are represented. A comparison of satellite-derived products with in situ observations may  
also yield useful insight into the strengths and weaknesses of various remote sensing techniques that  
are used. A climate models' ability to represent and capture the seasonality of a system under inter-  
and intra-annual climate variability could be considered more important than its agreement with  
130 observations in absolute values (Fang et al., 2016). The remainder of the study is structured as  
follows: Sect. 2 describes the datasets used, the study design and methods for analysing the datasets.  
Section 3 presents the results and the discussion, followed by the conclusions in Sect. 4.

## 2 Materials, methods and data

### 2.1 Study sites and in situ observations

135 In situ soil moisture measurements from the Council for Scientific and Industrial Research (CSIR)  
operated network of eddy covariance flux towers, in the Lowveld region of the Mpumalanga  
(Skukuza) and Limpopo (Malopeni) provinces are used. Several other soil moisture in situ  
measurements sites exist in the country. However, their data are not publicly available.

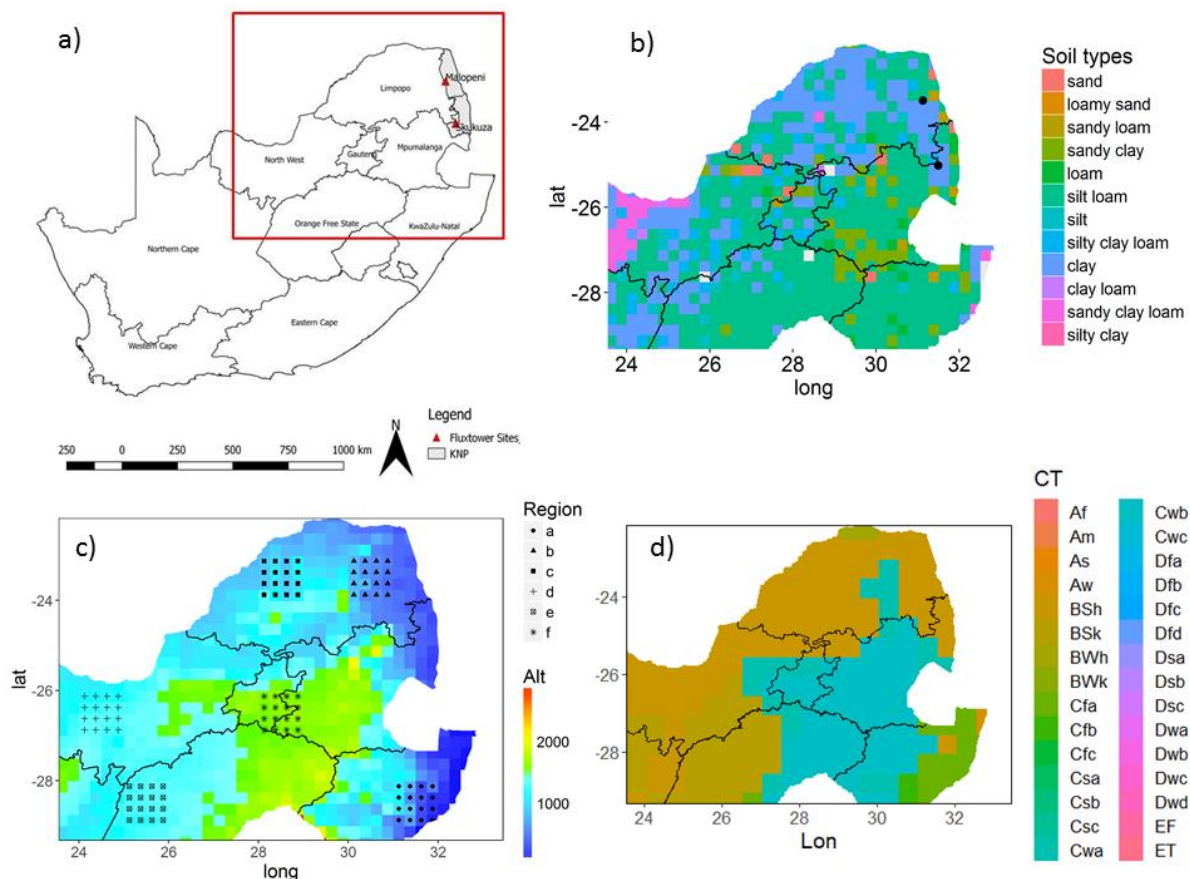

#### 2.1.1 Skukuza

140 The Skukuza flux tower site is a long-term measurement site, located within the Kruger National Park  
conservation area in South Africa (25.0197° S, 31.4969° E; Fig. 1). The Skukuza flux tower has been  
operational from 2000 to present. The site falls within a semi-arid savanna biome at an altitude of 370  
m above sea level, with a mean rainfall of 547 mm year<sup>-1</sup>, and average annual minimum (during the  
dry season) and maximum (during the wet season) temperatures of 14.5 and 29.5°C, respectively for  
the averaging period from 2001 to 2014. The vegetation is dominated by an overstory of *Combretum*  
145 *apiculatum* (Sond.), and *Sclerocarya birrea* (Hochst.) with a height of approximately 8-10 m, and a  
tree cover of approximately 30% (Archibald et al., 2009). The understory is a grass layer dominated  
by *Panicum maximum* (Jacq.), *Digitaria eriantha* (Steud.), *Eragrostis rigidior* (Pilg.) and  
*Pogonarthria squarrosa* (Roem. and Schult.). The soil is of the Clovelly form with a sandy loam  
texture (Feig et al., 2008), and the dominant soil type for the 25 km resolution grid cell where the flux  
150 tower is located is silty loam (Fig. 1). The Skukuza flux tower site is extensively described in previous  
studies including those by Archibald et al. (2009), Scholes et al. (2001) and Khosa et al. (2019). In  
situ soil moisture data are collected 90 m north of the tower, and the measurements are taken at two  
profiles which are 8 m apart. The sensors are located at four different depths for both profiles i.e., 5,  
15, 30 and 40 cm (Pinheiro and Tucker, 2001). Time-domain reflectometry (TDR) probes (Campbell  
155 Scientific CS615L) are used to measure soil moisture at a 30-minute temporal resolution. These  
measurements were averaged to a daily time period (using an 80 % threshold of half-hourly data to  
represent a day) to match the resolution of the other soil moisture products. For this study, the in situ  
data from the year 2001 to 2014 are used.

#### 2.1.2 Malopeni

160 The Malopeni flux tower is located 130 km North west of the Skukuza flux tower (23.8325° S,  
31.2145° E; Fig. 1), at an elevation of 384 m above sea level. The tower has been collecting data since  
2008 to present, however, data was not collected between January of 2010 and January of 2012 due to  
equipment failure. The site has a mean rainfall of 472 mm year<sup>-1</sup>, and annual average minimum and  
maximum air temperatures of 12.4 and 30.5°C respectively, for the averaging period from 2008 to

165 2014. The site is dominated by broadleaf *Colophospermum mopane*, which characterises a hot and dry savanna (Ramoelo et al., 2014), *Combretum apiculatum* and *Acacia nigrescens* are also abundant at the site. The grass layer is dominated by *Schmidtia pappophoroides* and *Panicum maximum*. The soil at the site is predominantly of the shallow sandy loam texture, and the dominant soil type for the 25 km resolution grid cell where the flux tower is located is silty loam (Fig. 1). The soil moisture probes are located at four different profiles and depths. The sensor types and depths positioning are the same for the Malopeni and Skukuza flux tower sites. Soil moisture is collected at four different profiles (i.e., 16 sensors at four depths per site) and averaged to represent surface and root zone soil moisture at the site, for Skukuza only sensors at two profiles are working (i.e., 8 sensors).

175 **Figure 1.** Maps indicating (a) South Africa, Kruger national park (KNP), flux tower sites (Skukuza and Malopeni) and the area considered for grid inter-comparison (red box), (b) dominant soil types (<https://soilgrids.org>) per grid cell, at a resolution of 25 km, (c) the altitude (Alt, m) at the study region at a 25 km resolution, with the selected grid points clusters ( i.e., a-f) demarcating landscape classes that belong to specific elevation categories labelled in the order of the increasing altitude, the elevation dataset is obtained from the national centers for environmental information (<https://www.ngdc.noaa.gov/mgg/fliers/06mgg01.html>)  
180 (d) Köppen-Geiger climate types (CT) across the study region at a 50 km resolution (<http://koepen-geiger.vu-wien.ac.at/present.htm>).

## 2.2 Datasets

### 2.2.1 Soils texture data

185 The “SoilGrids” dataset from the international soil reference information centre (ISRIC) was used in this study to map soil types (Fig. 1b). The data are available online (<https://soilgrids.org>), and is described in detail in the study by Hengl et al. (2017). The dataset has a spatial resolution of 250 m

and is resampled to 25 km, firstly by resampling to 1 km and then to 25 km, using the nearest neighbour method to match the resolution of the soil moisture products. We acknowledge that resampling from fine to coarse resolution might introduce a bias towards certain soil types. However, the nearest neighbour method is suitable for resampling categorical data. Soils were classified into 12 dominant types ranging between sand and silty clay as shown in Fig. 1d. The soil type data are available at various depths, here we only consider the data representing the surface (i.e., 0-5 cm).

## 2.2.2 Satellite observations

The European Space Agency climate change initiative (ESA-CCI) satellite-derived soil moisture datasets are used in this study (Liu et al., 2012; Yuan and Quiring, 2017). These global datasets are based on passive and active satellite microwave sensors, and provide surface soil moisture estimates at a resolution of ~25 km (i.e., 0.25°) (Fang et al., 2016; Yuan and Quiring, 2017). The ESA-CCI merges soil moisture estimates from the active and passive satellite microwave sensors into one dataset (<http://www.esa-soilmoisture-cci.org/>), using the backward propagating cumulative distribution function method (Dorigo et al., 2015; Fang et al., 2016). A detailed description of the merged active and passive sensors and their functioning is provided by Fang et al. (2016), Dorigo et al. (2015) and Liu et al. (2012). The merging of active and passive sensors is based on their sensitivity to vegetation density, as the accuracy of these products varies as a function of vegetation cover (Liu et al., 2012). In this study, version 3.2 (v3.2) of the ESA-CCI soil moisture data is used. The merged data product is used in this study as it has better data coverage compared to the individual products. Missing data in satellite products are not unusual since retrievals are normally at an interval of 2-3 days (Albergel et al., 2012). However, data from each of the different sensor types are also considered for the evaluation of long-term seasonal cycles.

## 2.3 Models for simulating soil moisture

### 2.3.1 CCAM-CABLE

The variable-resolution atmospheric model CCAM developed by the CSIRO in Australia (McGregor, 2005; McGregor and Dix, 2001, 2008) was used to dynamically downscale ERA reanalysis data to 8 km resolution over north-eastern South Africa (Fig. 1a) for the period 1979-2014. Similar downscaling of reanalysis data obtained over southern Africa using CCAM are described by Engelbrecht et al. (2011), Dedekind et al. (2016) and Horowitz et al. (2017). The ability of the CCAM model to realistically simulate present-day southern African climate has been extensively demonstrated (e.g. Engelbrecht et al., 2015, 2009, 2011; Malherbe et al., 2013; Winsemius et al., 2014). The CABLE soil sub-model expresses soil as a heterogeneous system consisting of three constituent phases namely water, air and solid (Kowalczyk et al., 2006; Wang et al., 2011). Air and water compete for the same pore space, and the change in their volume fractions is due to drainage, precipitation, ET and snowmelt. In this model, there is no heat exchange between the moisture and the soil due to the vertical movement of water, as soil moisture is assumed to be at ground temperature. The soil is partitioned into six layers, with the layer thickness of 0.022 m, 0.058 m, 0.154 m, 1.085 m and 2.875 m from the top layer. Only the top layer contributes to evaporation while plant roots extract water from all layers depending on the soil water availability and the fraction of plant roots in each layer (Wang et al., 2011). Soil moisture is solved numerically using the Richard's equation (Kowalczyk et al., 2006).

### 2.3.2 GLEAM

230 The Global Land Evaporation Amsterdam Model (GLEAM) version 3.1 is a set of algorithms used to estimate surface, root-zone soil moisture and terrestrial evaporation using satellite forcing data (Martens et al., 2017). The method is based on the use of the Priestley and Taylor (1972) evaporation model, stress module, and the rainfall interception model (Miralles et al., 2011). Three data sets from the GLEAM namely v3a, v3b and v3c were used in this study. The data are freely available at  
235 www.gleam.eu. Version 3a is based on satellite observed soil moisture, snow water equivalent and vegetation optical depth, reanalysis radiation and air temperature, and a multi-source precipitation product. Versions 3b and 3c are satellite-based with common forcing data excluding soil moisture and vegetation optical depth, these are based on different passive and active microwave sensors, i.e., ESA CCI for v3b and Soil Moisture and Ocean Salinity (SMOS) for v3c (Martens et al., 2017).

240 The different components of terrestrial processes (i.e., transpiration, open-water evaporation, bare soil evaporation, sublimation and water loss) are separately driven in GLEAM (Martens et al., 2017). Each grid cell in GLEAM contains fractions of four different land cover types namely: open water (e.g. dam, lake), short vegetation (i.e., grass), tall vegetation (i.e., trees) and bare soil. These fractions are based on the global vegetation continuous field product (MOD44B) except for the fraction of open  
245 water. The MOD44B product is based on the moderate resolution image spectroradiometer (MODIS) observations (Martens et al., 2017). Soil moisture is estimated separately for each of these fractions and then aggregated to the scale of the pixel based on the fractional cover of each land cover type. Root zone soil moisture is calculated using a multi-layered water balance equation which uses snowmelt and net precipitation as inputs, and drainage and evaporation as outputs (Miralles et al.,  
250 2011). The depth of soil moisture is a function of land-cover type comprising one layer of bare soil (0-10 cm), two layers for short vegetation (0-10, 10-100 cm) and three layers for tall vegetation (0-10, 10-100, and 100-250 cm) (Martens et al., 2017).

## 2.4 Analysis approach and data processing

### 2.4.1 Statistical analysis

255 The first part of the analysis focuses on evaluating the monthly time series data of soil moisture products at the site level using observations. The monthly temporal scale is considered because, on very short time scales such as daily and hourly, local effects can lead to a pronounced noise in the observations. Such noise, however, is anticipated to be filtered through a long term average. At a monthly time scale, the soil moisture seasonal cycle is well developed. A data threshold of 80 % is  
260 used to average daily data to monthly. Months that did not meet the 80 % threshold were excluded from the analysis.

Time series data for the evaluation sites, were extracted from the soil moisture products, using the flux tower's geographical coordinates. The satellite products present averaged soil moisture data per grid cell. A distance-weighted average (DWA) technique was used to interpolate the CCAM-CABLE  
265 model simulations to estimate soil moisture values representative of observational sites. The DWA method proved to be more representative than the nearest neighbour (NN) method, as the DWA method interpolates to the exact location of the tower by considering simulated values at grid points surrounding the location. It is noteworthy, that a comparison between the in-situ observations and satellite products in this study places much emphasis on phase agreement (e.g. seasonal cycle), as  
270 opposed to that of magnitudes. This is because satellite observations and GLEAM estimates are represented as spatial averages for each pixel, in which case an interpolation of such aerial averages to

a point (i.e., site), do not add further information that corresponds to the site. It is expected that data at the point and grid box scales should still comparatively present qualitative features that are characteristic of the climate system for the region, for example, seasonal cycles.

275 The soil moisture products were first converted to the percentage of volumetric soil moisture amounts for comparison purposes. As in Yuan and Quiring (2017), we assume that the soil moisture measurements at the 5 cm depth are representative of the depth range 0–10 cm. In situ data at depths 15, 30 and 40 cm were combined using the depth weighted average method to represent the 10-100 cm depth using Eq. (1):

$$280 \quad SM_{10-100} = \sum_{i=1}^n \frac{LT}{SD} \times SM(i) \quad (1)$$

where  $SM_{10-100}$  is the weighted soil moisture,  $n$  is the number of layers,  $LT$  is the layer thickness calculated as the difference between the soil depths,  $SD$  is the total soil depth of the soil profile and  $SM(i)$  the daily in situ soil moisture values at the  $i^{\text{th}}$  layer. The depth weighted average method as presented in this study (Eq. 1) has been used in other studies such as that by Yuan and Quiring (2017).  
285 Similarly, the data at depths 2.2 and 5.8 cm, and 15.4 and 40.9 cm from CCAM-CABLE are averaged to represent 0-10 and 10-100 cm respectively using Eq. (1).

**Table 1.** Overview of soil moisture datasets; satellite (grey) in percentage, modelled (blue), simulation (pink) and in situ observations (green) presented as a ratio ( $\text{m}^3 \text{m}^{-3}$ ) of soil to moisture per unit area.

Soil moisture product	Spatial resolution (km)	Spatial coverage	Soil depth (cm)	Period
ESA-Combined	25	Global	0-10	1978-2015
ESA-Active	25	Global	0-10	1991-2015
ESA-Passive	25	Global	0-10	1978-2015
CCAM-CABLE	8	Regional	2.2, 5.8, 15.4, 40.9, 108.5, 287.2 (bedrock)	2000-2014
Skukuza	Point data	Point	5, 15, 30, 40	2000-2017
Malopeni	Point data	Point	5, 15, 30, 40	2008-2017
GLEAM v3a	25	Global	0-10, 10-100	1980-2016
GLEAM v3b	25	Global	0-10, 10-100	2003-2015
GLEAM v3c	25	Global	0-10, 10-100	2011-2015

290 The soil moisture products used in this study (Table. 1) are under the same latitude and longitude projection. All the soil moisture projections are at the same spatial resolution of 25 km, except for the

CCAM-CABLE model with a resolution of 8 km. The bilinear interpolation method was used to resample the CCAM-CABLE simulations from 8 to 25 km to match the resolution of the other soil moisture products. To evaluate how close the modelled soil moisture estimates are to in situ measurements, we used the coefficient of determination ( $R^2$ ), as defined in Koirala and Gentry (2012), as well as the cross-wavelet analysis.

### 2.4.2 Cross-wavelet analysis

The cross-wavelet method analyse the frequency structure of a bivariate time series using the Morlet wavelet (Veleda et al., 2012). The wavelet method is suitable for analysing periodic phenomena of time series data, especially in situations where there is potential for frequency changes over time (Rosch and Schmidbauer, 2018; Torrence and Compo, 1998). The cross-wavelet analysis provides suitable tools to compare the frequency components of two time-series, thereby concluding their synchronicity at a given period and time. In this study, the cross-wavelet analysis is used to qualitatively compare the cyclic patters of the observations and the models' estimates. In particular, it is used to assess if there exist phase differences between dominating periodic features of the in situ observations and the models' estimates. The cross-wavelet analysis algorithm used is described in Rosch and Schmidbauer (2018) and is implemented within the "WaveletComp" package in the R software. This method has been used in other studies, such as that by Koirala and Gentry (2012), for investigating the climate change impacts on hydrologic response.

The cross-wavelet analysis only applies to complete datasets (i.e., without missing values). Since the in situ observations have missing data, the multiple imputations method as discussed in studies by Rubin (1987) and Rubin (1996) has been used to gap-fill the in situ time series. The multiple imputation procedure is implemented in the "Amelia" package also available in the standard repository for R packages. The number of imputed datasets was set to five and combined using Rubin's rules (Rubin, 1996). The multiple imputations method is only applied to the Skukuza dataset both the surface (Fig. C1.a) and root zone (Fig. C1.b). This is because the Skukuza data has fewer gaps compared to Malopeni (Fig. A1.b). The imputed soil moisture observations are shown in Appendix C together with the statistics of the measures of the distribution for both the gap filled and non-gap filled datasets. The cross-wavelet analysis is applied to non-stationary data using the default method (i.e., white noise) with the simulations repeated ten times.

### 2.4.3 Mutual information

The second part of the analysis inter-compares model simulations and satellite estimates of soil moisture at a regional scale. The MI is calculated between the residuals of the de-trended and de-seasonalised time series at a regional scale between the CCAM-CABLE simulations and GLEAM estimates. The de-trended and de-seasonalised procedure before the calculation of the MI is done to ensure that the computed MI is not attributed to the similarities in the trend and cyclic components of the signal, which may be correlated, but it is based on the residual components which are the uncorrelated features of the soil moisture signal. In this way, the MI calculation presents a comparison matrix for inter-model soil moisture spatial pattern comparison. In particular, the MI gives a sense of similarity between the models indicating the level of coincidence or overlap in the distribution of the residuals between a pair of CCAM-CABLE simulations and each of the GLEAM model estimates per grid point. In the case that MI values between models are low the inter-model reflects uncertainty in how the models capture the modelled processes.

335 The de-trending and de-seasonalising of the time series removes the systematic components of the  
signal including bias. This is achieved through an approach reported in a study by Cleveland et al.  
(1990) where the "stl" package, available in the standard package repository in R, is used to de-trend  
the time series into its components. The MI calculation is described in Kraskov et al. (2004) and is  
applied in this study using the "varrank" package which is also available in the R CRAN repository.  
340 The MI measure calculated from the residual components of the respective soil moisture signals  
presents a robust way of assessing if the respective models have a correspondence in spatial patterns  
of soil moisture across landscapes. In this paper, the MI is used as an index for classification of the  
models according to the coincidence in the distribution of residuals at regional level. The MI is  
calculated for the time series ranging between 2011 and 2014 using a de-trended and de-seasonalised  
time series with no systematic components including bias.

### 345 **3 Results and discussion**

#### **3.1 Evaluation of the satellite-estimated and model-simulated seasonal cycle soil moisture**

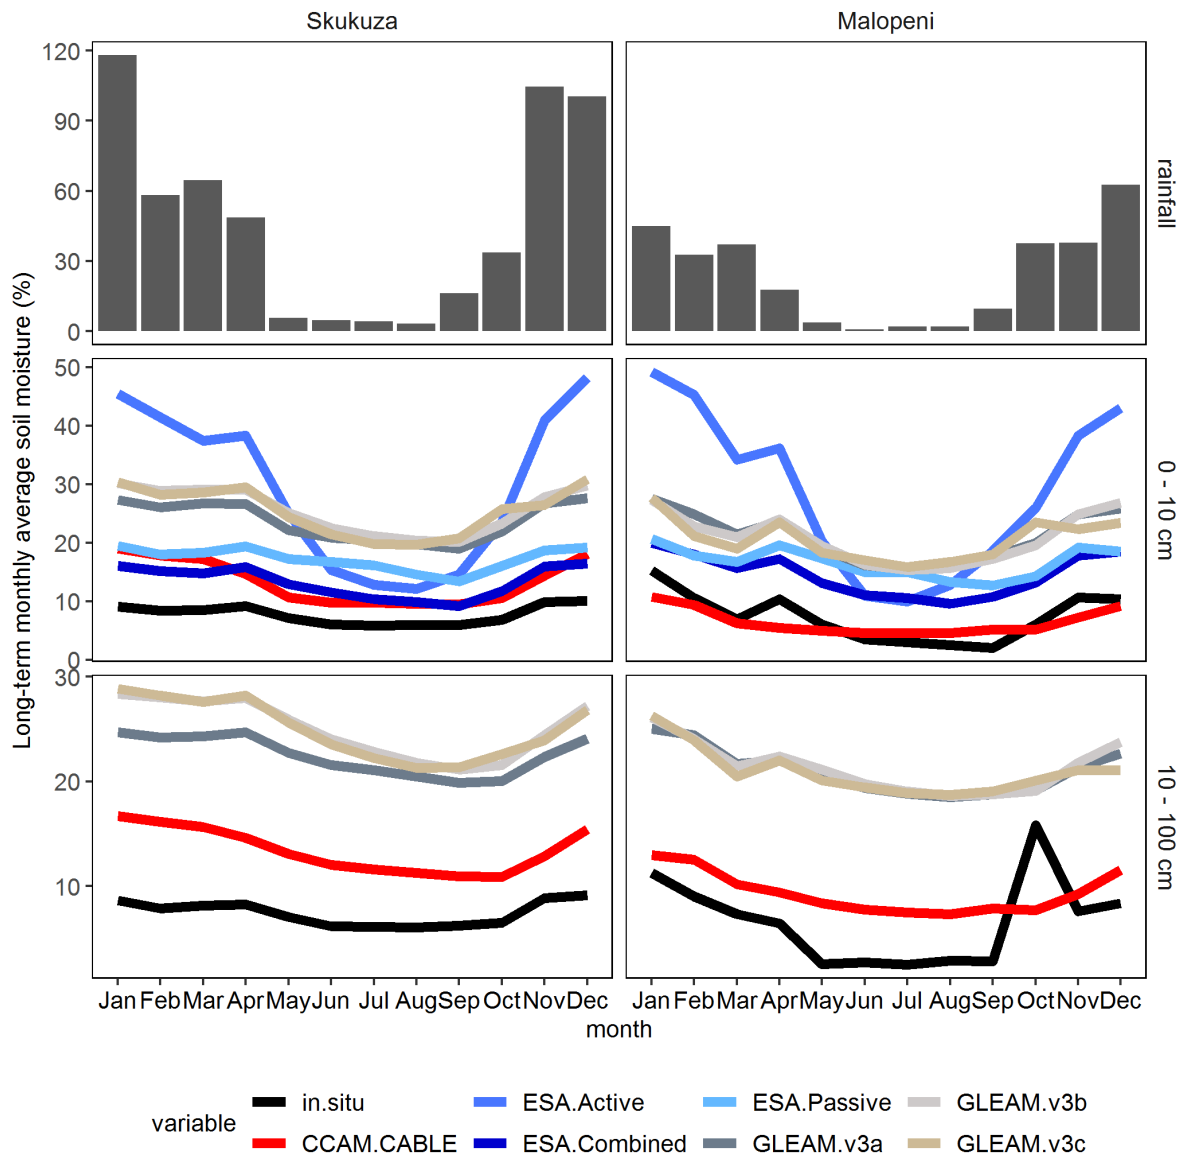

In this section, we discuss how the respective outputs reflect the key features of the observed soil  
moisture. As highlighted in the introduction, the variability of the simulation output, satellite-derived  
350 data and satellite-based model estimates are studied relative to the observations. Much focus is placed  
on investigating how well the periodic features of the soil moisture are reflected by the respective soil  
moisture datasets. The patterns of soil moisture at the study sites are mainly driven by rainfall, which  
is generally higher during the summer season, and low in winter as shown in Fig. 2. The long term  
surface soil moisture for both the sites follows a pattern comparable to that of rainfall as can be seen  
355 in Fig. 2.

##### **3.1.1 Long term seasonal cycles**

The soil moisture patterns presented in Fig. 2 show that the study sites mainly contain higher soil  
moisture at the surface than at the root zone, this is shown by both the modelled soil moisture and the  
observation. This is indicative that, water at these study sites is predominantly lost through runoff and  
360 ET, and only a small fraction infiltrates the soil as is stored at the root zone. In general, there is an  
agreement on the seasonal cycle of soil moisture (Fig. 2) between the various product outputs and the  
observations in terms of phase, especially at the surface. Notably, the observed soil moisture seasonal  
cycle at the surface at both Skukuza and Malopeni surface displays a local maximum in April and  
shows and increases from September to December and January. The general features of the observed  
365 signal are captured by all the models. The soil moisture amplitudes are less pronounced in the root  
zone, but with November and October maxima at Skukuza and Malopeni respectively. In some  
instances, there is a lag such as the one presented by GLEAM v3c (i.e., maxima in October instead of  
November) at the surface, both at Skukuza and Malopeni. The soil moisture patterns are consistent  
with the observed rainfall cycle which undergoes an onset in October and a cessation in April. The  
370 root-level soil-moisture pattern displays a signature of soil moisture retention, which relates to the  
persistence of dry and wet periods at various soil depths (Seneviratne et al., 2006). In light of this, it  
would be interesting to see how both the CCAM-CABLE simulation and the GLEAM soil moisture  
products depict the onset and cessation of the wet season, this will be discussed in Section 3.2. The  
CCAM-CABLE model outputs reflect that soil-moisture reaches its highest values in March rather  
375 than April for Skukuza at the surface. The output does not reproduce the recorded elevated soil  
moisture for Malopeni in April at the surface. This is probably since the CABLE soil-moisture

scheme does not take into account soil resistance (Whitley et al., 2016). Despite this, the long term CCAM-CABLE monthly means of soil moisture are relatively comparable to the observation even in terms of magnitude (Fig. 2).

380 GLEAM v3c, agrees with in situ measurements on the existence of an April soil moisture maximum, but it reflects the observed soil moisture increase, in November, a month earlier (i.e., in October). The satellite observations and GLEAM models (Fig. 2) display the same soil moisture signal as observed at the respective sites, indicating that the April maximum, in particular, is not an artefact of the point observations. We can safely deduce that the bias in GLEAM v3c is not induced by satellite-based  
 385 forcing data. However, this calls for further investigations on the sensitivity of the model to its driving data at a high resolution. We anticipate that at high temporal resolution there is a strong variability in the in situ soil moisture signal which may not entirely be captured by both CCAM-CABLE and GLEAM, possibly due to their relatively low spatial resolution. The relatively low resolution (8 km in the horizontal) in the case of CCAM-CABLE, in particular, potentially has strong implications on  
 390 how representative the effective drivers of soil moisture such as soil texture and vegetation covers are in terms of observations at specific sites.

**Figure 2.** Seasonal variation in the long term mean monthly rainfall (mm), surface (i.e., 0-10 cm) and root zone (i.e., 10-100 cm) soil moisture, based on in situ observations and a variety of soil moisture products. The in situ data is collected from two sites, namely Skukuza (2001-2014) and Malopeni (2008-2013).

The GLEAM models (Fig. 2) are generally consistent with in situ measurements in estimating soil moisture both in terms of phase, both at the surface and root zone. The magnitude of GLEAM v3a root zone estimates is lower than those of the other GLEAM models at the Skukuza site. This can be attributed to the unique multi-source weighted ensemble precipitation (MSWEP) data used to force GLEAM v3a (Martens et al., 2017), which is different to the precipitation forcing data used in GLEAM v3b and v3c. We further observe that the GLEAM models, ESA and in situ observations have the same length of the dry period (i.e., about 4 months), except for the ESA-Active observation which has a shorter dry period (i.e., about 3 months).

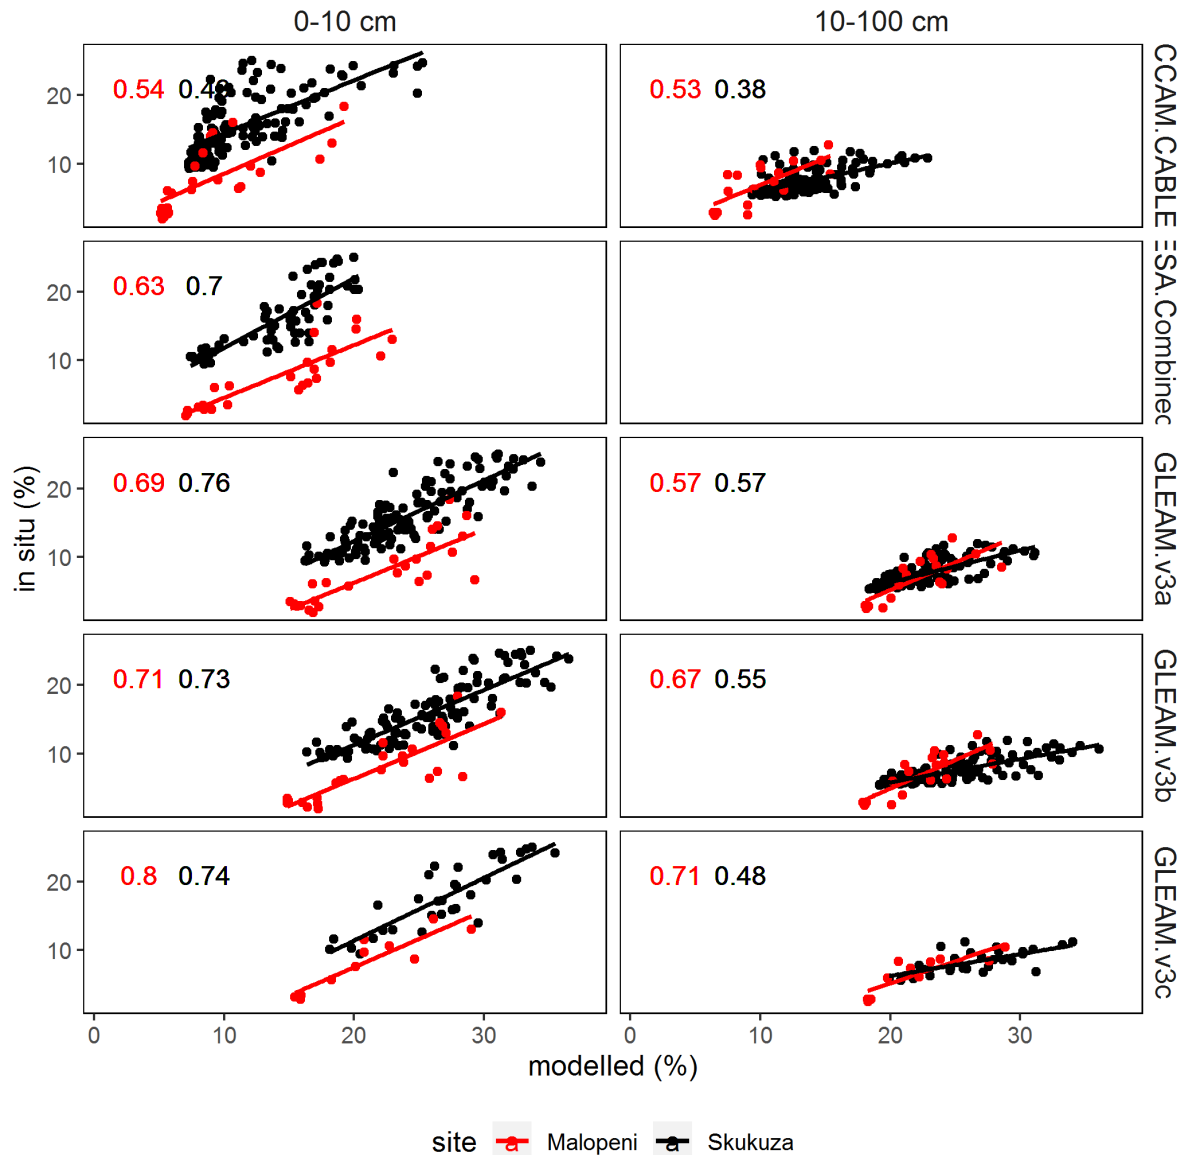

The ESA-Active satellite product is known to work best for moderate to densely vegetated areas as opposed to savanna sites such as Skukuza and Malopeni where tree cover is sparse (Dorigo et al., 2015). There is a minimal difference between the ESA-Passive and ESA-Combined satellite products both in terms of phase and magnitude. Generally, the ESA-Combined and ESA-Passive datasets have the least difference during the dry period for all sites. A number of studies evaluated the ESA products at a regional and global scale using in situ data and concluded that passive sensors displayed improved performance over bare to sparsely vegetated regions, whereas the active sensors perform better in moderately vegetated regions (Al-Yaari et al., 2014; Dorigo et al., 2015; Liu et al., 2012; McNally et al., 2016).

Using long term monthly averages, both the CCAM-CABLE and GLEAM models can capture the intrinsic seasonality of the soil moisture signal for the sites as reflected by both the in situ and satellite observations. This is despite their being different both in the forcing data and model structure. Studies by Wang and Franz (2017) and Seneviratne et al. (2010) suggest that local factors (e.g., vegetation, soil and topography) mostly control soil moisture variability at spatial scales less than 20 km, rather than meteorological forcing. For a fourteen-year averaging period, undoubtedly the monthly means are sensitive to anomalously high precipitation, and hence soil moisture in some months. It is therefore instructive to investigate how well the simulated and estimated patterns of soil moisture compared with the in situ data monthly for the respective years.

### 3.1.2 Intra- and inter-annual variability in soil moisture

This section presents a quantitative evaluation of the soil moisture time-series from the soil moisture products at a monthly time-resolution. The phase agreement of the short term seasonal cycles between the various outputs and observations are quantified in Fig. 3 using  $R^2$  values. The  $R^2$  values are generally higher at Malopeni compared to Skukuza at the root zone, and for the CCAM-CABLE and GLEAM v3c at the surface. This indicates that for the few months with observations at Malopeni there is also high comparability of the soil moisture signal. On account of missing values, the  $R^2$  values presented in Fig. 3 are based on different sample sizes. Therefore, their interpretation is made with this issue in mind. In particular, it is inconclusive whether the simulations and estimates are more comparable at Malopeni relative to the case in Skukuza. From Fig. 3 we can see that the models are able to explain more 50 % of the observed soil moisture variability at root zone and the surface at both sites, while at the root zone, the models can explain more than 38 and 53 % of the variability in the observed soil moisture at Skukuza and Malopeni respectively. The highest agreement ( $R^2 > 0.6$ ) with in situ data is observed for the GLEAM and ESA products at the surface. Lower  $R^2$  values are observed for the CCAM-CABLE model, this might be indicative that in some instances the modelled

signal is shifted relative to the observed signal in some years. This will be investigated in detail in the next section.

440 **Figure 3.** Quantitative monthly comparison between soil moisture products and observations at Skukuza (blue; 2001–2014) and Malopeni (red; 2008–2013), at the surface (0-10 cm) and root zone (10-100 cm), using the coefficient of determination ( $R^2$ ).

445 The ESA-combined satellite product produced  $R^2$  values of 0.70 and 0.63 for Skukuza and Malopeni respectively. The ESA data has been shown to generally capture soil moisture in different regions and climatic zones of the world (Loew et al., 2013; McNally et al., 2016; Wang et al., 2016; Zeng et al., 2015). Our study confirmed (Fig. 3) that the ESA-combined product captures local (i.e., South African semi-arid) conditions within an acceptable amount of certainty. A study conducted by Yuan and Quiring (2017) assessing the performance of CMIP5 models both at the surface and root zone, concluded that the models performed better at the root zone relative to the surface. These results  
 450 contradict the findings of this study, where we generally observe better agreement between soil moisture products and in situ measurements at the surface than at the root zone. Based on the general picture of the extent to which the soil moisture products proved to be representative of the quantitative

features of the soil moisture signal, as driven by precipitation at the site, it is compelling to further  
resolve qualitatively, for each year, how the various soil moisture outputs compare with the in situ  
455 observations. To this effect, the next section will present the results from a cross-wavelet analysis of  
the soil moisture output and the in situ observations.

### 3.1.3 Cross-wavelet analysis

In this section, a cross-wavelet transform (CWT) constructed from two continuous wavelet  
transforms (CWT) applied to the modelled and observed time series respectively is studied. The CWT  
460 is instrumental in depicting the relationship in time and frequency space between two time-series.  
This is achieved by analysing localised intermittent oscillations in the respective time series. By  
looking at the regions in time and frequency space with relatively large common power (represented  
by red colours; Fig. 4) and a consistent phase relationship (depicted by arrows), we gain a sense of  
whether there is a physical relationship between the observed and modelled soil moisture fields.  
465 Looking at Fig. 4 we learn that the soil moisture signals components with a common power are  
immediately identifiable and are portrayed as having periods (y-axis values) that lie between 8 and 15  
months. This is depicted by strong red colour regions bound by white lines, which marks the region  
with 10% significance level (i.e., 90 % confidence level). On comparing the surface and root zone  
cross-wavelets, we can conclude that the statistically significance cyclic components with the  
470 dominating common power are generally between the periods of 8 and 15 months. This can be  
associated with seasonal soil moisture variation as driven by meteorological drivers, most of which  
have a return period of about a year.

From Fig. 4a we can see based on the alignment of the arrow (Fig. B1) that the most common high  
power signals between modelled and observed data are in phase, in some instances with a time lag.  
475 This is identified by the direction of the arrows which are inclined either upwards or downwards, See  
Fig. B1 in Appendix B for an interpretation of the direction of the arrows. From the graph of the phase  
difference, we can see that there is an interchange of years in which the modelled field are leading or  
lagging in phase however, the phase difference is mostly very small. There is a time lag of two days  
on average between CCAM-CABLE simulations and in situ observations at the period of about 12  
480 months, and a lag of about six days on average between GLEAM v3a and the in situ observations at  
the surface. At the root zone, we observe a wider lag of between 14 and 24 days between the soil  
moisture products (i.e. CCAM-CABLE and GLEAM-v3a) and the observations. This further confirms  
that there is a better agreement between the soil moisture products and the observation at the surface  
than at the root zone.

In all models, precipitation is a source of soil moisture at the surface while heat and wind are sinks of  
moisture from the surface. As mentioned earlier the models introduce different assumptions about  
dominating drivers of root zone soil moisture for instance, which may potentially explain the  
existence of broader time lags at the root zone. We further observe, in Fig. 4, that there is an  
agreement between the models and observations on the seasonal and intra-annual signal of soil  
490 moisture at Skukuza, this is shown by orange depicted regions on the cross-wavelet graphs. These are  
the signal components mainly ranging between the periods of two to six months. This could be  
associated with anomalous years where the transition periods between the austral winter and summer  
may have months with below (dry) or above (wet) normal soil moisture conditions. Despite these  
periods having a relatively high common power, they are not demarcated as statistically significant.

495

**Figure 4.** Cross wavelet power spectrum of surface (SSM, 0-10 cm) and root zone (RZSM, 10-100 cm) soil moisture between in situ observations, CCAM-CABLE (a, b) and GLEAM v3a (c, d) at Skukuza respectively. The white contour lines indicate periods of significance at 10 %. The arrows pointing to the right indicates that the models and in situ observation are in phase while arrows point left reflecting that the models are anti-phase. The case where in situ observations are leading either CCAM-CABLE or GLEAM v3a is indicated by arrows pointing straight down. The dome shape (shaded areas) represents the cone of influence between 2001 and 2014. The red colour indicates weak variation while blue indicates the strong variation between the respective time series.

500

It would be interesting to establish how the qualitative insight gained in understanding the models' ability to capture the observed soil moisture signal at the two respective sites will translate to a regional level. An upscaling of the evaluation done at a point is not possible in the absence of site observation at a regional level. The rest of the discussion in this paper is dedicated to an inter-comparison of process-based model outputs and satellite-derived model outputs. The idea is to discuss the model outputs in connection with the broader landscapes classes within the region.

505

### 510 3.2 Linking soil moisture patterns to landscapes

So far we have investigated the capabilities of the models in capturing the temporal features of soil moisture at the flux tower sites. An interesting question to address is, to what extent do the respective models compare in capturing soil moisture organisation across different landscapes as characterised by altitude range, climatic zone, dominant soil, biome types and slope aspect within the considered 25km resolution. In the case where there are no in situ soil moisture fields, we may not reliably tell which product is the most representative of the soil moisture organisation, however, we can classify the models on the basis of their shared patterns at the selected landscapes. We consider six sub-regions which are numbered (a) to (f) as depicted in (Fig. 1c), whose characteristics soil, vegetation

515

520 and climate features are fully described in Table 2. The vegetation types for the study area used here are presented in a study by Khosa et al. (2019)

**Table 2.** A detailed description of the selected sub-regions (Fig. 1c) indicating elevation (<https://www.ngdc.noaa.gov/mgg/fliers/06mgg01.html>), climate (<http://koeppen-geiger.vu-wien.ac.at/present.htm>), vegetation and soil types (<https://soilgrids.org>).

Zone	Elevation range (m)	Climate type	Dominant vegetation type(s)	Dominant soil types
a	0-823	Oceanic	Savanna	Clay
b	824-1298	Humid	Savanna	Clay
c	1299-1317	Hot semi-arid	Savanna	Clay
d	1318-1322	Hot semi-arid	Grassland	Silt-loam
e	1323-1658	Cold semi-arid	Grassland	Silt-loam
f	1659-2440	Cold semi-arid	Grassland	Silt-loam

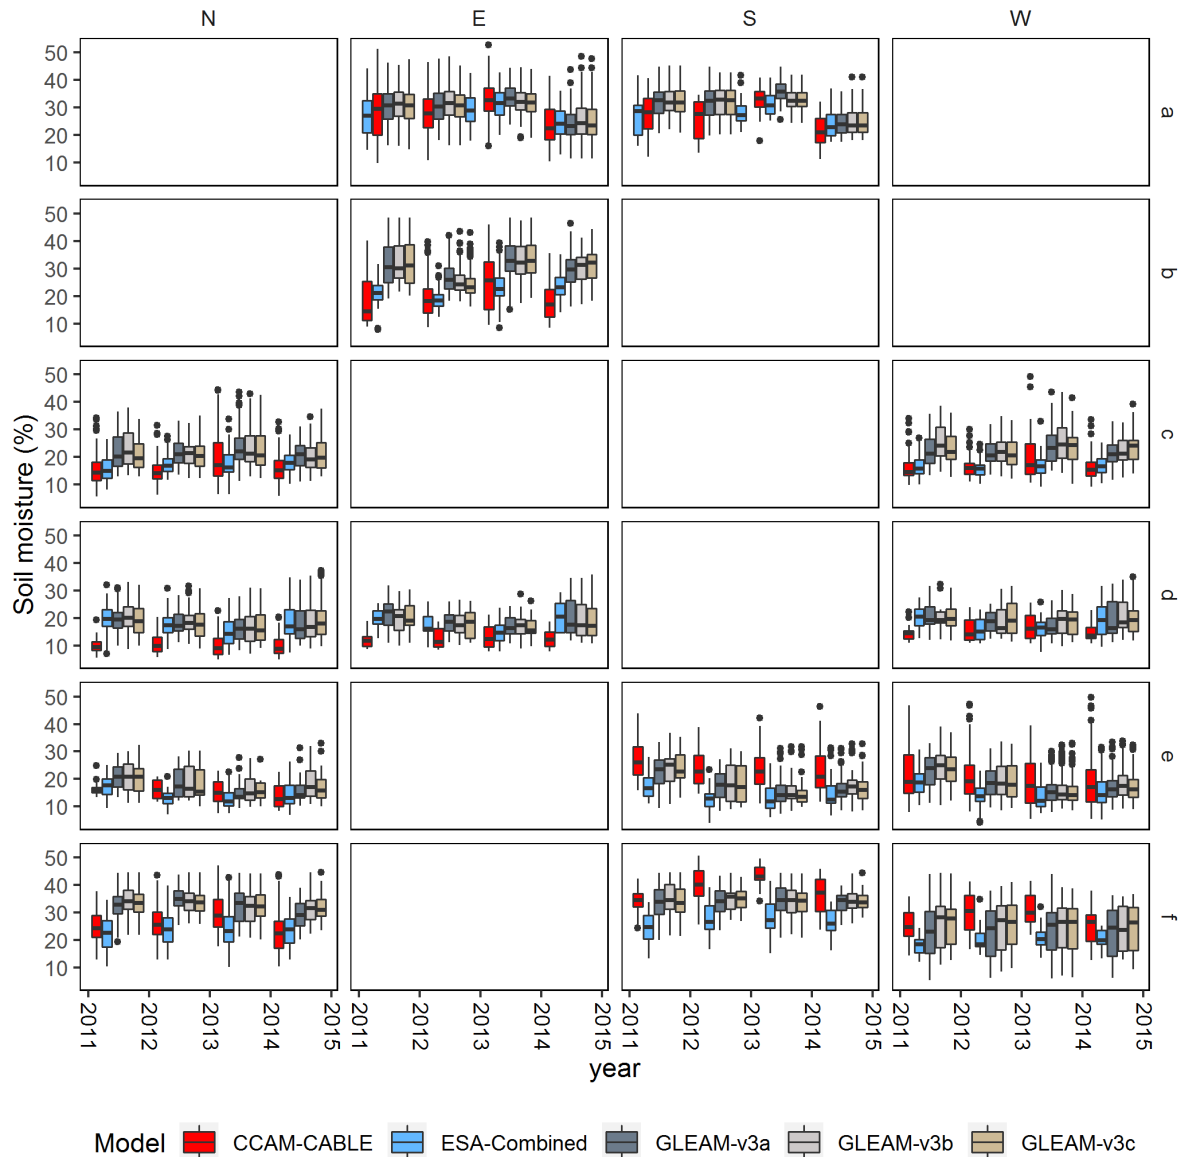

525 In Fig. 5 we see moisture pattern for austral summer (DJF) for the year 2011 to 2014. The box-and-whiskers plots summarise daily data points that are separated by a five days interval throughout the season for the respective five models. From Fig.5 we learn that the spread of soil moisture values for three GLEAM models fall within an overlapping interquartile range. This suggests that the spread of soil moisture values for the GLEAM models is relatively close.

530 By comparing the spread and median of soil moisture values across models, we can conclude that for the region (a), which is characterised by predominance of clay soil and relatively low elevation range, there is no clear variation of soil moisture spread that could be associated with models or the respective south- and east-facing slopes. In summary, the distribution of soil moisture values is comparable amongst the models and slopes. On the humid (b) and hot semi-arid (c, d) regions, we  
 535 learn that the soil moisture spread is comparable between CCAM-CABLE and ESA but relatively lower to that of the GLEAM models. It is worth reiterating at this point that GLEAM models also show higher soil moisture values relative to the in situ observations at the Malopeni at Skukuza flux tower sites, which share the same elevation range and climate type as region (b). For the three landscapes, there is no clear pattern which distinguishes the organization of soil moisture according to  
 540 slope direction. In the case where a landscape has slopes facing more than one direction, highly overlapping distributions indicate that topographic and thermal drivers of soil moisture do not lead to dominant or identifiable soil moisture patterns among the respective models.

For the cold and high lying semi-arid region, (e) and (f), CCAM-CABLE shows a noticeable variation in soil moisture with slope aspect, in which case north facing slopes turns out to have lower soil  
 545 moisture than South- and west-facing ones. For the north-facing slopes of the two regions, the relatively lower soil moisture values for CCAM-CABLE are corroborated by that of the ESA-combined model, which generally portray comparatively low soil moisture values for the two high-lying cold semi-arid regions. It is a well-known fact that along the Drakensberg range, which is close the regions (e) and (f), north- and east-facing slopes have more sunshine exposure than the south- and west-facing slopes (Bristow, n.d.). Notably, the CCAM-CABLE, ESA-Combined and GLEAM  
 550 models reflect contrasting patterns with slope-aspect for the high-lying areas. This calls for model evaluation against observations. Such an evaluation can potentially yield valuable information on which model assumptions or schemes can benefit from further refinements, taking into account dominant thermal and slope dependent soil moisture processes for the landscape.

555

**Figure 5.** Comparison of modelled soil moisture patterns across sub-regions (a-f) of increasing altitude, slopes of different aspect i.e., north (N), east (E), south (S) and west (W). The box-and-whiskers plots show the spread of the soil moisture values per model within the respective regions. The upper and lower end of the box enclose points that fall within the 25<sup>th</sup> and 75<sup>th</sup> percentiles while the dots denote values that fall beyond 1.5<sup>th</sup> of the interquartile range.

560

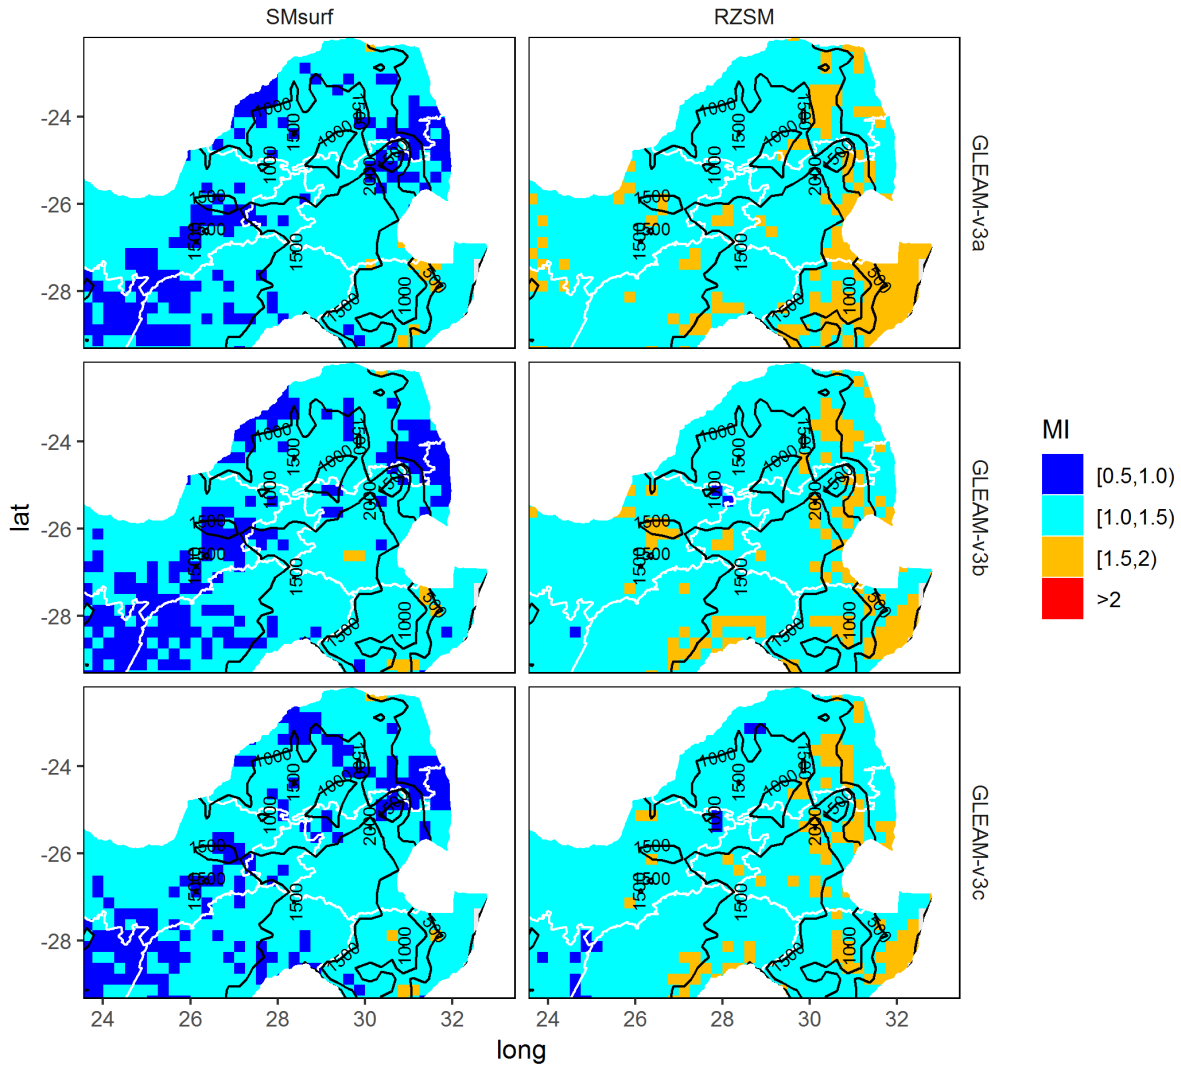

For the selected landscapes, we have learn that the three GLEAM models mostly reflect a spread of soil moisture values which is largely overlapping, while CCAM-CABLE shows the existence of distinct moisture distributions that can be associated with slope aspect especially on high lying regions. A clear continuous picture of how CCAM-CABLE compare with GLEAM models across the entire study domain can be obtained by investigating how different joint distributions of a pair of CCAM-CABLE and GLEAM residuals per grid point compare to a product of their marginal distributions. This is best quantified by the MI which is an information theory function that can be used as a measure of similarity between a pair of time series of residuals. The compared time series are computed on a common grid point for the respective models. The MI is equal to zero when the joint distribution of the pair coincides with the product of the marginal for the respective models. This

565

570

suggests that the respective models are portraying independent signals. For the studied datasets we expect that the MI values should be greater or equal to 2 in the extreme case when the two pairs are identical. Figure 6 depicts the MI which is calculated from a pair of de-trended and de-seasonalised time series of monthly averaged soil moisture for CCAM-CABLE and each of the three versions of GLEAM. The de-trending and de-seasonalising of each pair also lead to a removal of systematic biases. The obtained MI values are at least equal or greater than 0.5. This is true for both the surface and root zone. It is desirable to have the MI for all satellite data derived products, however, the ESA products did not have enough spatial data points to yield a fair comparison.

We can also see in Fig. 6 that the MI at the root zone is higher than at the surface, this could be suggestive that, the sensitivity of soil moisture to the driving processes is comparable between both GLEAM and CCAM-CABLE models at the root zone. The MI pattern for both the surface and root zone compliment the box-and-whisker plot, indicating that the coincidence in the soil moisture values is highest in the proximity of the lowest lying oceanic savanna region (a) which is dominated by the clay soil. For this region, the MI values ranges between 1.5 and 2. CCAM-CABLE has been depicted as having low soil moisture values relative to all versions of GLEAM on part of the humid savanna region (b) for the surface. We can also see that, on the humid savanna which include region (b), that the models predominantly have low MI values ranging between 0.5 and 1 at the surface. The lowest MI values at the surface are also noticeable on the cold semi-arid high-lying grasslands in the neighbourhood of regions (e) and (f). From Fig. 6, we can conclude that study the region is dominated by grid points with relatively high MI values that fall within the range [1 - 2). Lower MI values for the high-lying regions are indicative that there is a pronounced model uncertainty when it comes to the models response to processes that drive soil moisture for the region, while higher MI values, as seen on the rest of the regions, gives an indication that the respective models comparably responds to the dominating processes that drive soil moisture variation. This is the case at least qualitatively.

**Figure 6.** Mutual information (MI) computed on the residuals of monthly time series (2011-2014) of surface (SMsurf, 0-10 cm) and root zone (RZSM, 10-100 cm) soil moisture, between CCAM-CABLE simulations and GLEAM models estimates.

#### 600 4 Conclusions

In this study, the ability of a process-based simulation model (CCAM-CABLE), satellite data-driven model estimates (GLEAM) and satellite observations (ESA-Active, -Passive and -Combined) are evaluated against site-specific in situ observations from two flux tower sites namely, Skukuza and Malopeni. The evaluation was done for two soil depths namely the surface (i.e., 0-10 cm) and root zone soil moisture (i.e. 10-100 cm), to understand how the respective data products capture the characteristic patterns of soil moisture. The evaluation included an assessment of qualitative features of long term (i.e. multi-year), and short term (i.e., monthly) averages of the soil moisture signal relative to the in situ measurements. We generally learn that all GLEAM soil moisture products at all depths presented higher soil moisture magnitude range compared to observations while CCAM-CABLE and ESA-combined outputs turn to be relatively closer in magnitude to the observation both at Malopeni and Skukuza. The systematic difference in magnitude between the model output and observation may emanate from the difference in spatial scale between in situ measurements and the rest of the products. The coefficient of determination ( $R^2$ ) revealed that all the models can explain at least more than half of the soil moisture variation that is in the overserved states (i.e.,  $R^2 > 0.5$ ). We

615 also learn from this study that all GLEAM models compare well with the in situ observations in reflecting the seasonality of soil moisture. This is despite the noted systematic bias GLEAM of the soil moisture magnitudes.

A wavelet analysis was used to reveal, at a qualitative level, how periodic features, compare between the CCAM-CABLE, GLEAM models and in situ observations. We learn that at the surface, high  
620 power common features of the surface soil moisture signal are in phase with observations and come at a periodicity of about 12 months. We also learned that high power common soil moisture signals at the root zone have a relatively pronounced time lag. The time lag is of a time scale not exceeding a month at all soil depths (i.e., it lies between 5 and 20 days) for the periods ranging between 2001 and 2014) between CCAM-CABLE and GLEAM v3a.

625 The study also investigated through the use of mutual information (MI), how different joint distributions of pairs of grid points, among CCAM-CABLE and the respective GLEAM models compare, with a product of their marginal distributions. This gave a basis for classifying the models according to their similarity or dependence in capturing soil moisture responses to the underlying drivers. In this case, the emphasis is on evaluating the extent to which both approaches have a joint  
630 variation or shared MI. The analysis has successfully revealed that both the simulation and model estimates have a high similarity at the root zone as opposed to the surface for all GLEAM model outputs. The difference in the surface soil moisture between the CCAM-CABLE simulation and GLEAM models outputs at high lying areas, opens-up interesting questions relating to the extent to which the influence of different drivers of soil moisture is represented by the two approaches. To  
635 understand this, future research will benefit from investigating the sensitivity of the models to changes in soil moisture drivers, particularly change in vegetation cover and soil type on soil moisture memory. It would also be interesting to unearth the soil moisture organisation for the respective models, at much higher spatial resolution where processes that drive soil moisture may reliably be attributed to the patterns on the soil moisture signal. Despite CCAM-CABLE and GLEAM having  
640 relatively high MI for the majority of landscapes, application of these model outputs should take into account that systematic biases do exist, and that there is a high model uncertainty particularly at high lying areas.

*Team list and Author contribution:*

- Floyd – Developed research questions, analysed the data and compiled the manuscript.
- 645 ● Marna and Mohau –suggested datasets to be explored, reviewed the manuscript, and made inputs on data analysis approaches and research questions formulations.
- Gregor – Inputs into the formulation of research questions, provision of in situ data, and critical discussion and review of the manuscript.
- Francois – Led the CCAM-CABLE model simulations and introduced the lead author to the  
650 model structure and the dynamical downscaling methods.
- Michael – Supervisory role and manuscript review.

*Competing interests:* The authors declare that they have no conflict of interest.

## Appendix

840

### 5.1 Appendix B – Cross wavelet analysis

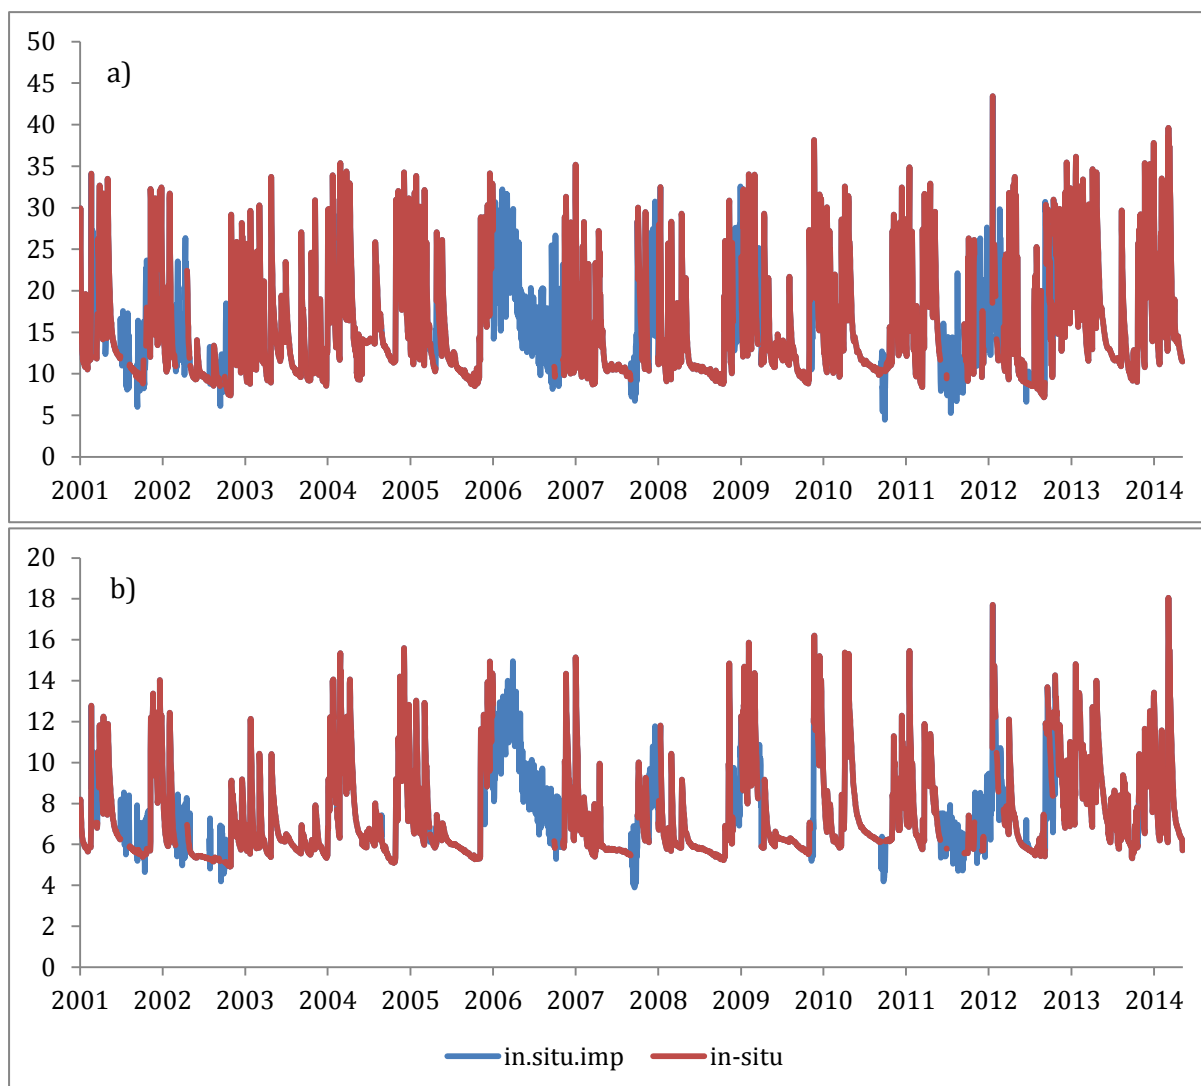

**Figure B1.** Phase interpretation between two time series  $x$  and  $y$ . When series  $x$  leads,  $y$  lags and vice versa. This figure is inspired by a study by (Rosch and Schmidbauer, 2018).

845

**Figure B2.** Phase difference between surface soil moisture simulated using CCAM-CABLE, and GLEAM v3a at Skukuza between 2001, and 2014 at period 12 at the surface.

## 5.2 Appendix C – Multiple imputation

850 **Figure C1.** Daily a) surface and b) root zone soil moisture time series at Skukuza showing the imputed parts (blue) of the time series and the observed parts (red).

**Table C1.** Statistics of the distribution of the imputed and observed time series of surface and rootzone soil moisture at the Skukuza site.

<b>Surface soil moisture</b>	Original data	Imputed data
Mean	15.59	15.76
Median	13.33	13.83
Standard deviation	6.21	6.10
Variance	38.68	37.22
<b>Root zone soil moisture</b>		
Mean	7.45	7.55
Median	6.49	6.69
Standard deviation	2.18	2.17
Variance	4.76	4.74
