12

13 Abstract

14 Shallow groundwater in the Prairie Pothole Region (PPR) is recharged predominantly by snowmelt
15 in the spring and supplies water for evapotranspiration through the summer and fall. This two-way
16 exchange is underrepresented in current land surface models. Furthermore, the impacts of climate
17 change on the groundwater recharge rates are uncertain. In this paper, we use a coupled land and
18 groundwater model to investigate the hydrological cycle of shallow groundwater in the PPR and
19 study its response to climate change at the end of the 21st century. The results show that the model
20 does a reasonably good job of simulating the timing of recharge. The mean water table depth
21 (WTD) is well simulated, except the model predicts deep WTD in northwestern Alberta. The most
22 significant change under future climate conditions occurs in the winter, when warmer temperature
23 changes the rain/snow partitioning, delaying the time for snow accumulation/soil freezing while
24 advancing early melting/thawing. Such changes lead to an earlier start to a longer recharge season,
25 but with lower recharge rates. Different signals are shown in the eastern and western PPR in the
26 future summer, with reduced precipitation and drier soils in the east but little change in the west.
27 The annual recharge increased by 25% and 50% in the eastern and western PPR, respectively.
28 Additionally, we found the mean and seasonal variation of the simulated WTD are sensitive to
29 soil properties and fine-scale soil information is needed to improve groundwater simulation on
30 regional scale.

31

32 Keywords: Groundwater, Recharge, Climate Change, Prairie Pothole Region, Hydrological Cycle,

33 Introduction

34 The Prairie Pothole Region (PPR) in North America is located in a semi-arid and cold region,
35 where evapotranspiration (ET) exceeds precipitation (PR) in summer and near-surface soil is
36 frozen in winter (Gray, 1970; Granger and Gray, 1989; Hayashi et al., 2003; Pomeroy et al., 2007;
37 Ireson et al., 2013; Dumanski et al., 2015). These climatic conditions have introduced unique
38 hydrological characters to the groundwater flow in the PPR (Ireson et al., 2013). During winters,
39 frozen soils reduce permeability and snow accumulates on the surface, prohibiting infiltration (Niu
40 and Yang 2006; Mohammed et al., 2018). At the same time, the water table slowly declines due to
41 a combination of upward transport to the freezing front by the capillary effect and discharge to
42 rivers (Ireson et al., 2013). In early spring, snowmelt becomes the dominant component of the
43 hydrological cycle and the melt water runs over frozen soil, with little infiltration contributing to
44 recharge. As the soil thaws, the increased infiltration capacity allows snowmelt recharge to the
45 water table, the previously upward water movement by capillary effect to reverse and move
46 downwards, and the water table to rise to its maximum level. In summer and fall, when high ET
47 exceeds PR, capillary rise may draw water from the groundwater aquifers to supply ET demands,
48 declining water table. These processes characterize the two-way water exchange between sub-
49 surface soils and groundwater aquifers.

50

51 Previous studies have suggested that substantial changes to groundwater interactions with sub-
52 surface soils are likely to occur under climate change (Tremblay et al., 2011; Green et al., 2011;
53 Ireson et al., 2013, 2015). Existing modeling studies on the impacts of climate change on
54 groundwater are either at global or basin/location-specific scales (Meixner et al., 2016). Global-
55 level groundwater studies focus on potential future recharge trends (Doll and Fiedler, 2008; Doll,

56 2009; Green et al., 2011), yet coarse resolution analysis from global climate models (GCMs)
57 provided insufficient specificity to inform decision making. Basin-scale groundwater studies
58 connect the climate with groundwater-flow models to understand the climate impacts on specific
59 systems (Maxwell and Kollet, 2008; Kurylyk and MacQuarrie, 2013; Dumanski et al., 2015).
60 Regional groundwater modeling studies, such as in the Colorado River Basin (Christensen et al.,
61 2004) and in the western U.S. (Niraula et al., 2017), have applied downscaled climate scenarios
62 from GCMs to drive large scale hydrology models. These studies identified research gaps
63 associated with poor representation of groundwater-soil interactions in models and uncertainties
64 in future climate projections.

65

66 It is challenging to represent groundwater flows in LSMs because the important two-way water
67 exchange between unsaturated soils and groundwater aquifers was neglected in previous LSMs.
68 Recently, this two-way exchange has been implemented in coupled land surface – groundwater
69 models (LSM-GW). For example, Maxwell and Miller (2005) used a groundwater model (ParFlow)
70 coupled with the Common Land Model (CLM) as a single column model. They found that the
71 coupled and uncoupled models were very similar in simulated sensible heat flux (SH), ET, and
72 shallow soil moisture (SM), but differed greatly in simulated runoff and deep SM. Later on, Kollet
73 and Maxwell (2008) incorporated the ET effect on redistributing moisture upward from shallow
74 water table depth (WTD) and found the surface energy partitioning is highly sensitive to the WTD
75 when the WTD is less than 5 m below ground surface. Niu et al. (2011) implemented a simple
76 groundwater model (SIMGM, Niu et al., 2007), into the community Noah LSM with multi-
77 parameterization options (Noah-MP LSM), by adding an unconfined aquifer at the bottom of soil
78 layers. More complex features such as three-dimensional subsurface flow and two-dimensional

79 surface were included in ParFlow v3 and evaluated over much of continental North America for a
80 very fine 1-km resolution (Maxwell et al., 2015). These recent development in coupled land and
81 groundwater models have advanced our knowledge on the important interactions between soil and
82 groundwater aquifer.

83

84 In cold regions, soil freeze-thaw processes further complicate this two-way exchange. Field studies
85 have found that frozen soil not only influences the timing and amount of downward recharge to
86 aquifers by reducing the soil permeability (Koren et al., 1999; Niu et al., 2006; Kelln et al., 2007),
87 but may also induce upward water transport from aquifers to soil freezing fronts (Spaans and Baker,
88 1996; Remenda et al., 1996; Hansson et al., 2004). In the modeling community, a range of
89 approaches have been applied to deal with frozen soil parameterizations. Earlier LSMs assumed
90 no significant heat transfer and soil water redistribution for sub-freezing temperature, for example,
91 in simplified SiB and BATS (Xue et al., 1991; Dickinson et al., 1993; Niu and Zeng, 2012). Koren
92 et al. (1999) suggested that the frozen soil is permeable due to macropores that exist in soil
93 structural aggregates, such as cracks, dead root passages, and worm holes. The NoahV3 model
94 adopted this scheme as its default option. Niu and Yang (2006) suggested to separate a model grid
95 into frozen and unfrozen patches, and these two patches have a linear effect on the soil hydraulic
96 properties. This treatment was incorporated into CLM 3.0 and Noah-MP in 2007 and 2011,
97 respectively.

98

99 The spatial heterogeneity of soil moisture and WTD requires high-resolution meteorological input
100 that direct outputs from GCMs are too coarse to provide. In GCMs, differences in simulated
101 precipitation stem from the choice of convection parameterization scheme (Sherwood et al., 2014;

102 Prein et al., 2015). An important approach to improve precipitation simulation is to conduct
103 dynamical downscaling using the convection-permitting model (CPM) (Ban et al., 2014; Prein et
104 al., 2015; Liu et al., 2017). The CPM uses a high spatial resolution (usually under 5-km) to
105 explicitly resolve convection without activating convection parameterization schemes. CPMs can
106 also improve the representation of fine-scale topography and spatial variations of surface fields
107 (Prein et al., 2013). These CPM added-values provide an excellent opportunity to investigate water
108 table dynamics in the PPR.

109

110 The objectives of this paper are to 1) investigate the performance of a regional scale coupled land-
111 groundwater model in simulating groundwater water levels, recharge and storage in a seasonally
112 frozen environment in PPR; and 2) explore the possible impacts of climate change on these
113 processes.

114

115 In this paper, we use a physical process-based LSM (Noah-MP) coupled with a groundwater
116 dynamics model (MMF model). The coupled Noah-MP-MMF model is driven by two sets of
117 meteorological forcing for 13 years under current and future climate scenarios. These two sets of
118 meteorological dataset are from a CPM dynamical downscaling project using the Weather
119 Research & Forecast (WRF) model with 4-km grid spacing covering the Contiguous U.S. and
120 Southern Canada (WRF CONUS, Liu et al., 2017). The paper is structured as follows: Section 2
121 introduces the groundwater observations for WTD evaluation in the PPR, the coupled Noah-MP-
122 MMF model, and the meteorological forcing from the WRF CONUS project. Section 3 evaluates
123 the model simulated WTD timeseries and shows the groundwater budget and hydrological changes
124 due to climate change. Section 4 and 5 offer a broad discussion and conclusion.

125 2. Data and Methods

126 2.1 Observational data

127 Groundwater observation data were obtained through several agencies: (1) the United States
128 Geological Survey (USGS) National Water Information System in the U.S.
129 (<https://waterdata.usgs.gov/nwis/gw>), (2) the Alberta Environment
130 ([http://aep.alberta.ca/water/programs-and-services/groundwater/groundwater-observation-well-
131 network/default.aspx](http://aep.alberta.ca/water/programs-and-services/groundwater/groundwater-observation-well-
131 network/default.aspx)), (3) the Saskatchewan Water Security Agency
132 (<https://www.wsask.ca/Water-Info/Ground-Water/Observation-Wells/>).

133

134 Initially, groundwater data from 160 wells were acquired, 72 in the U.S., 43 from Alberta, and 45
135 from Saskatchewan. We used the following criteria to select qualified stations for our study and
136 evaluate our model performance against these observations:

- 137 1) the location of the wells are within the PPR region;
- 138 2) a sufficiently long data record exists during the simulation period. We define the
139 observation availability as the available observation period within the 13-year simulation
140 period and select wells with observation availability greater than 80%;
- 141 3) we only take data from unconfined aquifers with shallow groundwater levels (mean WTD >
142 5 m);
- 143 4) we only take data with minimal anthropogenic effects (such as from pumping or irrigation).

144

145 These criteria reduced the observation data to 33 well records, with six in Alberta, 13 in
146 Saskatchewan and 14 from the U.S. **Table 1** summarizes the information for each selected well,
147 and **Fig. 1(a)** shows the location of the wells in our study area. It is noteworthy that most of the
148 groundwater sites have more permeable deposits (sand and gravel) as provincial and state agencies

149 don't monitor low permeability formations. More information about the selecting criteria are
150 provided in the supplemental materials.

151

152 **Fig. 1** (a) Topography of the Prairie Pothole Region (PPR) and station location of rain gauges (black dots) and
153 groundwater wells (red diamonds); (b) Topography of the WRF CONUS domain, with the black box indicating the
154 PPR domain.

155

156 **Table 1.** Summary of the locations and aquifer type and soil type of the 33 selected wells.

157

158

159 2.2 Groundwater and Frozen Soil Scheme in Noah-MP

160 In the present study, we used the community Noah-MP LSM (Niu et al. 2011; Yang et al. 2011),
161 coupled with a GW model – the MMF model (Fan et al. 2007; Miguez-Macho et al., 2007). This
162 coupled model has been applied in many regional hydrology studies in offline mode (Miguez-
163 Macho and Fan 2012; Martinez et al., 2016) and coupled with regional climate models (Anyah et
164 al., 2008; Barlage et al., 2015). We present here a brief introduction to the MMF groundwater
165 scheme and the frozen soil scheme in Noah-MP, further details can be found in previous studies
166 (Fan et al., 2007; Miguez-Macho et al., 2007; Niu and Yang, 2006).

167

168 Fig. 2 is a diagram of the structure of 4 soil layers (0.1, 0.3, 0.6 and 1.0 m) and the underlying
169 unconfined aquifer in Noah-MP-MMF. The MMF scheme defines explicitly an unconfined aquifer
170 below the 2-m soil and an auxiliary soil layer stretching to the WTD, which varies in space and
171 time [m]. The thickness of this auxiliary layer (z_{aux} [m]) is also variable, depending on the WTD:

172
$$z_{aux} = \begin{cases} 1, & WTD \geq -3 \\ -2 - WTD, & WTD < -3 \end{cases} \quad (1)$$

173

174 The vertical fluxes include gravity drainage and capillary flux, solved from the Richards' equation,

175
$$q = K_{\theta} \left(\frac{\partial \psi}{\partial z} - 1 \right), \quad K_{\theta} = K_{sat} * \left(\frac{\theta}{\theta_{sat}} \right)^{2b+3}, \quad \psi = \psi_{sat} * \left(\frac{\theta_{sat}}{\theta} \right)^b \quad (2)$$

176 where q is water flux between two adjacent layers [m/s], K_{θ} is the hydraulic conductivity [m/s] at
177 certain soil moisture content θ [m³/m³], ψ is the soil matric potential [m] and b is soil pore size
178 index. The subscript *sat* denotes saturation. The recharge flux from/to the layer above WTD, R ,
179 can be obtained according to WTD:

$$R = \begin{cases} K_k * \left(\frac{\psi_i - \psi_k}{z_{soil(i)} - z_{soil(k)}} - 1 \right), & WTD \geq -2 \\ K_{aux} * \left(\frac{\psi_4 - \psi_{aux}}{(-2) - (-3)} - 1 \right), & -2 > WTD \geq -3 \\ K_{sat} * \left(\frac{\psi_{aux} - \psi_{sat}}{(-2) - (WTD)} - 1 \right), & WTD < -3 \end{cases} \quad (3)$$

181

182 In the first case, WTD is in the resolved soil layers and z_{soil} is the depth of soil layer with the
 183 subscript k indicating the layer containing WTD while i is the layer above. The calculated water
 184 table recharge is then passed to the MMF groundwater routine.

185

186 The change of groundwater storage in the unconfined aquifer considers three components:
 187 recharge flux (R), river discharge (Q_r), and lateral flows (Q_{lat}):

$$\Delta S_g = (R - Q_r + \sum Q_{lat}) \quad (4)$$

189 where S_g [mm] is groundwater storage, Q_r [mm] is the water flux of groundwater-river exchange,
 190 and $\sum Q_{lat}$ [mm] are groundwater lateral flows to/from all surrounding grid cells. The groundwater
 191 lateral flow ($\sum Q_{lat}$) is the total horizontal flows between each grid cell and its neighbouring grid
 192 cells, calculated from Darcy's law with the Dupuit–Forchheimer approximation (Fan and Miguez-
 193 Macho 2010), as:

$$Q_{lat} = wT \left(\frac{h - h_n}{l} \right) \quad (5)$$

195 where w is the width of cell interface [m], T is the transmissivity of groundwater flow [m²/s], h
 196 and h_n are the water table head [m] of local and neighboring cell, and l is the length [m] between
 197 cells. T depends on hydraulic conductivity K and WTD:

198

$$T = \begin{cases} \int_{-\infty}^h K dz & WTD \geq -2 \\ \int_{-\infty}^{(z_{surf}-2)} K dz + \sum K_i * dz_i & WTD < -2 \end{cases} \quad (7)$$

199 For $WTD < -2$, K is assumed to decay exponentially with depth, $K = K_4 \exp(-z/f)$, K_4 is the
 200 hydraulic conductivity in the 4-th soil layer and f is the e-folding length and depends on terrain
 201 slope. For $WTD \geq -2$, i represents the number of layers between the water table and the 2-m bottom
 202 and z_{surf} is the surface elevation.

203

204 The river flux (Q_r) is also represented by a Darcy's law-type equation, where the flux depends on
 205 the gradient between the groundwater and the river depth and the riverbed conductance:

206

$$Q_r = RC \cdot (h - z_{river}) \quad (8)$$

207 with z_{river} is the depth of river [m] and RC is dimensionless river conductance, which depends on
 208 the slope of the terrain and equilibrium water table. Eq. (8) is a simplification which uses z_{river}
 209 rather than the water level in the river and, for this study, we only consider one-way discharge
 210 from groundwater to rivers. Finally, the change of WTD is calculated as the total fluxes fill or
 211 drain the pore space between saturation and the equilibrium soil moisture state (θ_{eq} [m³/m³]) in
 212 the layer containing WTD:

213

$$\Delta WTD = \frac{\Delta S_g}{(\theta_{sat} - \theta_{eq})} \quad (9)$$

214 If ΔS_g is greater than the pore space in the current layer, the soil moisture content of current layer
 215 is saturated and the WTD rises to the layer above, updating the soil moisture content in the layer
 216 above as well. Vice versa for negative ΔS_g as water table declines and soil moisture decreases.

217

218 **Fig. 2** Structure of the Noah-MP LSM coupled with MMF groundwater scheme, the top 2-m soil of 4 layers whose
 219 thicknesses are 0.1, 0.3, 0.6 and 1.0 m. An unconfined aquifer is added below the 2-m boundary, including an auxiliary
 220 layer and the saturated aquifer. Positive flux of R denotes downward transport. Two water table are shown, one within
 221 the 2-m soil and one below, indicating that the model is capable to deal with both shallow and deep water table.

222

223 There are two options in Noah-MP LSM for frozen soil permeability; option 1, the default option
 224 in Noah-MP, is from Niu and Yang (2006) and option 2 is inherited the Koren et al. (1999) scheme
 225 from NoahV3. Option 1 assumes that a model grid cell consists of permeable and impermeable
 226 patches and the area weighted sum of these patches gives the grid cell soil hydraulic properties.
 227 Thus, the total soil moisture (θ) in the grid cell is used to compute hydraulic properties as:

$$228 \quad \theta = \theta_{ice} + \theta_{liq} \quad (10)$$

$$229 \quad K = (1 - F_{frz})K_u = (1 - F_{frz})K_{sat} \left(\frac{\theta}{\theta_{sat}} \right)^{2b+3} \quad (11)$$

230 the subscript frz and u denote the frozen and unfrozen patches in the grid point. The impermeable
 231 frozen soil fraction is parameterized as:

$$232 \quad F_{frz} = e^{-\alpha(1-\theta_{ice}/\theta_{sat})} - e^{-\alpha} \quad (12)$$

233 $\alpha = 3.0$ is an adjustable parameter. The amount of the liquid water in soil layer is either θ_{liq} or
 234 $\theta_{liq,max}$, the maximum amount of liquid water, which is calculated by a more general form of the
 235 freezing-point depression equation:

$$236 \quad \theta_{liq,max} = \theta_{sat} \left\{ \frac{10^3 L_f (T_{soil} - T_{frz})}{g T_{soil} \psi_{sat}} \right\}^{-\frac{1}{b}} \quad (13)$$

237 where T_{soil} and T_{frz} are soil temperature and freezing point [K]; L_f is the latent heat of fusion [J
 238 kg^{-1}]; g is gravitational acceleration [m s^{-2}].

239

240 On the other hand, the option 2 uses only the liquid water volume to calculate hydraulic properties
241 and assumes a non-linear effect of frozen soil on permeability. Also, the option 2 uses a variant of
242 freezing-point depression equation with an extra term, $(1 + 8\theta_{ice})^2$, to account for the increased
243 interface between soil particles and liquid water due to the increase of ice crystals. Generally,
244 option 1 assumes that soil ice has a smaller effect on infiltration and simulates more permeable
245 frozen soil than option 2 (Niu et al., 2011). For this reason, the option 1 allows the soil water to
246 move and redistribute more easily within the frozen soil and we decide to use option 1 in our study.

247 2.3 Forcing Data

248 The output from the WRF CONUS dataset (Liu et al. 2017) are used as meteorological forcing to
249 drive the Noah-MP-MMF model. The WRF CONUS project consists of two simulations. The first
250 simulation is referred as the current climate scenario, or control run (CTRL), from Oct 2000 to Sep
251 2013, and forced with the 6-hourly 0.7° ERA-Interim reanalysis data. The second simulation is a
252 perturbation to reflect the future climate scenario, closely following the pseudo global warming
253 (PGW) approach in previous works (Rasmussen et al., 2014). The PGW simulation is forced with
254 6-hourly ERA-Interim reanalysis data plus a delta climate change signal derived from an ensemble
255 of CMIP5 models under the RCP8.5 emission scenario and reflects the climate change signal
256 between the end of 21st and 20th century.

257

258 **Fig. 3** shows the annual precipitation in the PPR from 4-km WRF CONUS from the current climate
259 and 32-km North America Regional Reanalysis (NARR, another reanalysis dataset commonly
260 used for land surface model forcing). Both datasets show similar annual precipitation pattern and
261 bias patterns compared to observations: underestimating of precipitation in the east and
262 overestimating in the west. However, the WRF CONUS shows significant improvement of
263 percentage bias in precipitation $((\text{Model-Observation})/\text{Observation})$ over the western PPR. For the
264 consistency of the same source of data for current and future climate, the WRF-CONUS is the best
265 available dataset for the coupled land-groundwater study in the PPR.

266

267 **Fig. 3** Evaluation of the annual precipitation from WRF CONUS (top) and NARR (bottom) against rain gauge
268 observation.

269

270 For the future climate study, the precipitation and temperature of the PGW climate forcing are
271 shown in **Fig. 4** and **Fig. 5**. The WRF CONUS projects more precipitation in the PPR, except in
272 the southeast of the domain in summer, where it shows a precipitation reduction of about 50 to 100
273 mm. On the other hand, the WRF CONUS projects strongest warming occurring in the northeast
274 PPR in winter (**Fig. 5**), about 6–8 °C. Another significant warming signal occurs in summer in the
275 southeast of domain, corresponding to the reduction of future precipitation, as seen in **Fig. 4**.

276

277 **Fig. 4** Seasonal accumulated precipitation from current climate scenario(CTRL), future climate scenario (PGW) and
278 projected change (PGW-CTRL) in the forcing data.

279

280 **Fig. 5** Seasonal averaged temperature from CTRL, PGW, and the projected change (PGW-CTRL).

281

282 2.4 Model Setup

283 The two Noah-MP-MMF simulations representing the current climate and future climate are
284 denoted as CTRL and PGW, respectively. The initial groundwater levels are from a global 1-km
285 equilibrium groundwater map (Fan et al., 2013) and the equilibrium soil moisture for each soil
286 layer is calculated at the first model timestep with climatology recharge, spinning up for 500 years.
287 Since the model domain is at a different resolution than the input data, the appropriate initial WTD
288 at 4-km may be different than the average at 1-km. To properly initialize the simulation, we spin
289 up the model using the forcing of current climate (CTRL) for the years from 2000 to 2001
290 repeatedly (in total 10 loops).

291

292 Due to different data sources, the default soil types along the boundary between the U.S. and
293 Canada are discontinuous. Thus, we use the global 1-km fine soil data (Shangguan et al., 2014,
294 <http://globalchange.bnu.edu.cn/research/soilw>) in our study region. The soil properties for the
295 aquifer use the same properties as the lowest soil layer from the Noah-MP 2-m soil layers.

296 3. Results

297 3.1 Comparison with groundwater observations

298 According to the locations of 33 groundwater wells in **Table 1**, the simulated WTD from the
299 closest model grid points are extracted. **Fig. 6** shows the modeled WTD bias from the CTRL run.
300 We also select the monthly WTD timeseries from 8 sites, the observation are in black dots and
301 CTRL in blue lines. See supplemental materials for the timeseries of 33 sites. The model produces
302 reasonable values of mean WTD, the mean bias are smaller than 1 m in most of sites, except in
303 Alberta, where the model predicts deep bias about 5 m in the northwestern part of PPR. The model
304 also successfully captures the annual cycle of WTD, which rises in spring and early summer,
305 because of snowmelt and rainfall recharge, and declines in summer and fall, because of high ET,
306 and in winter because of frozen near-surface soil. In all observations, the timing of the water table
307 rising and dropping is well simulated, as the timing and amount of infiltration and recharge in
308 spring is controlled by the freeze-thaw processes in seasonally frozen soil.

309

310 **Fig. 6.** WTD (m) bias from CTRL simulation and timeseries from 8 groundwater wells in PPR (black for observation and
311 blue for CTRL model simulation). See Table 2 CTRL column for the model statistics and supplemental materials for complete
312 timeseries from 33 wells.

313

314 On the other hand, the model simulated WTD seasonal variation is smaller than observations. The
315 small seasonal variation could be due to the misrepresentation between the lithology from the
316 observational surveys and the soil types in the model grids. As mentioned in Section 2.2, the
317 groundwater aquifer uses the same soil types as the bottom layer of the resolved 2-m soil layers.
318 While sand and gravel are the dominant lithology in most of the sites, they are mostly clay and
319 loam in the model (Table 1). For sandy soil reported in most of the sites, small capacity and fast
320 responses to infiltration lead to large water table fluctuations, whereas, in the model, clay and loam

321 soil allows low permeability and large capacity, and smoothens responses to recharge and capillary
322 effects. Furthermore, the 4-layer soils are vertically homogeneous in soil type and the groundwater
323 model uses the lowest level soil type as the aquifer lithology. For many part of the PPR, where
324 groundwater level are perched at the top 5-m due to a layer called glacial till. These
325 geohydrological characteristics cannot be reflected in this model and contribute to the deep WTD
326 bias simulated in Alberta. This shortcoming of the model was also reported in a study taken place
327 in the Amazon rainforest (Miguez-Macho et al., 2012).

328

329 3.2 Climate change signal in Groundwater fluxes

330 The MMF groundwater model simulates three components in the groundwater water budget, the
331 recharge flux (R), lateral flow (Q_{lat}), and discharge flux to rivers (Q_r). Because the topography is
332 usually flat in the PPR, the magnitude of groundwater lateral transport is very small (Q_{lat} less than
333 5 mm per year). On the other hand, the shallow water table in the PPR region is higher than the
334 local river bed, thus, the Q_r term is always discharging from groundwater aquifers to rivers. As a
335 result, the recharge term is the major contributor to the groundwater storage in the PPR, and its
336 variation (usually between -100 to 100 mm) dominates the timing and amplitude of the water table
337 dynamics. The seasonal accumulated total groundwater fluxes in the PPR ($R+Q_{lat} - Q_r$) are
338 shown in **Fig. 7**. The positive (negative) flux in blue (red) means the groundwater aquifer is gaining
339 (losing) water, causing the water table to rise (decline).

340

341 **Fig. 7** Seasonal accumulated total groundwater fluxes ($R+$) for current climate (CTRL, top), future climate (PGW,
342 middle) and projected change (PGW-CTRL, bottom) in forcing data. Black dashed lines in PGW-CTRL separate the
343 PPR into eastern and western halves.
344

345 Under current climate conditions, the total groundwater fluxes show strong seasonal fluctuations,
346 consistent with the WTD timeseries shown in **Fig. 6**. On average, in fall (SON) and winter (DJF),
347 there is a 20-mm negative recharge, driven by the capillary effects and drawing water from aquifer
348 to dry soil above. Spring (MAM) is usually the season with a strong positive recharge because
349 snowmelt provides a significant amount of water, and soils thawing allow infiltration. The large
350 amount of snowmelt water contributes to more than 100 mm of positive recharge in the eastern
351 domain. It is until summer (JJA), when strong ET depletes soil moisture and results in about 50
352 mm of negative recharge.

353

354 Under future climate conditions, the increased PR in fall and winter leads to wetter upper soil
355 layers, resulting in a net positive recharge flux (PGW – CTRL in SON and DJF). However, the
356 PGW summer is impacted by increased ET under a warmer and drier climate, due to higher
357 temperature and less PR. As a result, the groundwater uptake by the capillary effect is more critical
358 in the future summer. Furthermore, there is a strong east-to-west difference in the total
359 groundwater flux change from PGW to CTRL. In the eastern PPR, the change in total groundwater
360 flux exhibits obvious seasonality while the model projects persistent positive groundwater fluxes
361 in the western PPR.

362

363 3.3 Water budget analysis

364 **Fig. 8** and **Fig. 9** show the water budget analysis for the eastern and western PPR (divided by the
365 dotted line in 103° W in Fig. 7), respectively. Four components are presented in the figures, i.e.
366 (1) PR and ET; (2) surface and underground runoff (*SFCRUN* and *UDGRUN*); and surface
367 snowpack; (3) the change of soil moisture storage and (4) groundwater fluxes and the change of
368 storage. In the current and future climate, these budget terms are plotted in annual accumulation
369 ((a) and (b) for CTRL and PGW), whereas their difference are plotted in each month individually
370 ((c) for PGW-CTRL).

371
372 Under current climate conditions, during snowmelt infiltration and rainfall events, water infiltrates
373 into the top soil layer, travels through the soil column and exits the bottom of the 2-m boundary,
374 hence, the water table rises. During the summer dry season, ET is higher than PR and the soil
375 layers lose water through ET, therefore, the capillary effect takes water from the underlying aquifer
376 and the water table declines. In winter, the near-surface soil in the PPR is seasonally frozen, thus,
377 a redistribution of subsurface water to the freezing front results in negative recharge, and the water
378 table declines.

379
380 In the eastern PPR, the effective precipitation (PR-ET) is found to increase from fall to spring, but
381 decrease in summer in PGW (**Fig. 8(1c)**). Warmer falls and winters in PGW, together with
382 increased PR, not only delay snow accumulation and bring forward snowmelt, but also change
383 the precipitation partition – more as rain and less as snow. This warming causes up to 20 mm of
384 snowpack loss (**Fig.8(2c)**). The underground runoff starts much earlier in PGW (December)
385 (**Fig.8(2b)**) than in CTRL (February) (**Fig.8(2a)**). On the other hand, the warming in PGW also

386 changes the partitioning of soil ice and soil water in subsurface soil layers (**Fig. 8(3c)**). For late
387 spring in PGW, the springtime recharge in the future is significantly reduced due to early melting
388 and less snowpack remaining (**Fig. 8(4c)**). In the PGW summer, reduced PR (50 mm less) and
389 higher temperatures (8 °C warmer) lead to reduction in total soil moisture, and a stronger negative
390 recharge from the aquifer. Therefore, the increase of recharge from fall to early spring compensates
391 the recharge reduction due to stronger ET in summer in the eastern PPR, and changes little in the
392 annual mean groundwater storage (1.763 mm per year).

393

394 **Fig. 8** Water budget analysis in the eastern PPR in (a) CTRL, (b) PGW and (c) PGW – CTRL. Water budget terms
395 include: (1) *PR & ET*, (2) surface snow, surface runoff and underground runoff (*SNOW*, *SFCRUN*, and *UDGRUN*),
396 (3) change of soil moisture storage (soil water, soil ice and total soil moisture, ΔSMC) and (4) groundwater fluxes
397 and the change of groundwater storage (R , Q_{lat} , Q_r , ΔS_g). The annual mean soil moisture change (PGW-CTRL) is
398 shown with black dashed line in (3). The Residual term is defined as $Res = (R+Q_{lat}-Q_r)-\Delta S_g$ in (4). Note that in (a)
399 and (b) the accumulated fluxes and change in storage are shown in lines, whereas in (c) the difference in (PGW-CTRL)
400 is shown for each individual month in bars.

401

402 These changes in water budget components in the western PPR (**Fig. 9**) are similar to those in the
403 eastern PPR (**Fig. 8**), except in summer. The reduction in summer PR in the western the PPR (less
404 than 5 mm reduction) is not as obvious as that in the eastern PPR (50 mm reduction) (**Fig. 4**). Thus,
405 annual mean total soil moisture in future is about the same as in current climate (Fig. 9(3c)) and
406 results in little negative recharge in PGW summer (**Fig. 9(4c)**). Therefore, the increase in annual
407 recharge is more significant (10 mm per year), an increase of about 50% of the annual recharge in
408 the current climate (20 mm per year) (**Fig. 9(4c)**).

409

410 **Fig. 9** Same as Fig. 8. Water budget analysis in the **western PPR**: in (a) CTRL, (b) PGW and (c) PGW – CTRL.
411 Water budget terms include: (1) *PR & ET*, (2) surface snow, surface runoff and underground runoff (*SNOW*, *SFCRUN*,
412 and *UDGRUN*), (3) change of soil moisture storage (soil water, soil ice and total soil moisture, ΔSMC) and (4)
413 groundwater fluxes and the change of groundwater storage (R , Q_{lat} , Q_r , ΔS_g). The annual mean soil moisture change
414 (PGW-CTRL) is shown with black dashed line in (3). The Residual term is defined as $Res = (R+Q_{lat}-Q_r)-\Delta S_g$ in (4).
415 Note that in (a) and (b) the accumulated fluxes and change in storage are shown in lines, whereas in (c) the difference
416 in (PGW-CTRL) is shown for each individual month in bars.
417

418 In both the eastern and western PPR, the water budget components for the groundwater aquifer are
419 plotted in **Fig. 8(4)** and **Fig. 9 (4)**, with the changes of each flux (PGW-CTRL) printed at the
420 bottom. The groundwater lateral flow is a small term in areal average and has little impact on the
421 groundwater storage. Nearly half of the increased recharge in both the eastern and western PPR is
422 discharged to river flux ($Q_r = 2.26$ mm out of $R = 4.15$ mm in the eastern PPR and $Q_r = 5.20$ mm
423 out of $R = 10.72$ mm in western PPR). Therefore, the groundwater storage change in the eastern
424 PPR (1.76 mm per year) is not as great as that in the western PPR (5.39 mm per year).

425
426 These two regions of the PPR show differences in hydrological response to future climate because
427 of the spatial variation of the summer PR. As shown in both **Fig. 4** (PGW-CTRL), **Fig. 8(1)** and
428 **Fig. 9(1)**, the reduction of future PR in summer in the eastern PPR is significant (50 mm). The
429 spatial difference of precipitation changes in the PPR further results in the recharge increase
430 doubling in the western PPR compared to the eastern PPR.

431

432 4. Discussion

433 4.1 Improving WTD Simulation

434 In Section 3.1, we show that the model is capable of simulating the mean WTD in most sites, yet
435 predicts deep groundwater in Alberta and underestimates its seasonal variation. These results may
436 be due to misrepresentations between model default soil type and the soil properties in the
437 observational wells. To test this theory, an additional simulation, REP, is conducted by replacing
438 the default soil types in the locations of these 33 groundwater wells with sand-type soil, which is
439 the dominant soil types reported from observational surveys. The timeseries of the REP and default
440 CTRL are shown in Fig. 10 (also see supplemental materials for the complete 33 sites) and a
441 summary of the mean and standard deviation of the two simulations are provided in Table 2.

442

443 **Fig. 10** Same as Fig. 6, WTD (m) bias from CTRL simulation and timeseries from 8 groundwater wells in PPR (black for
444 observation and blue for CTRL model simulation, and red for the replacing soil type simulation). REP is the additional
445 simulation by replacing the default soil type in the model with sandy soil type.

446

447 The REP simulation with sandy soil show two sensitive signals: (1) REP WTD are shallower than
448 the default simulation; (2) and exhibit stronger seasonal variation. These two signals can be
449 explained by the WTD equation in the MMF scheme:

$$450 \quad \Delta WTD = \frac{\Delta(R + Q_{lat} - Q_r)}{(\theta_{sat} - \theta_{eq})} \quad (14)$$

451 Eq. (14) represents that the change of WTD in a period of time is calculated by the total
452 groundwater fluxes, $\Delta(R + Q_{lat} - Q_r)$, divided by the available soil moisture capacity of current
453 layer $(\theta_{sat} - \theta_{eq})$. In REP simulation, the parameters θ_{sat} for the dominant soil type in
454 observational sites (sand/gravel) is smaller than those in default model grids (clay loam, sandy
455 loam, loam, loamy sand, etc.). Therefore, changing the θ_{sat} is essentially reducing the storage in

456 the aquifer and soil in this model grid. Given the same amount of groundwater flux, in the REP
457 simulation, the mean WTD is higher and the seasonal variation is stronger than the default CTRL
458 run.

459

460 In the REP simulation, we replaced soil type only at a limited number of sites because the
461 geological survey data in high resolution and large area extent is not yet available for the whole
462 PPR. At point scale, the WTD responses to climate change over these limited number of sites show
463 diverse results and uncertainties (see supplemental materials). For the rest of the domain, the
464 default soil type from global 1-km soil map is used. The REP modifications of soil types at point-
465 scale have small contribution to the water balance analysis (Fig. 8 & 9) at regional-scale. Our
466 results and conclusions for groundwater response to PGW doesn't change. We are currently
467 undertaking a soil property survey project in the PPR region to obtain soil properties at high spatial
468 resolution, both horizontal and vertical. This may provide better opportunity to improve WTD
469 simulation as well as assess climate-groundwater interaction in future studies.

470

471 4.2 Climate Change Impacts on Groundwater Hydrological Regime

472 The warming and increased precipitation in cold seasons in future climate lead to later snow
473 accumulation, higher recharge in winter and earlier melting in spring compared to current climate.
474 Such changes in snowpack loss have been hypothesized in mountainous as well as high-latitude
475 regions (Taylor et al 2013; Ireson et al., 2015; Meixner et al., 2016; Musselman et al., 2017). In
476 addition to the amount of recharge, the shift of recharge season is also noteworthy. Under current
477 climate conditions in spring, soil thawing (in March) is generally later than snowmelt (in February)
478 by a month in the PPR. Thus, the snowmelt water in pre-thaw spring would either re-freeze after

479 infiltrating into partially frozen soil or become surface runoff. Under the PGW climate, the warmer
480 winter and spring allows snowmelt and soil thaw to occur earlier in the middle of winter (in January
481 and February, respectively). As a result, the recharge season starts earlier in December, and last
482 longer until June, results in longer recharge season but with lower recharge rate.

483
484 Future projected increasing evapotranspiration demand in summer desiccates soil moisture,
485 resulting in more water uptake from aquifers to subsidize dry soil in the future summer. This
486 groundwater transport to soil moisture is similar to the “buffer effect” documented in an offline
487 study in the Amazon rainforest (Pokhrel et al., 2014). In , shallow water tables exist in the critical
488 zone, where WTD ranges from 1 to 5 meters below surface and could exert strong influence on
489 land energy and moisture fluxes feedback to the atmosphere (Kollet and Maxwell, 2008; Fan ,
490 2015). Previous coupled atmosphere-land-groundwater studies at 30-km resolution showed that
491 groundwater could support soil moisture during summer dry period, but has little impacts on
492 precipitation in Central U.S. (Barlage et al., 2015). It would be an interesting topic to study the
493 integrated impacts of shallow groundwater to regional climate in the convection permitting
494 resolution (resolution < 5-km).

495
496 4.3 Fine-scale interaction between groundwater and Prairie pothole wetlands
497 Furthermore, groundwater exchange with prairie pothole wetlands are complicated and critical in
498 the PPR. Numerous wetlands known as potholes or sloughs provide important ecosystem services,
499 such as providing wildlife habitats and groundwater recharge (Johnson et al., 2010). Shallow
500 groundwater aquifers may receive water from or lose water to prairie wetlands depending on the
501 hydrological setting. Depression-focused recharge generated by runoff from upland to depression

502 contributes to sufficient amount of water input to shallow groundwater (5-40 mm/year) (Hayashi
503 et al., 2016).

504

505 On the other hand, groundwater lateral flow exchange center of a wetland pond to its moist margin
506 is also an important component in the wetland water balance (van der Kamp and Hayashi, 2009;
507 Brannen, et al., 2015; Hayashi et al., 2016). However, this groundwater-wetland exchange
508 typically occurs on local scale (from 10 to 100 m) and thus, is challenging to represent in current
509 land surface models or climate models (resolution from 1 km to 100 km). In this paper, we focus
510 on the groundwater dynamics on regional scale, which is still unable to capture these small wetland
511 features in this study. We admit this limitation and are currently developing a sub-grid scheme to
512 represent small scale open water wetlands as a fraction within a grid cell and calculate its feedback
513 to regional environments. Future studies on this topic will provide valuable insights on these key
514 ecosystems and their interaction under climate change.

515

516 Conclusion

517 In this study, a coupled land-groundwater model is applied to simulate the interaction between the
518 groundwater aquifer and soil moisture in the PPR. The climate forcing is from a dynamical
519 downscaling project (WRF CONUS), which uses the convection-permitting model (CPM)
520 configuration in high resolution. The goal of this study is to investigate the groundwater responses
521 to climate change, and to identify the major processes that contribute to these responses in the PPR.
522 To our knowledge, this is the first study applying CPM forcing in a hydrology study in this region.
523 We have three main findings:

524

525 (1) the coupled land-groundwater model shows reliable simulation of mean WTD, however
526 underestimates the seasonal variation of the water table against well observations. This could be
527 attributed to several reasons, including misrepresentation of topography and soil types, as well as
528 vertical homogenous soil layers used in the model. We further conducted an additional simulation
529 (REP) by replacing the model default soil types with sand-type soil and the simulated WTDs were
530 improved in both mean and seasonal variation. However, inadequacy of soil properties in deeper
531 layer and higher spatial resolution is still a limitation.

532

533 (2) Recharge markedly increases due to projected increased PR, particularly from fall to spring
534 under future climate conditions. Strong east-west spatial variation exists in the annual recharge
535 increases, 25% in the eastern and 50% in the western PPR. This is due to the significant projected
536 PR reduction in PGW summer in the eastern PPR but little change in the western PPR. This PR
537 reduction leads to stronger ET demand, which draws more groundwater uptake due to the capillary
538 effect, results in negative recharge in the summer. Therefore, the increased recharge from fall to

539 spring is consumed by ET in summer, and results in little change in groundwater in the eastern
540 PPR, while gaining water in the western PPR.

541

542 (3) The timing of infiltration and recharge are critically impacted by the changes in freeze-thaw
543 processes. Increased precipitation, combined with higher winter temperatures, results in later snow
544 accumulation/soil freezing, partitioned more as rain than snow, and earlier snowmelt/soil thaw.
545 This leads to substantial loss of snowpack, shorter frozen soil season, and higher permeability in
546 soil allowing infiltration. Late accumulation/freezing and early melting/thawing leads to an early
547 start of a longer recharge season from December to June, but with a lower recharge rate.

548

549 Our study has some limitations where future studies are encouraged:

550 (1) Despite the large number of groundwater wells in PPR, only a few are suitable for long-term
551 evaluation, due to data quality, anthropogenic pumping, and length of data record. As remote
552 sensing techniques advance, observing terrestrial water storage anomalies derived from the
553 GRACE satellite may provide substantial information on WTD, although the GRACE information
554 needs to be downscaled to a finer scale before comparisons can be made with regional hydrology
555 models at km-scale (Pokhrel et al., 2013).

556

557 (2) This study is an offline study of climate change impacts on groundwater. It is important to
558 investigate how shallow groundwater in the earth's critical zone could interact with surface water
559 and energy exchange to the atmosphere and affect regional climate. This investigation would be
560 important to the central North America region (one of the land atmosphere coupling "hot spots",
561 Koster et al., 2004).

Fig. 8 Water budget analysis in the eastern PPR in (a) CTRL, (b) PGW and (c) PGW – CTRL. Water budget terms include: (1) *PR* & *ET*, (2) surface snow, surface runoff and underground runoff (*SNOW*, *SFCRUN*, and *UDGRUN*), (3) change of soil moisture storage (soil water, soil ice and total soil moisture, ΔSMC) and (4) groundwater fluxes and the change of groundwater storage (R , Q_{lat} , Q_r , ΔS_g). The annual mean soil moisture change (PGW-CTRL) is shown with black dashed line in (3). The Residual term is defined as $Res = (R + Q_{lat} - Q_r) - \Delta S_g$ in (4). Note that in (a) and (b) the accumulated fluxes and change in storage are shown in lines, whereas in (c) the difference in (PGW-CTRL) is shown for each individual month in bars.

storage change: 5.390 mm
 recharge change: 10.727 mm
 river flux change: 5.207 mm
 lateral flux change: 0.000 mm

816

817

818 **Fig. 9** Same as Fig. 8. Water budget analysis in the western PPR: in (a) CTRL, (b) PGW and (c) PGW – CTRL.

819 Water budget terms include: (1) *PR* & *ET*, (2) surface snow, surface runoff and underground runoff (*SNOW*, *SFCRUN*,

820 and *UDGRUN*), (3) change of soil moisture storage (soil water, soil ice and total soil moisture, ΔSMC) and

821 groundwater fluxes and the change of groundwater storage (R , Q_{lat} , Q_r , ΔS_g). The annual mean soil moisture change

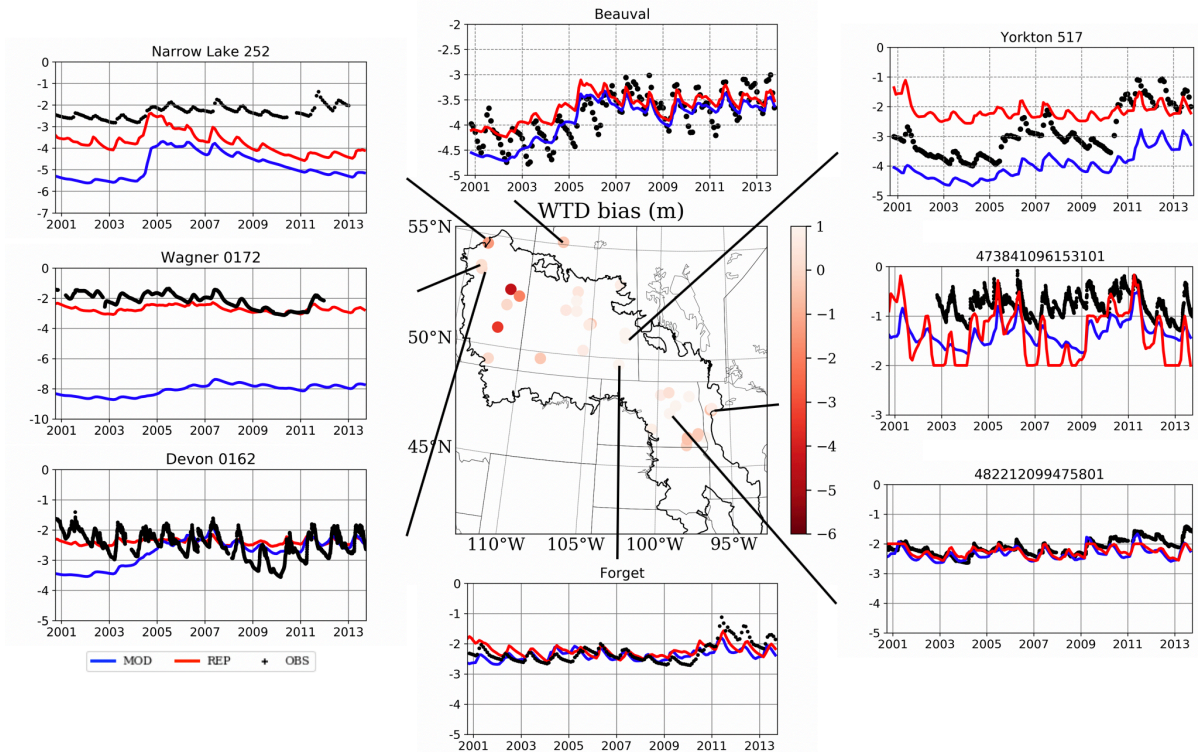

822 (PGW-CTRL) is shown with black dashed line in (3). The Residual term is defined as $Res = (R + Q_{lat} - Q_r) - \Delta S_g$ in (4).

823 Note that in (a) and (b) the accumulated fluxes and change in storage are shown in lines, whereas in (c) the difference

824 in (PGW-CTRL) is shown for each individual month in bars.

825

826

827
 828 **Fig. 10** Same as Fig. 6, WTD (m) bias from CTRL simulation and timeseries from 8 groundwater wells in PPR (black for
 829 observation and blue for CTRL model simulation, and red for the replacing soil type simulation). REP is the additional
 830 simulation by replacing the default soil type in the model with sandy soil type.
