50 ABSTRACT

51 The continental tropics play a leading role in the terrestrial energy, water, and carbon
52 cycles. Land-atmosphere interactions are integral in the regulation of these fluxes across
53 multiple spatial and temporal scales over tropical continents. We review here some of the
54 important characteristics of tropical continental climates and how land-atmosphere
55 interactions regulate them. Along with a wide range of climates, the tropics manifest a
56 diverse array of land-atmosphere interactions. Broadly speaking, in tropical rainforest
57 climates, light and energy are typically more limiting than precipitation and water supply
58 for photosynthesis and evapotranspiration, whereas in savanna and semi-arid climates,
59 water is the critical regulator of surface fluxes and land-atmosphere interactions. We
60 discuss the impact of the land surface, how it affects shallow and deep clouds and how
61 these clouds in turn can feed back to the surface by modulating surface radiation and
62 precipitation. Some results from recent research suggest that shallow clouds may be
63 especially critical to land-atmosphere interactions. On the other hand, the impact of land
64 surface conditions on deep convection appears to occur over larger, non-local, scales and
65 may be a more relevant land-atmosphere feedback mechanism in transitional dry to wet
66 regions and climate regimes.

67 1 Introduction

68 The Tropics play a substantial role in regulating the global hydrologic and carbon cycles.
69 Tropical rainforests are one of the main terrestrial carbon sinks [*Nakicenovic*, 2000;
70 *Friedlingstein et al.*, 2006] but their projected responses to a warming climate remain
71 unclear because of uncertainties associated with the representation of abiotic and biotic
72 processes in models as well as confounding factors such as deforestation and changes in
73 land use and land cover [*Wang et al.*, 2009; *Davidson et al.*, 2012; *Fu et al.*, 2013;
74 *Saatchi et al.*, 2013; *Hilker et al.*, 2014; *Boisier et al.*, 2015; *Doughty et al.*, 2015; *Gatti*
75 *et al.*, 2015; *Knox et al.*, 2015; *Saleska et al.*, 2016]. The ecosystems of tropical
76 monsoonal and seasonal wet-dry climates are also important contributors to the global
77 carbon cycle, especially with respect to the interannual variability of the tropical
78 terrestrial carbon sink [*Poulter et al.*, 2014; *Jung et al.*, 2017; *Green et al.*, 2019].

79 Some regions of the tropics have been further identified as hotspots in which land-
80 atmosphere interactions modify the climate [*Dirmeyer et al.*, 2011; *Koster et al.*, 2011;
81 *Green et al.*, 2017] either locally, i.e. at horizontal scales on the order of a few boundary
82 layer heights, regionally, at scales up to a few hundreds of kilometers, or at larger scales,
83 over several of thousands of kilometers, through coupling between the surface and the
84 overlying atmosphere [*Lintner and Neelin*, 2009]. These interactions may in turn
85 dramatically affect the future state of rainforests [*Cox et al.*, 2004].

86

87 While tropical land-atmosphere interactions are often examined through the lens of
88 coupling between land surface states (e.g., soil moisture) and rainfall, other aspects of the
89 coupling are also important. For example, even under nonprecipitating conditions,
90 surface radiation, temperature and vapor pressure deficit (VPD) may be altered [*Lawton*
91 *et al.*, 2001; *Pielke et al.*, 2016; *Green et al.*, 2017] through coupling with clouds,
92 aerosols and shallow (non-precipitating) convection [*Avissar and Nobre*, 2002; *Medvigy*
93 *et al.*, 2011; *Seneviratne*, 2013; *Cook et al.*, 2014; *Guillod et al.*, 2015; *Krakauer et al.*,
94 2016; *Martin et al.*, 2016; *Green et al.*, 2017; *Khanna et al.*, 2017; *Martin et al.*, 2017;
95 *Thiery et al.*, 2017; *Vogel et al.*, 2017]. In addition, tropical forests can exhibit important
96 variations in canopy photosynthetic capacity with new leaves [*Lopez et al.*, 2016; *Saleska*
97 *et al.*, 2003, 2016]. These variations can further feed back onto the atmosphere on
98 seasonal time scales [*Green et al.*, 2017]. It is clear that the tropical energy, water, and
99 carbon cycles cannot be understood in isolation; rather, the interactions among these
100 cycles are essential. For example, knowledge of such interactions must be taken into
101 account to ascertain whether the terrestrial tropics will act as a future carbon sink or
102 source [*Zhang et al.*, 2015; *Swann et al.*, 2015].

103

104 The two-way interactions that occur between the land surface and overlying atmosphere
105 represent one of the more uncertain aspects of the terrestrial climate system, particularly
106 in the Tropics [*Betts and Silva Dias*, 2010]. While the land surface is widely recognized
107 as integral to the occurrence of important tropical climate phenomena such as monsoons
108 [*Zeng and Neelin*, 1999; *Zeng et al.*, 1999], isolating and quantifying its precise role
109 remains elusive. Indeed, such efforts have frequently been hampered by the paucity of

110 observational data, not to mention the complex and multiple pathways through which
111 land-atmosphere interactions can take place.

112

113 Several notable field campaigns have been conducted in the tropics with the purpose of
114 advancing knowledge of land-atmosphere interactions. One of the most well-known
115 campaigns was the Large-Scale Biosphere-Atmosphere Experiment in Amazonia (LBA)
116 [*Avissar et al.*, 2002; *Keller et al.*, 2004], which aimed at refining our understanding of
117 climatological, hydrological, biogeochemical and ecological processes of the Amazon
118 and their linkages, in addition to the anthropogenic impacts (e.g., land-use land cover
119 changes and deforestation) on these. Among many other topics, LBA generated
120 fundamental insights on the structure of the tropical atmosphere, processes generating
121 precipitation, and the seasonal variability of surface turbulent fluxes in tropical
122 rainforests [*Avissar and Nobre*, 2002; *Betts et al.*, 2002; *Laurent et al.*, 2002; *Machado*
123 *and Laurent*, 2002; *Acevedo et al.*, 2004; *Khairoutdinov and Randall*, 2006; *Fitzjarrald*,
124 *2007*; *Juárez et al.*, 2007; *Restrepo-Coupe et al.*, 2013]. One thrust of LBA research
125 sought to isolate the effect of deforestation on precipitation, both in a local context as
126 well as remotely via teleconnections [*Avissar et al.*, 2002; *Werth and Avissar*, 2002].
127 Such research has pointed to deforestation decreasing precipitation, albeit with uncertain
128 magnitude and dependence on the spatial scales involved. Even now, two decades after
129 the inception of LBA, the relationship between tropical deforestation and precipitation
130 remains uncertain, despite progress with respect to key processes such as vegetation
131 access to deep water in the dry season [*Oliveira et al.* 2005], and modulation of energy
132 availability for photosynthesis via cloud cover [*Betts and Dias*, 2010].

133

134 Another field campaign, the African Monsoon Multidisciplinary Analysis (AMMA)
135 campaign, focused on the West African monsoon system, especially the Sahel transition
136 zone [*Redelsperger et al.*, 2006; *Boone et al.*, 2009b]. Building on previous field work in
137 the region [*e.g. HAPEX-Sahel*, *Gourtorbe et al.* 1993], AMMA generated fundamental
138 understanding of mesoscale convective systems and surface processes [*Lebel et al.*, 2009;
139 *Taylor et al.*, 2009; *Boone et al.*, 2009a; *Lohou et al.*, 2010; *Couvreur et al.*, 2011a;
140 2011b]. More recently, the 2014-2015 Green Ocean Amazon (GO-Amazon) campaign

141 [*Martin et al.*, 2016] sought to quantify the impact of atmospheric composition and
142 aerosols under clean and polluted conditions on cloud formation and radiation over the
143 Amazon basin, as well as on shallow to deep convection development [*Anber et al.*,
144 2015a; *Tang et al.*, 2016; *Giangrande et al.*, 2017].

145

146 The remainder of this review article is organized as follows. In sections 2-4, we introduce
147 some fundamental considerations of the climate system components necessary for
148 understanding tropical land-atmosphere interactions, including convection, clouds, and
149 rainfall (Section 2), surface turbulent fluxes (Section 3), and vegetation and ecosystem
150 processes (Section 4). We then synthesize prior work on tropical land-atmosphere
151 interactions from both local and non-local perspectives (Section 5). We close this review
152 (Section 6) by highlighting what we view as the outstanding issues, challenges, and
153 knowledge gaps for tropical land-atmosphere interactions. For example, we argue that
154 shallow cloud feedback and its impact on radiation has received too little attention
155 compared to precipitation feedback, in rainforests especially.

156 2 Convection, clouds, and rainfall in the Tropics

157 The net radiative heating of the atmosphere in the global tropics—arising from the top-
158 of-the-atmosphere imbalance of net incoming solar (shortwave) radiation exceeding
159 outgoing terrestrial (longwave) radiation—leads to one of the defining hallmarks of the
160 tropics, namely very high rain rates. This is not to say, of course, that rainfall in the
161 tropics is high everywhere or at all times, as climates within the tropics can be both wet
162 and dry. Indeed, many of earth’s desert regions are found on the margins of the tropics,
163 and apart from deserts, parts of the tropics may experience very dry conditions
164 seasonally. In this review, we will exclude consideration of deserts and focus on the
165 humid tropics.

166

167 2.1 Shallow vs. deep convection

168 The distinction between shallow and deep convection remains imprecise, as these have
169 been regarded as both fundamentally distinct or as a continuum, in both observations and
170 model convection parameterizations [*Khairoutdinov and Randall*, 2006; *Bretherton and*

171 *Park, 2009; Park and Bretherton, 2009; Rio et al., 2009; Wu et al., 2009; Del Genio and*
172 *Wu, 2010; Hohenegger and Bretherton, 2011; Böing et al., 2012; D’Andrea et al., 2014;*
173 *Rochetin et al., 2014b*]. We will loosely refer to shallow convection as convection
174 confined below the freezing level (typically less than 3km deep) and comprising non-
175 precipitating clouds small characteristic motion scales (typically less than a km in the
176 horizontal).

177

178 An important point is that shallow convection is frequently generated by thermals rooted
179 in the boundary layer and is thus ultimately related to surface sensible (H) and latent heat
180 (LE) flux and their partitioning [*Gentine et al., 2013a; 2013b; de Arellano et al., 2014;*
181 *Tawfik et al., 2014, 2015a,b*]. Within the Amazon, shallow convection and associated
182 clouds frequently occur over the vegetated surface, while over cooler and more humid
183 river basins, shallow clouds are virtually absent [*Gentine et al., 2013a; Rieck et al., 2014;*
184 *2015; see also Figure 1*]. In addition, shallow convection is strongly influenced by the
185 diurnal cycle of surface radiation and surface turbulent heat fluxes [*Gentine et al., 2013a;*
186 *2013b; de Arellano et al., 2014*].

187

188 On the other hand, we use the term deep convection in association with deep,
189 precipitating clouds. Deep convection may be triggered by a suite of thermodynamic or
190 dynamic processes, including: boundary layer thermals [*D’Andrea et al., 2014; Guillod et*
191 *al., 2014; Rochetin et al., 2014a; 2014b; Anber et al., 2015a*], radiative destabilization
192 [*Anber et al., 2015b*], cold pools (cold density currents due to rain evaporation that cools
193 the air within precipitating downdrafts) [*Engerer et al., 2008; Del Genio and Wu, 2010;*
194 *Böing et al., 2012; Feng et al., 2015; Torri et al., 2015; Gentine et al., 2016; Heever,*
195 *2016; Drager and van den Heever, 2017*] forced vertical motions such as via mesoscale
196 and large-scale circulations [*Werth and Avissar, 2002; Roy et al., 2003*] or propagating
197 tropical wave activity [*Kuang, 2008; 2010*]. As such, deep convection may be viewed as
198 less dependent on the surface state compared to shallow convection.

199

200 Over the central Amazon a large fraction of wet season precipitation occurs during the
201 nighttime (Figure 2). Moreover, during the daytime in both the dry and the wet seasons,

202 the diurnal cycle reflects not only locally surface-triggered deep convection
203 [*Khairoutdinov and Randall, 2006; Ghate and Kollias, 2016*] but also propagating
204 mesoscale convective systems and squall lines throughout the Amazon basin [*Greco et*
205 *al., 1990; Ghate and Kollias, 2016; Rickenbach et al., 2002*]. However, during the dry
206 season, precipitation occurs more frequently with the “popcorn type” deep convection
207 that is more locally triggered and thus directly related to the state of the land surface
208 [*Ghate and Kollias, 2016*] (see an example here <https://youtu.be/c2-iquZziPU>). While
209 shallow convection does not produce much rainfall, it exerts significant influence on deep
210 convection through its control on surface radiative fluxes and on transport of moisture
211 into the lower troposphere. More discussion will be given in Section 4.2.

212

213 2.2 Considerations for modeling tropical clouds, convection, and rainfall

214 Current generation climate models struggle to represent both shallow and deep
215 convection over continents and their transitions [*Guichard et al., 2004; Bechtold et al.,*
216 *2013; Yin et al., 2013; D’Andrea et al., 2014; Couvreux et al., 2015*], especially in the
217 tropics, as they exhibit substantial errors in the phasing and intensity of both the diurnal
218 and seasonal cycles of convection [*Bechtold et al., 2013*], as well as biases in the
219 climatological distribution of rainfall over land. For example, over the Amazon, many
220 climate models underestimate surface precipitation, evapotranspiration, and specific
221 humidity [*Yin et al., 2013*], with the dry bias in moisture extending upwards into the
222 lower free troposphere [*Lintner et al., 2017*]. Such biases may reflect deficiencies or
223 errors in how convection is represented in models [*Yano and Plant, 2012; Stevens and*
224 *Bony, 2013; Bechtold et al., 2014*]. Indeed, in current generation climate models, cloud
225 processes occur at scales smaller than resolved grid-scale prognostic variables and
226 therefore need to be parameterized, i.e. represented as a function of the resolved-scale
227 variables. This is important as it means that climate models do not explicitly represent the
228 small-scale convective physics of the climate system. Evaluation of model performance
229 for the Central Amazon can be found in Adams et al. [2013, 2015, 2017].

230

231 Cloud resolving models (CRMs) that include explicit convection at scales of ~1km
232 alleviate many of the biases evident in coarser-scale, parameterized convection climate

233 models, especially in terms of the diurnal cycle of convection or the sign and magnitude
234 of the feedbacks between deep convection and surface evaporative fraction [*Grabowski*
235 1999, *Taylor et al.*, 2013; *Anber et al.*, 2015a]. Nonetheless, due to convective wave
236 coupling in the Tropics, a simple prescription of lateral boundary conditions in small-
237 domain CRMs may be problematic, as the convective scales ultimately interact with and
238 are coupled to planetary scales. With a sufficiently large domain and fine enough
239 resolution, coupling between the convective scales and planetary scales may be explicitly
240 resolved, but simulations of this nature are likely to be computationally too expensive for
241 many applications. However, techniques exist to represent the effect of large-scale
242 dynamics on the convective scales, which, when combined with cloud resolving
243 simulations, yield powerful tools for understanding land-atmosphere interactions in the
244 tropics, as we elaborate further below.
245

246 3 Surface turbulent fluxes in the Tropics

247 A major component of land-atmosphere interactions considered is related to surface
248 turbulent fluxes and associated momentum, energy, water and trace gases exchanges
249 between the land surface and atmosphere [*Goulden et al.*, 2004; *Fisher et al.*, 2009;
250 *Restrepo-Coupe et al.*, 2013]. Surface turbulent flux measurements are usually obtained
251 from eddy-covariance methods, typically located above the canopy [*Baldocchi et al.*,
252 2001]. Observing turbulent fluxes is challenging in tropical environments given logistics,
253 cost, maintenance, and harsh environmental factors such as intense rainfall, high wind,
254 and relative humidity, which impact sensors [*Campos et al.*, 2009; *Da Rocha et al.*, 2009;
255 *Restrepo-Coupe et al.*, 2013; *Zahn et al.*, 2016; *Chor et al.*, 2017; *Gerken et al.*, 2017]. In
256 light of these challenges, it is perhaps not surprising that even the best estimates of
257 surface turbulent fluxes manifest large uncertainties [*Mueller et al.*, 2011].
258

259 Apart from site level measurements, which are limited to a small number of locations
260 around the tropics, remote sensing observations can provide indirect information about
261 surface turbulent fluxes and other relevant quantities over tropical land regions. Remote
262 sensing observations are useful for generalizing and comparing fluxes across the tropics,

263 even if they are not as direct as site level measurements. Yet, there are considerable
264 uncertainties in remote sensing and reanalysis estimates of rainfall [*Washington et al.*,
265 2013; *Levy et al.*, 2017], radiation [*Jimenez et al.*, 2011], and surface turbulent fluxes
266 [*Jung et al.*, 2009; *Alemohammad et al.*, 2016] and especially in terms of upscaling point
267 observations to larger areas as those measurements are fundamentally indirect.

268

269 While direct, satellite-based retrievals of carbon (e.g., gross primary production (GPP))
270 and water fluxes would be most suitable for the study of tropical land-atmosphere
271 interactions, such retrievals are beyond current remote sensing capabilities. However,
272 some recent work demonstrates that existing satellite observations, especially Solar-
273 Induced Fluorescence (SIF), may be leveraged to remotely assess surface turbulent fluxes
274 in the tropics. In contrast to the normalized difference vegetation index (NDVI) or many
275 other vegetation indices which are indirect byproducts of photosynthesis [*Morton et al.*,
276 2014], SIF (at the leaf scale) is directly related to the ecosystem-scale photosynthesis
277 rate, providing important information on the impact of stressors on photosynthesis and is
278 available from existing remote sensing platforms [*Frankenberg et al.*, 2011; *Joiner et al.*,
279 2011; *Frankenberg et al.*, 2012; *Joiner et al.*, 2013; *Frankenberg et al.*, 2014; *Guanter et*
280 *al.*, 2014; *Lee et al.*, 2015; *Duveiller and Cescatti*, 2016; *Liu et al.*, 2017; *Thum et al.*,
281 2017; *Alexander et al.*, 2017]. SIF is thus an important indicator of the rates of
282 photosynthesis and transpiration through stomatal (small pores at the leaf surface)
283 regulation [*Alemohammad et al.*, 2017; *Pagán et al.*, 2019]. Indeed, during
284 photosynthesis plants take up CO₂ from the atmosphere while releasing water to the
285 atmosphere through stomata. We note that recent developments in observations of SIF
286 seem to indicate that the major fraction of the SIF signal might be related to chlorophyll
287 photosynthetically active radiation and that changes in SIF yield (equivalent to light use
288 efficiency) may account for only a small fraction of the observed SIF signal [*Du et al.*,
289 2017]. This is still an open topic to better understand what is actually observed by SIF
290 remote sensing.

291

292 *Alemohammad et al.* [2016] applied a machine learning algorithm based on remotely-
293 sensed SIF, called WECANN (Water Energy and Carbon Artificial Neural Network) to

294 derive surface turbulent fluxes. WECANN reproduces exhibits reasonable interannual
295 variability and its seasonality is constrained by the use of SIF [*Alemohammad et al.*,
296 2016], yet like any other products it is not a direct observation of the fluxes, which are
297 only available at sparse tower observations. WECANN performs well compared to eddy-
298 covariance observations and has less uncertainty compared to many other retrievals (see
299 [*Alemohammad et al.*, 2017]).

300

301 Given the paucity of flux towers and associated surface flux measurements across the
302 tropics, we use WECANN to calculate surface flux climatologies across the continental
303 tropics. WECANN has been validated against available flux tower data and outperforms
304 other products in terms of reproducing both the seasonality and interannual variability
305 [*Alemohammad et al.*, 2017]. While remote sensing retrievals are not perfect and cannot
306 be considered the truth, they do provide spatially extensive data coverage, including
307 regions with sparse (or no) site-level measurements (e.g., Congo). In what follows, we
308 present climatologies of evapotranspiration (ET) and gross primary production (GPP) and
309 compare these against precipitation (based on GPCP 1DD v1.2 [*Huffman et al.*, 2001])
310 and net radiation (based on CERES SYN [*Kato et al.*, 2013]) in order to understand the
311 typical seasonal cycles of those energy, water, and carbon fluxes across the continental
312 tropics.

313

314 We first focus on the main tropical rainforests and the northeastern savanna (Cerrado)
315 region of Brazil (Figure 3). In the wetter part of the Amazon, net radiation, R_n , peaks in
316 the dry season (August to November) (Figure 3) when precipitation (Figure 4) and cloud
317 cover—especially shallow cloud cover, including fog—are reduced, [*Anber et al.*,
318 2015a]. As a result of reduced dry season cloud cover, incident surface solar radiation
319 increases, and both GPP (Figure 5) and ET (Figure 6) increase in the dry season (Figure
320 3). As discussed further in the next section, the forest in the climatologically wetter
321 Amazon is primarily light limited, while water stress there is moderate in the dry season.
322 The seasonal cycle is more pronounced for GPP than for ET (Figure 3): canopy
323 photosynthetic regeneration [*Lopez et al.*, 2016; *Saleska et al.*, 2003, 2006, 2016] is an
324 important factor affecting the seasonal cycle of GPP in rainforests potentially increasing

325 the maximum rate of GPP in the dry season. In addition, canopy evaporation (of
326 intercepted rain) comprises a large fraction of total ET in the wet season [Scott *et al.*,
327 1997; Oleson *et al.*, 2008; Miralles *et al.*, 2010; Sutanto *et al.*, 2012; van Dijk *et al.*,
328 2015; Andreassen *et al.*, 2016] and partly compensates for reduced transpiration in the wet
329 season. In fact, because of this compensation, the wettest parts of the Amazon exhibit
330 weak ET seasonality. On the other hand, most land-surface models exaggerate water
331 stress in the Amazon [Powell *et al.*, 2013], and typically exhibit much lower rates of ET
332 and GPP in the dry season and simulate opposite seasonality of net ecosystem exchange
333 compared to observations [de Gonçalves *et al.*, 2013; Alemohammad *et al.*, 2016; 2017].
334 This exaggerated water stress results from incorrect access to deep soil water, whether
335 due to limited groundwater representation [Maxwell and Condon, 2016], because of the
336 functional relationship of the water stress representation which does not obey physical
337 constraints (such as flow down potential gradients as in plant hydraulics models)
338 [Kennedy *et al.*, 2019] or simply because their assumed rooting depth is too shallow [Fan
339 *et al.*, 2017].

340

341 In contrast to the everwet western and central Amazon, over the Cerrado region of
342 Northeastern Brazil, the seasonal cycles of Rn, precipitation, GPP and ET are much more
343 pronounced, with a marked dry season (Figure 3). The seasonal cycle of GPP tracks
344 precipitation, and water stress, exhibiting a strong increase during the wet season.
345 Similarly, ET increases sharply in the wet season and then decreases more slowly than
346 precipitation in the dry region (Figure 3). Conversely, net radiation increases sharply
347 during the dry season. This region clearly exhibits a strong water stress response.

348

349 Turning to the Maritime Continent, rainfall is intense throughout the year and seasonality
350 is modest, with a short peak in November to January (Figure 3). Much of the seasonal
351 cycle is attributable to monsoon circulations, which are strongly influenced by
352 topography and the land- and ocean-surface thermal contrast [Chang 2005]. The
353 topography and the distribution of island land masses leads to strong local variability
354 (Figure 4e) and pronounced diurnal cycles in convection are evident [Nitta, 1987;
355 Hamada *et al.*, 2008]. Additionally, the Madden Julian Oscillation, an important mode of

356 climate variability in the tropical Indo-Pacific with a lifecycle of 30-90 days, strongly
357 impacts rainfall on intraseasonal timescales [*Hidayat and Kizu, 2009*]. Convective
358 activity in the region also regulates the East Asian Monsoon [*Huang and Sun, 1992*]. The
359 region is also influenced by topographic effects and land-sea breeze interactions, which
360 may impart considerable regional heterogeneity. Given the relatively constant regional-
361 averaged precipitation with regular convection occurring over course of the annual cycle,
362 ET and GPP remain near steady throughout the entire year in this mostly light limited
363 environment (Figure 3).

364

365 The Congo basin exhibits two rainy seasons (Figure 3), with peaks in March-April-May
366 and September-October-November, related to seasonal changes in moisture convergence
367 associated with the African Easterly jet and Intertropical Convergence Zone (ITCZ) over
368 the Atlantic [*Washington et al., 2013*]. Throughout the year, monthly-mean precipitation
369 is much less than that observed over the Amazon or Indonesia. The seasonality of GPP
370 and, to a lesser extent, ET tracks that of precipitation, with substantial decreases during
371 the June to August dry season and even more pronounced reduction during the December
372 to February period. This seasonality in GPP and ET (Figure 3) suggests that the Congo
373 basin should exhibit substantially more water stress during dry seasons compared to the
374 Amazon or Indonesian rainforests [*Guan et al. 2015*].

375

376 Integrated over the entire tropical latitudinal band, precipitation is highest in DJF and
377 MAM when the wet season extends over most of the Amazon and adjacent savanna
378 regions (Figure 4). This seasonal cycle of tropical-mean precipitation largely determines
379 the seasonal cycle of GPP. GPP peaks during the wet season in South America, as GPP is
380 highest in the savanna regions while GPP over the rainforest exhibits less seasonal
381 variations (Figure 6). The seasonal pattern of ET resembles GPP (Figure 6). Indeed, the
382 seasonality in ET reflects the combined influences of 1) the seasonality of water
383 availability in drier, water-limited regions, 2) the seasonality of surface radiation in the
384 wetter, more energy-limited portion of the Amazon and 3) changes in photosynthetic
385 capacity throughout the year. The seasonal cycle of sensible heat flux (Figure 7) largely
386 follows water stress, especially in the rainforest where radiation remains high throughout

387 the year, with an increase during the dry season. Water stress is further apparent in the
388 evaporative fraction, EF, the ratio of latent heat flux to the sum of latent and sensible heat
389 fluxes (Figure 8). Tropically-averaged EF does not evolve much over the year; the
390 modest seasonality may be understood in terms of variation of the latitudinal peak in
391 radiation and compensation of decreased canopy interception by transpiration (because of
392 increased net surface radiation) in the dry season. However, in transitional and dry
393 regions, EF exhibits much more seasonal variation. The surface moist static energy flux,
394 $H+LE$, shows some slight variations in SON and JJA but otherwise remains relatively
395 steady across longitudes because of the compensation between the increased H and
396 reduced ET in the dry season. In the dry to wet transition, SON, moist static energy flux
397 exhibits an interesting peak at about -60 longitude (Figure 9) through the combined
398 increase in radiation, due to reduced cloudiness, inducing higher sensible heat flux and
399 maintained high ET rates.

400

401 Over tropical Africa, the precipitation is highest in JJAS during the wet phase of the West
402 African Monsoon, with a secondary maximum in DJF corresponding to the Southern
403 African Monsoon (Figure 4). Similarly the latitudinal-averaged GPP and ET increase
404 during the West African Monsoon (Figure 5, Figure 6), accompanied by a strong
405 decrease in sensible heat flux (Figure 7). In DJF the southern African Monsoon displays
406 increased water flux (Figure 6) and photosynthesis tracking the increased rainfall (Figure
407 4). The Congo rainforest clearly exhibits two brief rainy seasons (Figure 3, Figure 8),
408 with peaks in March-April-May and September-October-November (Figure 3) and
409 displays substantial water stress and strong reduction in EF to values below 0.6 during
410 the dry season (Figure 8).

411

412 4 Vegetation and ecosystem processes in the Tropics

413 We cannot understand tropical land-atmosphere interactions, not to mention the basic
414 features of terrestrial tropical climate, without consideration of vegetation and ecosystem
415 processes. Indeed, over land, what is viewed as the Tropics has traditionally been defined
416 with vegetation and ecosystems implicitly considered, as in the Köppen climate

417 classification scheme [Köppen, 1884]. Under this scheme, the terrestrial Tropics is
418 divided into three main *groups*—tropical rainforest, tropical monsoon, and tropical wet
419 and dry (or savanna)—all of which are characterized by annual mean temperatures
420 exceeding 18°C but which differ in terms of precipitation amount and seasonality.

421

422 One outstanding challenge in simulating tropical land regions is determining why most
423 contemporary land-surface models incorrectly represent the wettest rainforest GPP and
424 ET rates, their seasonal cycles, and how they relate to water stress? In the wettest tropical
425 forests, such as the western portion of the Amazon or Indonesia, energy and light limit
426 the rates of ET and GPP. It is thus reasonable to conclude that soil moisture and water
427 stress should have minor effects in such regions, and consequently, that precipitation
428 variability should not matter much. In fact, there exist sharp vertical gradients in the
429 canopy (as well as at the surface of the soil in the dry season) in terms of light and water
430 availability, along with nutrient allocation as well (Figure 10). Understory species receive
431 only a small amount of mostly diffuse light. However, water is typically not limiting for
432 low-canopy species, as relative humidity is high and VPD is low, leading to low stress on
433 understory conductance [Leuning, 1995; Leuning *et al.*, 1995; Wang and Leuning, 1998;
434 Medlyn *et al.*, 2011; 2012; Heroult *et al.*, 2013].

435

436 On the other hand, tall canopy species receive a large amount of radiation, especially in
437 the dry season, causing sunlit leaf warming and higher leaf VPD (e.g., Penman-Monteith
438 equation) that lead to heat and water stress [Jardine *et al.*, 2014]. Leaf and xylem water
439 status are regulated by the relative demand of sap from transpiration, which depends on
440 leaf VPD. It also depends on sap supply to the leaves, the rate of which is controlled by
441 the xylem conductivity and which is high for tall tropical rainforest trees [Liu *et al.*,
442 2019]. This conductivity is reduced by cavitation in the xylem (formation of air bubbles
443 blocking the ascent of sap flow from the roots to the leaves) [Martinez-Vilalta *et al.*,
444 2014; Martinez-Vilalta and Garcia-Forner, 2016]. To avoid leaf desiccation and xylem
445 cavitation stomatal closure is usually observed during peak daytime sunlight hours in
446 rainforest top canopy species [Brodribb, 2003; Pons and Welschen, 2003; Zhang *et al.*,
447 2013]. This limits the risk of leaf desiccation or xylem cavitation (Figure 11), in those

448 usually efficient xylems. This type of behavior with strong stomatal regulation appears to
449 be typical in the tropical rainforests [*Fisher et al.*, 2006; *Konings and Gentine*, 2016],
450 even though this appears to contradict results from isotopic measurements showing that
451 stomata remain relatively open [*Ometto et al.*, 2006]. On seasonal time scales, this is
452 modulated by the change in photosynthetic capacity of the canopy due to leaf flush and
453 canopy regeneration [*Saleska et al.*, 2003, 2006]. More work is needed to understand
454 stomatal and canopy regulation of tropical rainforests in response to stressors, especially
455 given the importance of rainforests in the global carbon cycle.

456

457 In tall canopy species the flow in the xylem from the roots may be limited as the xylem
458 hydraulic conductivity is inversely proportional to height, though this is partially
459 compensated by a more efficient xylem (higher specific conductivity) [*Liu et al.*, 2019].
460 However, higher evaporative demand in the dry season and/or under anomalously dry
461 conditions can only be partially be mitigated by the more efficient xylem and by the plant
462 internal storage; stomatal shutdown may therefore be inevitable to avoid desiccation and
463 xylem cavitation (Figure 11) [*Dawson*, 1993; *Phillips et al.*, 1997; 2004; *Lee et al.*, 2005;
464 *Oliveira et al.*, 2005; *Phillips et al.*, 2008; *Scholz et al.*, 2011; *Zeppel et al.*, 2014;
465 *Konings and Gentine*, 2016]. In summary, water stress in tropical rainforest canopy
466 species may not primarily be due to soil water stress but rather to atmospheric demand or
467 a combination of soil moisture stress and atmospheric demand. The reduction of leaf and
468 xylem water potentials increase stress in the soil-plant continuum. Radiation, temperature
469 and VPD are therefore essential to understand tropical wet forests dryness response.

470

471 Land-surface and ecosystem models, apart from a few exceptions [*Xu et al.*, 2016;
472 *Kennedy et al.*, 2019], do not represent plant hydraulics and typically only rely on an
473 empirical reduction of stomatal and ecosystem conductance, and therefore transpiration
474 and GPP, as functions of root-averaged soil moisture or water potential (e.g., [*Noilhan
475 and Planton*, 1989; *Sellers et al.*, 1996a; 1996b; *Ek*, 2003; *Boulet et al.*, 2007; *Gentine et
476 al.*, 2007; *Ngo-Duc et al.*, 2007; *Stoekli et al.*, 2008; *Balsamo et al.*, 2009; *Boone et al.*,
477 2009a; *Bonan et al.*, 2011; *Lawrence et al.*, 2011; *Niu et al.*, 2011; *Bonan et al.*, 2012;
478 *Canal et al.*, 2014; *Han et al.*, 2014; *Naudts et al.*, 2014; *De Kauwe et al.*, 2015; *Chaney*

479 *et al.*, 2016; *Chen et al.*, 2016; *Haverd et al.*, 2016 among others). The root profile
480 averaging of soil moisture or water potential to define water stress exaggerates the impact
481 of surface drying, as in reality deeper roots may still effectively transport water to the
482 plant xylem even if surface roots experience dry conditions and therefore can maintain
483 overall high rates of GPP and transpiration.

484

485 The inclusion of plant hydraulics in tall canopy species leads to strong differentiation
486 between leaf (and upper xylem) and soil water potential (Figure 11) during midday,
487 especially in the dry season. Indeed, leaf and xylem water potentials substantially drop
488 because of the large transpiration rates through the stomata and because the xylem cannot
489 be instantaneously refilled due to the large flow drag in the elongated xylem. As a result,
490 plant hydraulics induce a shutdown of stomata during the day reducing the transpiration
491 rate near peak solar hours, also known as “midday depression,” [*Malhi et al.*, 1998;
492 *Williams et al.*, 1998; *Harris et al.*, 2004] in order to reduce desiccation of the leaf and
493 xylem. In addition, plant hydraulics also induces a natural hydraulic redistribution of
494 water in the root profile reducing dryness in the upper profile in the dry season [*Lee et*
495 *al.*, 2005; *Oliveira et al.*, 2005; *Domec et al.*, 2010; *Prieto and Ryel*, 2014; *Kennedy et*
496 *al.*, 2019], using deep root moisture rather than surface soil moisture when needed, as the
497 water flows down gradient of water potentials. This is fundamentally different from
498 typical parameterizations using average water stress of the root water profile, which are
499 oversensitive to surface water stress, in typical parameterizations. Both of those effects
500 lead to reduced sensitivity to water stress and help maintain higher rates of transpiration
501 throughout the entire dry season, whereas typical land surface models overestimate water
502 stress in the dry season [*de Gonçalves et al.*, 2013; *Alemohammad et al.*, 2016; 2017].

503

504 5 Tropical land-atmosphere interactions: Local and nonlocal 505 perspectives

506 Having reviewed some of the important components of tropical land-atmosphere
507 interactions, we now turn to the coupling of these components. Often, land-atmosphere
508 interactions are framed in terms of a one dimensional column, comprising a “point” of

509 interest, although a point here may be understood not only as a site (such as an eddy
510 covariance flux tower) but also as spatial averages of varying scales. While this local,
511 column view is certainly instructive, we suggest that it is also necessary to consider land-
512 atmosphere interactions through an interplay with remote influences, i.e., a nonlocal
513 perspective. This may be especially true in the tropics, given the strong coupling that
514 exists between convective and large-scales. We will revisit the seasonality of tropical
515 climate through the lens of these local and nonlocal perspectives of land-atmosphere
516 interactions.

517

518 5.1 Quantifying land-atmosphere interactions

519 [*Green et al.*, 2017] recently developed a method to define the feedback between the
520 biosphere and atmosphere using multivariate conditional Granger causality (based on
521 lagged autoregressive vectors). We here use a similar framework using ET from
522 WECANN and precipitation from GPCP as well as photosynthetically active radiation
523 from CERES (Figure 12).

524

525 Most of the feedback between surface ET and precipitation occurs in the climatically
526 transitional and/or monsoonal regions, such as the savanna region of Northeastern Brazil
527 and the monsoonal regions over South Asia, the Sahel, Southern Africa, and Northern
528 Australia. In Brazil, these results are consistent with spatial transition inherent in the
529 convective margins concept introduced by Lintner and Neelin (2007; see also Figure 13)
530 and the impact of soil moisture and evapotranspiration on setting the location of the
531 transition between the dry and wet regions. The Sahelian and Southern African Monsoon
532 are also located in regions between very dry (deserts) and humid regions, where surface
533 feedback may be crucial for the penetration of the Monsoonal flow inland [*Lintner and*
534 *Neelin*, 2009; *Lintner et al.*, 2015]. Indeed, the biosphere in this region modulates the
535 local climate state: multiple equilibrium states, corresponding to different ecosystem
536 initial conditions, may exist under the same external (e.g., top of the atmosphere solar)
537 forcing [*Wang et al.*, 2000]. The effect of vegetation on land-atmosphere coupling
538 manifests itself at multiple timescales. At short timescales after precipitation, evaporation
539 is accelerated with intercepted water in the canopy. However, at longer timescales

540 vegetation acts to delay and prolong evaporation of water stored in the root zone. The
541 magnitude and timescale of these sources of water recycling vary depending on
542 ecosystem structure, including rooting depth and canopy structure, which may co-evolve
543 with atmospheric conditions at the interannual timescale [Nicholson, 2000]. This
544 represents a clear pathway for two-way feedbacks between the land surface and
545 precipitation.

546

547 We further emphasize that those feedbacks (Figure 12) are likely to also be influenced by
548 non-local conditions, with regional and large-scale changes in ocean to land flow and the
549 in-land distance of penetration influencing local coupling. We note that climate models
550 seem to exhibit soil moisture (and therefore evapotranspiration)- precipitation feedbacks
551 in similar tropical regions, when averaged across models, even though individual model
552 response varies [Koster *et al.*, 2011; Seneviratne, 2013] (one degree pixel and monthly
553 time scales). We emphasize that the PAR radiation product is very uncertain in the
554 tropics [Jimenez *et al.*, 2011] as it ultimately relies on a model to obtain surface incoming
555 radiation, which might explain the reduced biosphere-precipitation feedback strength in
556 the wet tropics compared to other regions. It is also likely that the bulk of the radiative
557 feedbacks are taking place at smaller times scales such as the ones observed with MODIS
558 (Figure 15). This shallow cloud cover is relatively steady spatially and in time, especially
559 in the dry season.

560

561 5.2 A local view of tropical land-atmosphere interactions

562 A critical aspect of land-atmosphere interactions in tropical rainforests is related to
563 shallow clouds and fog rather than deep convective clouds. Clearly, much of the focus of
564 tropical land-atmosphere interactions has been on feedbacks involving precipitating deep
565 convection, and the impact of surface heterogeneity on convective rainfall. On the other
566 hand, the coupling of the land surface to radiation has been relatively understudied.
567 Shallow clouds lead to reduced productivity and transpiration [Anber *et al.*, 2015a], yet
568 the latter depends on cloud thickness as cumulus clouds (shallow convection) generate
569 more diffuse light and may consequently boost photosynthesis when they are not too

570 thick [Pedruzo-Bagazgoitia *et al.*, 2017], Figure 14. Fog on the other hand, strongly
571 diminishes the amount of incident light for ecosystems. Fog [Anber *et al.*, 2015a] and
572 shallow clouds [Giangrande *et al.*, 2017] appear to be two of the primary differences
573 between the dry and the wet season (in addition to the preferential occurrence of
574 nighttime mesoscale convective systems in the rainy season, which are not directly
575 relevant for land-atmosphere interactions associated with daytime processes). Low-level
576 cloudiness largely affects the surface incoming radiation by reducing shortwave surface
577 incoming radiation in the wet season, especially in the morning [Anber *et al.*, 2015a;
578 Giangrande *et al.*, 2017], which in turn leads to strong reduction in GPP and ET. These
579 clouds are also tightly connected to surface processes and especially the surface energy
580 partitioning. Indeed, nighttime fog, which often persists into the early daylight hours.
581 This fog is due to nighttime longwave cooling in very humid boundary layers, due for
582 instance to evening rain in the wet season [Anber *et al.*, 2015a]. Shallow clouds are
583 themselves directly forced by surface-generated thermals, i.e. boundary layer processes,
584 and they are modified by the sensible and latent heat flux magnitude [de Arellano *et al.*,
585 2014, 2019]. Shallow convection and low-cloud cover are also tightly connected to
586 ecosystem seasonality and to the diurnal cycle [Anber *et al.*, 2015a; Tang *et al.*, 2016;
587 Giangrande *et al.*, 2017].

588

589 Historically, the study of land-atmosphere interactions in the Tropics, and tropical
590 rainforests in particular, has emphasized effects of heterogeneity, especially due to
591 deforestation, on the generation of deep convection through mesoscale circulations (see
592 [Lawrence and Vandecar, 2015] for a complete review, as well as [Avisar and Pielke,
593 1989; Pielke and Avisar, 1990; Pielke *et al.*, 1991; Dalu *et al.*, 1996; Avisar and
594 Schmidt, 1998; Taylor *et al.*, 2007; 2009; 2011; Rieck *et al.*, 2015; Khanna *et al.*, 2017]).
595 The hypothesis behind this is that deforestation reduces EF and surface roughness
596 [Khanna *et al.*, 2017]. The associated increased buoyancy flux over the deforested areas,
597 mostly reflecting a shift toward increased sensible heating, induces mesoscale
598 circulations. These circulations enhance cloudiness through local buoyancy fluxes,
599 turbulent kinetic energy generation, and low-level moisture advection from adjacent
600 forested areas, thus providing all the key ingredients for moist convection generation

601 [Rieck *et al.*, 2014; 2015]. It seems unlikely however that momentum roughness plays a
602 major role in this high radiation environment [Park *et al.*, 2017], where circulations are
603 mostly buoyancy-driven. Instead, the heat and moisture roughness lengths [Park *et al.*,
604 2017] as well as leaf area index and stomatal conductance, which scales the magnitude of
605 the evapotranspiration flux, are the main players, in addition to changes in soil moisture
606 availability, for the circulation. The impact of the deforestation on surface fluxes and
607 local circulation can change from buoyancy-driven to surface roughness driven as the
608 spatial scale of the deforestation increases [Khanna *et al* 2017].

609

610 Induced mesoscale circulations and associated deep convection are clearly observable
611 with remote sensing observations [Khanna *et al.*, 2017] and are more important in the dry
612 season [Khanna *et al.*, 2017], when convection is more locally, and regionally, triggered
613 [Anber *et al.*, 2015a; Ghate and Kollias, 2016]. Once precipitation occurs, cold pools,
614 i.e., density currents induced by ice melt and evaporating rain in downdrafts, dominate
615 the surface-induced mesoscale circulation [Rieck *et al.*, 2015], and reduce the surface
616 heterogeneity signal. In the wet season, the relative contribution of local forcing to the
617 total rainfall is small as the bulk of the precipitation is due to mesoscale convective
618 systems or larger-scale systems propagating throughout the basin, less tightly connected
619 to surface and boundary layer processes [Ghate and Kollias, 2016].

620

621 Even during the dry season, a large fraction of the Amazon and of Indonesia only
622 experience minimal water stress (Figure 8 and Figure 7) so that increased radiation
623 generates higher rates of photosynthesis (Figure 5) and ET (Figure 6) [Anber *et al.*,
624 2015a]. Indeed, higher transpiration in the dry season (due to the higher demand which is
625 not entirely compensated by the slight water stress) can compensate the effect of reduced
626 rain reevaporation intercepted by the canopy. As a result the feedback loop between
627 precipitation and ET is weakened and the impact of the dry season on ET (and hence
628 clouds) is strongest (Figure 14). In addition, the feedback of shallower clouds and surface
629 radiation may be more important, Figure 14, than the feedback of deeper clouds and
630 precipitation, as those shallow clouds are preferentially triggered over drier surfaces.
631 Because shallow clouds have a small life cycle (typically less than 30 minutes) compared

632 to deep convective and mesoscale systems, they are more directly connected to the
633 underlying surface conditions and interact more with the local conditions.

634

635 Fewer studies have studied changes in shallow clouds [*Wang et al.*, 2000; *Lawton et al.*,
636 2001; *Chagnon et al.*, 2004; *Ray et al.*, 2006; *Wang et al.*, 2009; *Pielke et al.*, 2011; *Rieck
637 et al.*, 2014; *Anber et al.*, 2015a], even though the impact of changes in the surface
638 energy partitioning and heterogeneity on low-level clouds is clear and spatially
639 systematic (Figure 15). Given the importance of cloud cover on shortwave radiation and
640 their importance for the differentiation between the dry and wet seasons over wet tropical
641 rainforests we believe that this low-cloud feedback might be quite critical for rainforest
642 ecosystem functioning. Indeed it was pointed out by [*Morton et al.*, 2014; *Anber et al.*,
643 2015a; *Morton and Cook*, 2016] that light changes between the dry and wet season due to
644 changes in cloud cover were one of the primary reasons for changes in the seasonality of
645 surface fluxes, in addition to leaf flush out [*Lopes et al.*, 2016; *Saleska et al.*, 2016]. At
646 sub-daily scales, the shading due to low clouds reduces surface temperature and
647 ecosystem respiration [*Mahecha et al.*, 2010; *Peterhansel and Maurino*, 2011; *Thornley*,
648 2011; *Hadden and Grelle*, 2016; *Ballantyne et al.*, 2017]. This reduction depends
649 strongly on the cloud cycling and thickness. As a result, cloud-induced reductions in
650 respiration can cancel reductions in photosynthesis, such that the net effect of cloud
651 shading on net ecosystem exchange is unclear. *Horn et al.* [2015] showed that by
652 explicitly calculating the surface coupling leads to a change in the length scales of clouds,
653 and a reduction of the cloud life time. As a result, and although the cloud cover remains
654 almost the same there are larger populations of smaller shallow cumuli. This responses to
655 vegetation influence also the moisture transport and the cloud characteristics [*Sikma et al.*,
656 2019].

657

658 In addition to regulating radiative energy balance at the surface, [*Wright et al.*, 2017]
659 have shown that shallow convection transports moisture, provided by plants’
660 transpiration, from the atmospheric boundary layer to the lower troposphere during the
661 late dry season and early dry to wet transition seasons (July-September) [*Fu and Li*,
662 2004]. This mechanism, referred to as the “shallow convective moisture pump”, plays an

663 important role in priming the atmosphere for increasing deep convection (e.g., [Schiro *et*
664 *al.*, 2016; Zhuang *et al.*, 2017]), and wet season onset over the Amazon [Wright *et al.*,
665 2017].

666

667 The results discussed until now omitted the relation between physical processes and the
668 atmospheric composition, and more specifically the role of chemical reactions and
669 aerosols. Over rainforests, the pristine and undisturbed conditions of the atmospheric
670 boundary layer described in the seminal study by [Garstang and Fitzjarrald, 1999] are
671 currently undergoing rapid changes due to atmospheric composition modifications. Their
672 direct impact on the radiative and microphysical properties are due to biomass burning
673 and enhancement of concentrations of secondary organic aerosol precursors. Biomass
674 burning in Amazonia leads to increased aerosol optical depth and to abnormal
675 distributions of the heating rate profile. Analyzing systematic experiments performed by
676 large-eddy simulations, Feingold *et al.*, [2005] studied the processes that lead to the
677 suppression of clouds. Firstly, at the surface there are clear indications that the latent and
678 sensible heat flux are reduced, yielding convective boundary layers characterized by less
679 turbulent intensity and by delays in the morning transition [Barbaro and Vilà-Guerau de
680 Arellano, 2014]. Both aspects tend to reduce cloud formations. Secondly, [Barbaro and
681 Vilà-Guerau de Arellano, 2014] indicated that the vertical location of the smoke layer is
682 crucial in determining the dynamics of the boundary layer which can delay the onset of
683 shallow cumulus. In turn, and ass. As described by [Feingold *et al.*, 2005], smoke
684 confined in the well-mixed sub-cloud layer might positively benefit the cloud formation
685 since it distributes the heat uniformly that contributes to enhance convection. On the
686 other hand, smoke layers located within the cloud layer tend to stabilize the cloud layer
687 and therefore decrease the possibility of cloud formation. These results are very much
688 dependent on the aerosol optical properties defined by their heating, scattering and
689 hygroscopic properties. As a first indicative figure, the mentioned LES study and
690 observations by [Koren *et al.*, 2004] stressed that smoke layers with an aerosol optical
691 depth larger than 0.5 might already lead to cloud suppression by 50%. Yu *et al.* [2008]
692 have shown observationally that the influence of aerosols on shallow clouds varies with
693 meteorological conditions. When the ambient atmosphere is drier (relative humidity

694 $\leq 60\%$), cloud burning effect (evaporation of cloud droplets) due to increased absorption
695 of solar radiation by aerosols outweighs the increase of cloud droplets due to aerosol-
696 cloud microphysical effect. The reduced shallow clouds can further enhance the surface
697 dryness. In contrast, when the ambient atmosphere is relatively humid (relative humidity
698 $\geq 60\%$), the aerosol-cloud microphysical effect outweighs the cloud burning effect,
699 leading to an increase of shallow clouds and relative humidity near surface. In so doing,
700 aerosols can amplify the original moisture anomalies near the surface. Aerosols have also
701 shown to increase the lifetime of mesoscale convection over Congo and Amazon, due to
702 the delay of the precipitation that enhances ice formation and increased lifetime of the
703 mature and decay phase of deep convection [*Chakraborty et al.*, 2016].

704

705 These modifications are not only related to the direct emission of aerosol, but also to
706 changes in the gas phase chemistry that act as a precursor for the formation of secondary
707 organic aerosol. *Andreae et al.*, [2002] showed large differences in NO_x and ozone (O_3)
708 mixing ratio throughout the Amazon from rather pristine conditions with NO_x and ozone
709 levels below 0.1 ppb and 20 ppb, to values above 0.1 ppb and maximum levels of O_3 near
710 50 ppb near Manaus. Recent field experiments within the Green Ocean Amazon
711 campaign (GoAmazon) [*Fuentes et al.* 2016; *Martin et al.*, 2016] corroborate these
712 levels as well as the high levels of the bio-organic compounds, in particular isoprene and
713 monoterpene. Closely related, these changes are accentuated by anthropogenic emissions,
714 from Manaus. The unique distribution of aerosols in Amazonia might explain observed
715 differences in deep convection, in particular lightning frequency, between Amazonia, the
716 Maritime continent and the Congo basin [*Williams et al.* 2004]. To represent these
717 chemistry changes and their effect on convection adequately, the dynamics that drive
718 processes such as the entrainment of pollutants from the free troposphere need to be taken
719 into account [*Vila-Guerau de Arellano et al.*, 2011]. As a result of this interaction
720 between radiation, the land surface, dynamics and chemical processes, the frequency of
721 the clear convective vs. shallow cloudy conditions may be modified in the future. Current
722 efforts in monitoring them and improving the parameterizations of convection are under
723 way [*Dias et al.*, 2014]. These efforts should include also in an integrated manner the
724 combined role of dynamics and chemistry to quantify relevant processes Two of them are

725 relevant and difficult to be represented in large-scale models. First, the role of canopy in
726 controlling the emission and deposition of the aerosol precursors on tropical rain forest
727 [Freire *et al.*, 2017]. Second ventilation of pollutants from the sub-cloud layer into the
728 cloud layer, i.e. mass flux parameterizations, under representative Amazon conditions
729 [Ouwensloot *et al.*, 2013].

730

731 In addition to affecting cloud microphysics, biomass burning in the tropics significantly
732 affects the global carbon budget. For example, in September and October of 2015 fires in
733 the Maritime continent released more terrestrial carbon (11.3 Tg C) than the
734 anthropogenic emissions of the EU (8.9 Tg C) [Huijnen *et al.*, 2016]. The extent of forest
735 fires in this region is tied to El Niño-induced drought conditions, and antecedent sea
736 surface temperature (SST) patterns are closely related to burned area at the global scale,
737 particularly in hotspots concentrated in the tropics [Chen *et al.*, 2016]. Aerosol emissions
738 and biomass burning exert a strong control on land-atmosphere coupling of the carbon
739 and water cycles, and the consequences of this coupling is observable globally.

740

741 5.3 Nonlocal view of tropical land-atmosphere interactions

742 5.3.1 Moisture tracking and source attribution

743 A fundamental consideration in the study of the hydrologic cycle over tropical continents
744 is where the moisture for precipitation ultimately derives. In fact, many of the seminal
745 studies of tropical land region water cycle in the 1980s and 1990s focused on the concept
746 of recycling, i.e., the contribution of evapotranspiration over a region of interest to
747 precipitation in that region [Salathi *et al.* 1983, Brubaker *et al.* 1993; Eltahir and Bras,
748 1994; Trenberth 1999]. While these early studies typically estimated recycling used bulk
749 formulas derived under simplifying assumptions, more sophisticated approaches for
750 estimating recycling have emerged [van der Ent *et al.* 2010, including comprehensive
751 moisture tracking operating on subdaily inputs on models and reanalysis, e.g., the
752 Dynamic Recycling Model [Dominguez *et al.* 2006], the Water Accounting Model (van
753 der Ent *et al.* 2010), and Lagrangian approaches using parcel dispersion models such as

754 Flexpart [Gimeno et al. 2012]. Contemporary estimates of recycling ratios for the
755 Amazon Basin range from 25%-35% [Zemp et al. 2014].

756 These more sophisticated approaches have also enabled identification and quantification
757 of upstream sources of moisture that lead to downstream rainfall over tropical land
758 regions [Dirmeyer et al., 2007; Drumond et al., 2014; Hoyos et al., 2018; Stohl and
759 James, 2005]. For example, by combining a Lagrangian back trajectory approach with
760 rainfall and leaf area index data, [Spracklen et al., 2012] quantified the linkage between
761 downstream rainfall amount and upstream air mass exposure to vegetation (Figure 17).
762 Over more than half of the tropical land surface, Spracklen et al. estimate a twofold
763 increase in downstream rainfall for those air masses passing over extensive vegetation
764 compared those passing over little upstream vegetation. Based on these estimates and
765 extrapolating current Amazonian deforestation trends into the future, these authors
766 project wet and dry season rainfall decreases of 12 and 21%, respectively, by the year
767 2050. In some regions, such attributions underscore the importance of upstream land
768 regions as moisture sources: for example, [Drumond et al., 2014] used the FLEXPART
769 model forced with ERA-Interim reanalysis to estimate $E - P$ along trajectories passing
770 over the La Plata Basin in subtropical South America to establish that much of the
771 moisture entering this region derives from the Amazon Basin to the north and west.

772

773 5.3.2 Large-scale coupling, idealized modeling

774 Some studies have attempted to frame tropical land-atmosphere interactions in larger-
775 scale, and implicitly non-local, way [Zeng and Neelin 1999, Lintner et al. 2013; Berg et
776 al. 2017; Langenbrunner et al. 2019]. For example, Lintner et al. [2013] developed an
777 idealized prototype for diagnosing large-scale land-atmosphere coupling constructed
778 from coupling the vertically-integrated temperature and moisture equations to a simple
779 bucket soil moisture model. From this model, they derived analytic sensitivity of
780 precipitation to soil moisture spatial variation along a transect to various process
781 parameters related to convection and radiation, such as the timescale for convective
782 adjustment and the strength of cloud-radiative feedback. Schäfli et al., [2012] developed
783 a conceptually similar model from which an analytic expression for the ratio of
784 evapotranspired moisture integrated along flow path to precipitation (or recycling ratio)

785 was obtained (Figure 16). Such idealized model frameworks, which consider tropical
786 land-atmosphere interactions by coupling both water and energy cycles, can be helpful in
787 interpreting and diagnosing linkages between local and non-local feedbacks.

788

789 5.4 Land-atmosphere interactions and their impact on tropical seasonality

790 One of the outstanding issues in the study of tropical land region climates involves
791 controls on precipitation seasonality, particularly its regional variability. Generally, the
792 seasonality follows the variation in maximum solar heating, but other factors, such as
793 ocean thermal inertia, topography, dynamics and circulation, and moisture transport, as
794 well as the state of the land surface, can exert considerable influence on the timing and
795 amplitude of tropical land region seasonal evolution. Over the Amazon basin, seasonality
796 exhibits marked variation in both latitude and longitude: for example, at 5S, the dry-to-
797 wet transition proceeds from the central Amazon eastward toward the Atlantic coast
798 [*Liebmann and Marengo, 2001*]. It is also worth noting a pervasive tendency for the dry-
799 to-wet season transition to occur much more rapidly than the wet-to-dry transition, as
800 evident in tropical monsoon systems including South Asia, West Africa, and South
801 America.

802

803 Analyzing multiple observational and reanalysis products, [*Fu and Li, 2004*] identified a
804 strong influence of surface turbulent fluxes on the dry-to-wet transition and its
805 interannual variability over the Amazon. In particular, their results link earlier wet
806 season onset to wetter conditions in the antecedent dry season: the higher latent fluxes at
807 the end of a wetter dry season encourage weaker convective inhibition (CIN) and
808 enhance CAPE, both of which are more favorable to wet season rainfall occurrence.
809 However, these authors also underscore the participation of the large-scale circulation
810 and its role in establishing a background environment (e.g., moisture convergence) to
811 support wet season rainfall. Incursion of cold fronts into the southern Amazon may act as
812 triggers for rapid initiation of wet season onset once the local thermodynamics become
813 favorable [*Li et al., 2006*].

814

815 Recent research suggests that the land-atmosphere coupling is integral to the earlier
816 occurrence of determining earlier occurrence of wet season onset over western and
817 southern Amazonia, relative to that of eastern Amazonia. Both in situ and satellite
818 ecological observations have consistently shown that rainforests increase their
819 photosynthesis, and thus evapotranspiration (ET), during late dry season across
820 Amazonia (e.g., [Huete *et al.*, 2006; Lopes *et al.*, 2016; Munger *et al.*, 2016; Wehr *et al.*,
821 2016]). The wet season onset over the Southern Hemisphere portion of western
822 Amazonia occurs during September to October, about two to three months before the
823 Atlantic ITCZ [Fu *et al.*, 2016]. Using several satellite measurements, including the
824 isotopic signature of deuterium in atmospheric water vapor (HDO) and SIF, Wright *et al.*
825 [2017] have shown that increasing late dry season ET is the primary source of increasing
826 water vapor in the lower troposphere that initiates the increase of deep convection and
827 rainfall over southern Amazonia. In particular, the increase of water vapor with enriched
828 HDO in the boundary layer and free troposphere follows the increase of photosynthesis
829 during late dry season prior to wet season onset. During this period, the water vapor
830 HDO is too high to be explained by transport from Atlantic Ocean, and is consistent with
831 that from plant transpiration. Such a moistening of the atmosphere starts in western
832 southern Amazonia, the part of Amazonia that is most remote from the Atlantic Ocean
833 with high biomass. It then progresses towards eastern southern Amazonia. Thus, during
834 the late dry season this appears to contribute to the timing and spatial variation of the
835 initial moistening of the atmosphere, that ultimately lead to wet season onset over
836 southern Amazonia.

837

838 Wet season onset over southern Amazonia has been increasingly delayed since the late
839 1970s [Marengo *et al.*, 2011; Fu *et al.*, 2013]. In addition to the influence of global
840 circulation change, such a change has been attributed to land use. For example, [Butt *et al.*,
841 2011] have compared long-term rainfall data between deforested and forested areas
842 over part of the southern Amazonia. They observed a significant delay in wet season
843 onset over the deforested areas, consistent with that implied by Wright *et al.* [2017]. In
844 addition, [Zhang *et al.*, 2008; 2009] have shown that biomass burning aerosols, which

845 peak in late dry season, can also weaken and delay dry to wet season transition by
846 stabilizing the atmosphere, reducing clouds and rainfall.

847 6 Discussion – conclusions

848 In this review paper, we have discussed some of the important aspects of land-
849 atmosphere interactions pertaining to the tropics. While our review is by no means
850 exhaustive, it illustrates some of the key processes in the coupled tropical land-
851 atmosphere system acting across multiple spatial and temporal scales, especially in
852 rainforest ecosystems.

853

854 We have argued that feedbacks between the land surface and precipitation in the tropics
855 are possibly non-local in nature (for instance due to the weak temperature gradient) and
856 may mostly impact moisture advection from the ocean and the position of deep
857 convection onset. Local rainfall feedback associated with mesoscale heterogeneities
858 appear to be rather small in magnitude, at least compared to the annual-mean rainfall, and
859 not sufficiently spatially systematic to truly affect ecosystem functioning.

860

861 Moreover, we contend that land surface-cloud feedbacks, especially those involving
862 shallow clouds and fog, are critical in terms of regulating light (direct and diffuse),
863 temperature, and water vapor deficit over tropical forest, but such feedbacks have
864 received relatively less attention. Remote sensing platforms provide useful information
865 for quantifying such feedbacks, but these need to be complemented by ground
866 measurements. Eddy-covariance measurements may prove difficult to use, as mesoscale
867 circulations alter the homogeneity assumption of eddy-covariance methods.

868

869 We have also discussed errors and biases in the representation of tropical continental
870 climates in current generation climate and Earth system models. Multi-model
871 assessments of soil moisture-precipitation feedback strength in ensembles of earth system
872 models such as [Koster *et al.*, 2004] manifest strong land-precipitation feedbacks in
873 similar transitional regions as the ones observed [Green *et al.*, 2017], which seems to be
874 mostly related to modification of the moisture advection penetration distance from the

875 ocean rather than to local feedbacks. These feedbacks appear to be of relatively minor
876 importance in the core of tropical rainforests but are more critical for more marginal
877 rainfall regions (savanna). These regions are of critical importance for the terrestrial
878 global carbon cycle, providing the main terrestrial sink, but might be severely impacted
879 by climate change and droughts in particular [*Laan Luijkx et al.*, 2015]. Whether the
880 interannual variability in surface CO₂ flux in those regions is a zero-sum game with wet
881 years compensating dry years still is an open question especially in the context of rising
882 CO₂ concentration.

883

884 The core of rainforests seems to be more affected by radiation feedbacks at relatively
885 small spatial scales (~1km), which can be dramatically influenced by land cover and land
886 use change. Projected rates of future deforestation are poorly constrained, especially
887 regionally, though in recent years, the Congo and Indonesia have experienced increasing
888 deforestation while the deforestation rate in the Amazon has dropped.

List of Figures

1858

1859 Figure 1: Snapshot of cloud cover over the Amazon basin on 2018, Sept 25 (courtesy
1860 NASA Earth Observatory, MODIS visible bands). Small clouds are shallow convective
1861 clouds, highlighting surface Bowen ratio changes between the river and the forest. On the
1862 left, the deep convective cells do not follow the surface heterogeneity (and is much larger
1863 in scale). Not the cold pool bow effect on the bottom left corner, with no clouds within the
1864 cold pools and clouds on the edge of the cold pool.

1865

1866 Figure 2: Diurnal cycle in local hour of dry (red) and wet (blue) season observations of
1867 precipitation at K34, near Manaus, along with their standard deviation averaged across
1868 years 2010-2014.

1869 Figure 3: Seasonal variations in Evapotranspiration (ET) from WECANN, Precipitation
1870 (Precip) based on GPCP in units of energy (W/m², by multiplying it by the latent heat of
1871 vaporization), Net Radiation (R_n) from CERES and Gross Primary Production (GPP)
1872 based on WECANN informed by Solar-Induced Fluorescence (SIF) over the wet part of
1873 the Amazon (top left), the Savanna region of Brazil (top right), over Indonesia (bottom
1874 left) and over the Congo basin (bottom right).

1875 Figure 4: Seasonality of Precipitation based on GPCP in the tropics in December-
1876 January-February (a), March-April-May (b), June-July-August (c), and September-
1877 October-November (SON) and its latitudinal average (e).

1878 Figure 5: same as Figure 4 but for Gross Primary Production (GPP)

1879 Figure 6: same as Figure 4 for latent heat flux LE

1880 Figure 7: same as Figure 4 for sensible heat flux H

1881 Figure 8: same as Figure 4 for evaporative fraction (EF), the ratio of LE to H+LE.

1882 Figure 9: same as Figure 4 for sea-level surface moist static energy flux, the sum of
1883 sensible heat flux H and latent heat flux

1884 Figure 10: Schematic showing the vertical structure of light and water limitations in a
1885 tropical forest.

1886 Figure 11: Climatology of the diurnal cycle of leaf water potential and top soil water
1887 potential in the dry and wet seasons in Caxiuana, Brazil simulated by the Community
1888 Land Model (CLM) with plant hydraulics.

1889 Figure 12: Land-atmosphere feedback strength (change in the variance due to the
1890 feedback) between Precipitation and ET (top) and Photosynthetically Active Radiation
1891 (PAR) (bottom) based on recent metric developed by Green et al. [2017] using a
1892 multivariate Granger causality approach.

1893 Figure 13: (a) Schematic of the key elements of the convective margins framework as
1894 applied along an inflow path across northeastern South America. The solid blue and
1895 black lines are precipitation and vertically-integrated moisture for steady-state conditions,
1896 while the dashed blue and black lines correspond to precipitation and vertically-
1897 integrated moisture “smeared out” in the presence of time-varying, transient behavior.
1898 Adapted from Figure 2 of Lintner and Neelin (2009). (b) Rainfall longitudinal transects
1899 from the Climate Anomaly Monitoring System (CAMS) raingauge-derived precipitation
1900 data for September-October-November for the period 1950-2000 for El Niño (red), La
1901 Niña (blue), and all (black) years, averaged over 3.75°S-1.75°S. From Figure 4b of
1902 Lintner and Neelin (2007).

1903 Figure 14: Mesoscale heterogeneity impact on cloud generation in the dry season. a)
1904 Typical perspective regarding the impact of deforestation and clearings generating deep
1905 convective clouds and b) more realistic impact, in terms of mostly a modification of
1906 shallow convection cloud cover, impacting radiation more than precipitation.

1907 Figure 15: MODIS visible image of the Northwestern Amazon as the basin transition into
1908 the wet season. In the dry season surface heterogeneity whether due to rivers, forest-
1909 deforested patches or land-ocean contrast are very clear. In the wet season those sharp
1910 gradients disappear as cloud cover mostly dominated by deep convection starts
1911 organizing at scales independent from the surface heterogeneity.

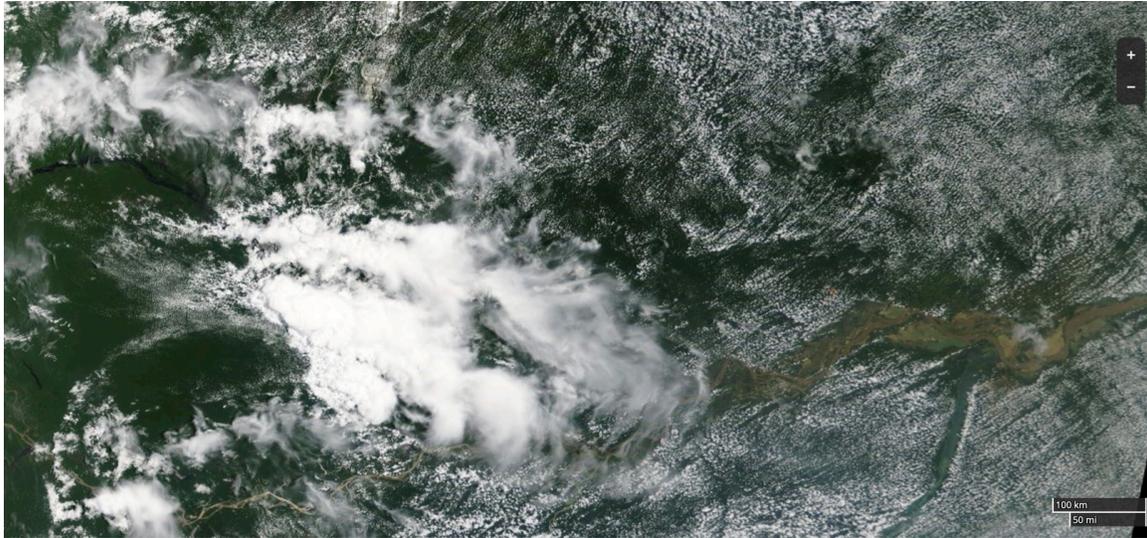

1912 Figure 16: Continental recycling ratio, ρ , and recycling length scale, λ , normalized by
1913 length scale, L , along the inflow direction x for atmospheric moisture either increasing or
1914 decreasing along the inflow path in the idealized model of Schäfli et al. (2012). ρ
1915 represents how much of the rainfall is derived from terrestrial evapotranspiration, while λ
1916 represents the length scale over which evapotranspired water is removed from the
1917 atmosphere via precipitation. Generally ρ increases for larger distances into the
1918 continental interior, meaning recycling increases in importance, while λ decreases. From
1919 Figure 8 of Schäfli et al. (2012).

1920 Figure 17: 10 day-back trajectory analysis over several regions of the continental tropics,
1921 along with LAI, mean TRMM estimated rainfall, and GLDAS ET estimates.
