33 **Abstract**

34 Evapotranspiration (ET) is critical in linking global water, carbon and energy cycles. Yet direct

35 measurement of global terrestrial ET is not feasible. Here, we first reviewed the basic theory and

36 state-of-the-art approaches for estimating global terrestrial ET, including remote sensing-based

37 physical models, machine learning algorithms and land surface models (LSMs). We then utilized

38 four remote sensing-based physical models, two machine-learning algorithms and fourteen LSMs

39 to analyze the spatial and temporal variations in global terrestrial ET. The results showed that the

40 ensemble means of annual global terrestrial ET estimated by these three categories of approaches

41 agreed well, ranging from 589.6 mm yr⁻¹ (6.56×10⁴ km³ yr⁻¹) to 617.1 mm yr⁻¹ (6.87×10⁴ km³ yr⁻¹).

42 For the period 1982-2011, both the ensembles of remote sensing-based physical models and

43 machine-learning algorithms suggested increasing trends in global terrestrial ET (0.62 mm yr⁻²,

44 $p<0.05$ and 0.38 mm yr⁻², $p<0.05$, respectively). In contrast, the ensemble mean of LSMs showed

45 no statistically significant change (0.23 mm yr⁻², $p>0.05$), even though many of the individual

46 LSMs reproduced an increasing trend. Nevertheless, all the twenty models used in this study

47 showed anthropogenic Earth greening had a positive role in increasing terrestrial ET. The
48 concurrent small inter-annual variability, i.e. relative stability, found in all estimates of global
49 terrestrial ET, suggests there exists a potential planetary boundary in regulating global terrestrial
50 ET, with the value being around 600 mm yr^{-1} . Uncertainties among approaches were identified in
51 specific regions, particularly in the Amazon Basin and arid/semi-arid regions. Improvements in
52 parameterizing water stress and canopy dynamics, utilization of new available satellite retrievals
53 and deep learning methods, and model-data fusion will advance our predictive understanding of
54 global terrestrial ET.

57

58 **1. Introduction**

59 Terrestrial evapotranspiration (ET) is the sum of the water loss to the atmosphere from plant tissues
60 via transpiration and that from the land surface elements including soil, plants and open water
61 bodies through evaporation. Processes controlling ET play a central role in linking the energy
62 (latent heat), water (moisture flux), and carbon cycles (photosynthesis-transpiration trade-off) in
63 the earth system. Over 60% of precipitation on the land surface is returned to the atmosphere
64 through ET (Oki and Kanae, 2006), and the accompanying latent heat (λET , λ is the latent heat of
65 vaporization) accounts for more than half of the solar energy received by the land surface
66 (Trenberth et al., 2009). ET is also coupled with the carbon dioxide exchange between canopy and
67 atmosphere through vegetation photosynthesis. These linkages make ET an important variable in
68 both the short-term numerical weather forecast and long-term climate prediction. Moreover, ET is
69 a critical indicator for ecosystem functioning across a variety of spatial scales. For enhancing our

70 predictive understanding of earth system and sustainability, therefore, it is essential to accurately
71 assess land surface ET in a changing global environment.

72 However, large uncertainty still exists in quantifying the magnitude of global terrestrial ET and its
73 spatial and temporal patterns, despite extensive research (Allen et al., 1998; Liu et al., 2008;
74 Miralles et al., 2016; Mueller et al., 2011; Tian et al., 2010). The previous estimates of global land
75 mean annual ET range from 417 mm yr⁻¹ to 650 mm yr⁻¹ for the whole or part of the 1982-2011
76 period (Mu et al., 2007; Mueller et al., 2011; Vinukollu et al., 2011a; Zhang et al., 2010). This
77 large discrepancy among independent studies may be attributed to lack of sufficient measurements,
78 uncertainty in forcing data, inconsistent spatial and temporal resolutions, ill-calibrated model
79 parameters and deficiencies in model structures. Of the four components of ET (transpiration, soil
80 evaporation, canopy interception, and open-water evaporation), transpiration (T_v) contributes the
81 largest uncertainty, as it is modulated not only by surface meteorological conditions and soil
82 moisture but also by the physiology and structures of plants. Changes in non-climatic factors such
83 as elevated atmospheric CO₂, nitrogen deposition, and land covers also serve as influential drivers
84 of T_v (Gedney et al., 2006; Mao et al., 2015; Pan et al., 2018b; Piao et al., 2010). As such, the
85 global ratio of transpiration to ET (T_v/ET) has long been of debate, with the most recent
86 observation-based estimate being 0.64 ± 0.13 constrained by the global water-isotope budget (Good
87 et al., 2015). Most earth system models are thought to largely underestimate T_v/ET (Lian et al.,
88 2018).

89 Global warming is expected to accelerate the hydrological cycle (Pan et al., 2015). For the period,
90 1982 to the late 1990s, ET was reported to increase by about 7 mm (~1.2%) per decade driven by
91 an increase in radiative forcing and consequently global and regional temperatures (Douville et al.,
92 2013; Jung et al., 2010; Wang et al., 2010). The contemporary near-surface specific humidity also

93 increased over both land and ocean (Dai, 2006; Simmons et al., 2010; Willett et al., 2007). More
94 recent studies confirmed that, since the 1980s, global ET has showed an overall increase (Mao et
95 al., 2015; Yao et al., 2016; Zeng et al., 2018a; Zeng et al., 2012; Zeng et al., 2016; Zhang et al.,
96 2015; Zhang et al., 2016b). However, the magnitude and spatial distribution of such a trend are far
97 from determined. Over the past 50 years, pan evaporation decreased throughout the world (Fu et
98 al., 2009; Peterson et al., 1995; Roderick and Farquhar, 2002), implying an increase in actual ET
99 given the pan evaporation paradox. Moreover, the increase in global terrestrial ET was found to
100 cease or even be reversed during 1998 to 2008, primarily due to the decreased soil moisture supply
101 in the Southern Hemisphere (Jung et al., 2010). To reconcile the disparity, Douville et al. (2013)
102 argued that the peak ET in 1998 should not be taken as a tipping point because ET was estimated
103 to increase in the multi-decadal evolution. More efforts are needed to understand the spatial and
104 temporal variations of global terrestrial ET and the underlying mechanisms that control its
105 magnitude and variability.

106 Conventional techniques, such as lysimeter, eddy covariance, large aperture scintillometer and the
107 Bowen ratio method, are capable of providing ET measurements at point and local scales (Wang
108 and Dickinson, 2012). However, it is impossible to directly measure ET at the global scale because
109 dense global coverage by such instruments is not feasible and the representativeness of point-scale
110 measurements to comprehensively represent the spatial heterogeneity of global land surface is also
111 doubtful (Mueller et al., 2011). To address this issue, numerous approaches have been proposed
112 in recent years to estimate global terrestrial ET and these approaches can be divided into three
113 main categories: 1) remote sensing-based physical models, 2) machine learning algorithms, and 3)
114 land surface models (Miralles et al., 2011; Mueller et al., 2011; Wang and Dickinson, 2012).
115 Knowledge of the uncertainties in global terrestrial ET estimates from different approaches is the

116 prerequisite for future projection and many other applications. In recent years, several studies have
117 compared multiple terrestrial ET estimates (Khan et al., 2018; Mueller et al., 2013; Wartenburger
118 et al., 2018; Zhang et al., 2016b). However, most of these studies analyzed multiple datasets of the
119 same approach or focused on investigating similarities and differences among different
120 approaches. Few studies have been conducted to identify uncertainties in multiple estimates of
121 different approaches.

122 In this study, we integrate state-of-the-art estimates of global terrestrial ET, including data-driven
123 and process-based estimates, to assess its spatial pattern, inter-annual variability, environmental
124 drivers, long-term trend, and response to vegetation greening. Our goal is not to compare the
125 various models and choose the best one, but to identify the uncertainty sources in each type of
126 estimate and provide suggestions for future model development. In the following sections, we first
127 have a brief introduction to all methodological approaches and ET datasets used in this study. We
128 then quantify the spatiotemporal variations in global terrestrial ET during the period 1982-2011
129 by analyzing the results from the current state-of-the-art models. Finally, we discuss some
130 suggested solutions for reducing the identified uncertainties.

131 **2. Methodology and data sources**

132 **2.1 Overview of approaches to global ET estimation**

133 **2.1.1 Remote sensing-based physical models**

134 Satellite remote sensing has been widely recognized as a promising tool to estimate global ET,
135 because it is capable of providing spatially and temporally continuous measurements of critical
136 biophysical parameters affecting ET, including vegetation states, albedo, fraction of absorbed
137 photosynthetically active radiation, land surface temperature and plant functional types (Li et al.,
138 2009). Since the 1980s, a large number of methods have been developed using a variety of satellite

139 observations (Zhang et al., 2016a). However, part of these methods such as surface energy balance
140 (SEB) models and surface temperature-vegetation index (T_s -VI) are usually applied at local and
141 regional scales. At the global scales, the vast majority of existing remote sensing-based physical
142 models can be categorized into two groups: the Penman-Monteith (PM) based and the Priestley-
143 Taylor (PT) based models.

144 A) Remote sensing models based on Penman-Monteith equation

145 The Penman equation, derived from the Monin-Obukhov similarity theory and surface energy
146 balance, uses surface net radiation, temperature, humidity, wind speed and ground heat flux to
147 estimate ET from an open water surface. For vegetated surfaces, canopy resistance was introduced
148 into the Penman equation by Monteith (Monteith, 1965) and the PM equation is formulated as:

$$149 \quad \lambda ET = \frac{\Delta(R_n - G) + \rho_a C_p VPD / r_a}{\Delta + \gamma(1 + r_s / r_a)} \quad (1)$$

150 where Δ , R_n , G , ρ_a , C_p , γ , r_s , r_a , VPD are the slope of the curve relating saturated water vapor
151 pressure to air temperature, net radiation, soil heat flux, air density, the specific heat of air,
152 psychrometric constant, surface resistance, aerodynamic resistance and vapor pressure deficit,
153 respectively. The canopy resistance term in the PM equation exerts a strong control on
154 transpiration. For example, based on the algorithm proposed by Cleugh et al. (2007), the MODIS
155 (Moderate Resolution Imaging Spectroradiometer) ET algorithm improved the model performance
156 through inclusion of environmental stress into canopy conductance calculation and explicitly
157 accounted for soil evaporation (Mu et al., 2007). Further, Mu et al. (2011) improved the MODIS
158 ET algorithm by considering nighttime ET, adding soil heat flux calculation, separating dry canopy
159 surface from the wet, and dividing soil surface into saturated wet surface and moist surface.
160 Similarly, Zhang et al. (2010) developed a Jarvis-Stewart-type canopy conductance model based
161 on normalized difference vegetation index (NDVI) to take advantage of the long-term Advanced

162 Very High Resolution Radiometer (AVHRR) dataset. More recently, this model was improved by
163 adding a CO₂ constraint function in the canopy conductance estimate (Zhang et al., 2015). Another
164 important revision for the PM approach is proposed by Leuning et al. (2008). The Penman-
165 Monteith-Leuning method adopts a simple biophysical model for canopy conductance, which can
166 account for influences of radiation and atmospheric humidity deficit. Additionally, it introduces a
167 simpler soil evaporation algorithm than that proposed by Mu et al. (2007), which potentially makes
168 it attractive to use with remote sensing. However, PM-based models have one intrinsic weakness:
169 temporal upscaling which is required in translating instantaneous ET estimation into a longer time-
170 scale value (Li et al., 2009). This could be easily done at the daily scale under clear-sky conditions
171 but faces challenge at weekly to monthly time-scales due to lack of cloud coverage information.

172 B) Remote sensing models based on Priestley-Taylor equation

173 The Priestley–Taylor (PT) equation is a simplification of the PM equation without parameterizing
174 aerodynamic and surface conductance (Priestley and Taylor, 1972) and can be expressed as:

$$175 \quad \lambda ET = f_{stress} \times \alpha \times \frac{\Delta}{\Delta + \gamma} \times (R_n - G) \quad (2)$$

176 where f_{stress} is a stress factor and is usually computed as a function of environmental conditions. α
177 is the PT parameter with a value of 1.2–1.3 under water unstressed conditions and can be estimated
178 using remote sensing. Although the original PT equation works well in estimating potential ET
179 across most surfaces, the Priestley-Taylor coefficient, α , usually needs adjustment to convert
180 potential ET to actual ET (Zhang et al., 2016a). Instead, Fisher et al. (2008) developed a modified
181 PT model that keeps α constant but scales down potential ET by ecophysiological constraints and
182 soil evaporation partitioning. The accuracy of their model has been validated against eddy
183 covariance measurements conducted at a wide range of climates and plant functional types (Fisher
184 et al., 2009; Vinukollu et al., 2011b). Following this idea, Yao et al. (2013) further developed a

185 modified Priestley-Taylor algorithm that constrains soil evaporation using the Apparent Thermal
186 Inertia derived index of soil water deficit. Miralles et al. (2011) also proposed a novel PT type
187 model, Global Land surface Evaporation: the Amsterdam Methodology (GLEAM). GLEAM
188 combines a soil water module, a canopy interception model and a stress module within the PT
189 equation. The key distinguishing features of this model are the use of microwave-derived soil
190 moisture, land surface temperature and vegetation density, and the detailed estimation of rainfall
191 interception loss. In this way, GLEAM minimizes the dependence on static variables, avoids the
192 need for parameter tuning, and enables the quality of the evaporation estimates to rely on the
193 accuracy of the satellite inputs (Miralles et al., 2011). Compared with the PM approach, the PT
194 based approaches avoid the computational complexities of aerodynamic resistance and the
195 accompanying error propagation. However, the many simplifications and semi-empirical
196 parameterization of physical processes in the PT based approaches may lower its accuracy.

197 **2.1.2 Vegetation index-based empirical algorithms and machine learning methods**

198 The principle of empirical ET algorithms is to link observed ET to its controlling environmental
199 factors through various statistical regressions or machine learning algorithms of different
200 complexities. The earliest empirical regression method was proposed by Jackson et al. (1977). At
201 present, the majority of regression models are based on vegetation indices (Glenn et al., 2010),
202 such as NDVI and enhanced vegetation index (EVI), because of their simplicity, resilience in the
203 presence of data gaps, utility under a wide range of conditions and connection with vegetation
204 transpiration capacity (Maselli et al., 2014; Nagler et al., 2005; Yuan et al., 2010). As an alternative
205 to statistical regression methods, machine learning algorithms have been gaining increased
206 attention for ET estimation due to their ability to capture the complex nonlinear relationships
207 between ET and its controlling factors (Dou and Yang, 2018). Many conventional machine

208 learning algorithms, such as artificial neural networks, random forest, and support vector machine
209 based algorithms have been applied in various ecosystems (Antonopoulos et al., 2016; Chen et al.,
210 2014; Feng et al., 2017; Shrestha and Shukla, 2015) and have proved to be more accurate in
211 estimating ET than simple regression models (Antonopoulos et al., 2016; Chen et al., 2014; Kisi
212 et al., 2015; Shrestha and Shukla, 2015; Tabari et al., 2013). In up-scaling FLUXNET ET to the
213 global scale, Jung et al. (2010) used the model tree ensemble method to integrate eddy covariance
214 measurements of ET with satellite remote sensing and surface meteorological data. In a recent
215 study (Bodesheim et al., 2018), the random forest approach was used to derive global ET at a half-
216 hourly time-scale.

217 **2.1.3 Process-based land surface models (LSMs)**

218 Although satellite-derived ET products have provided quantitative investigations of historical
219 terrestrial ET dynamics, they can only cover a limited temporal record of about four decades. To
220 obtain terrestrial ET before 1980s and predict future ET dynamics, LSMs are needed, as they are
221 able to represent a large number of interactions and feedbacks between physical, biological, and
222 biogeochemical processes in a prognostic way (Jimenez et al., 2011). ET simulation in LSMs is
223 regulated by multiple biophysical and physiological properties or processes, including but not
224 limited to stomatal conductance, leaf area, root water uptake, soil water, runoff and sometimes
225 nutrient uptake (Famiglietti and Wood, 1991; Huang et al., 2016; Lawrence et al., 2007). Although
226 almost all current LSMs have these components, different parameterization schemes result in
227 substantial differences in ET estimation (Wartenburger et al., 2018). Therefore, in recent years,
228 the multi-model ensemble approach has become popular in quantifying magnitude, spatiotemporal
229 pattern and uncertainty of global terrestrial ET (Mueller et al., 2011; Wartenburger et al., 2018).

230 Yao et al. (2017) showed that a simple model averaging method or a Bayesian model averaging
231 method is superior to each individual model in predicting terrestrial ET.

232 **2.2 Description of ET models used in this study**

233 In this study, we evaluate twenty ET products that are based on remote sensing-based physical
234 models, machine-learning algorithms, and LSMs to investigate the magnitudes and spatial patterns
235 of global terrestrial ET over recent decades. Table 1 lists the input data, adopted ET algorithms,
236 limitations, and references for each product. We use a simple model averaging method when
237 calculating the mean value of multiple models.

238 Four physically-based remote sensing datasets, including Process-based Land Surface
239 Evapotranspiration/Heat Fluxes algorithm (P-LSH), Global Land surface Evaporation: the
240 Amsterdam Methodology (GLEAM), Moderate Resolution Imaging Spectroradiometer (MODIS)
241 and PML-CSIRO (Penman-Monteith-Leuning), and two machine-learning datasets, including
242 Random Forest (RF) and Model Tree Ensemble (MTE), are used in our study. Both machine
243 learning and physical-based remote sensing datasets (totally six datasets) were considered as
244 benchmark products. The ensemble mean of benchmark products was calculated as the mean value
245 of all machine learning and physical-based satellite estimates since we treated each benchmark
246 dataset equally.

247 Three of the four remote sensing-based physical models quantify ET through PM approaches. P-
248 LSH adopts a modified PM approach coupling with biome-specific canopy conductance
249 determined from NDVI (Zhang et al., 2010). The modified P-LSH model used in this study also
250 accounts for the influences of atmospheric CO₂ concentrations and wind speed on canopy stomatal
251 conductance and aerodynamic conductance (Zhang et al., 2015). MODIS ET model is based on
252 the algorithm proposed by Cleugh et al. (2007). Mu et al. (2007) improved the model performance

253 through the inclusion of environmental stress into canopy conductance calculation, and explicitly
254 accounting for soil evaporation by combining complementary relationship hypothesis with PM
255 equation. The MODIS ET product (MOD16A3) used in this study was further improved by
256 considering night-time ET, simplifying vegetation cover fraction calculation, adding soil heat flux
257 item, dividing saturated wet and moist soil, separating dry and wet canopy, as well as modifying
258 algorithms of aerodynamic resistance, stomatal conductance, and boundary layer resistance (Mu
259 et al., 2011). PML-CSIRO adopts the Penman-Monteith-Leuning algorithm, which calculates
260 surface conductance and canopy conductance by a biophysical model instead of classic empirical
261 models. The maximum stomatal conductance is estimated using the trial-and-error method (Zhang
262 et al., 2016b). Furthermore, for each grid covered by natural vegetation, the PML-CSIRO model
263 constrains ET at the annual scale using the Budyko hydrometeorological model proposed by Fu
264 (1981). GLEAM ET calculation is based on the PT equation, which requires fewer model inputs
265 than PM equation, and the majority of these inputs can be directly achieved from satellite
266 observations. Its rationale is to make the most of information about evaporation contained in the
267 satellite-based environmental and climatic observations (Martens et al., 2017; Miralles et al.,
268 2011). Key variables including air temperature, land surface temperature, precipitation, soil
269 moisture, vegetation optical depth and snow-water equivalent are satellite-observed. Moreover,
270 the extensive usage of microwave remote sensing products in GLEAM ensures the accurate
271 estimation of ET under diverse weather conditions. Here, we use the GLEAM v3.2 version which
272 has overall better quality than previous version (Martens et al., 2017).

273 The first used machine learning model, MTE, is based on the Tree Induction Algorithm (TRIAL)
274 and Evolving Trees with Random Growth (ERROR) algorithm (Jung et al., 2009). The TRIAL
275 grows model trees from the root node and splits at each node with the criterion of minimizing the

276 sum of squared errors of multiple regressions in both subdomains. ERROR is used to select the
277 model trees that are independent from each other and have best performances under Schwarz
278 criterion. Canopy fraction of absorbed photosynthetic active radiation (fAPAR), temperatures,
279 precipitation, relative humidity, sunshine hours, and potential radiation are used as explanatory
280 variables to train MTE (Jung et al., 2011). The second machine learning model is the random forest
281 (RF) algorithm whose rationale is generating a set of independent regression trees through
282 randomly selecting training samples automatically (Breiman, 2001). Each regression tree is
283 constructed using samples selected by bootstrap sampling method. After fixing individual tree in
284 entity, the final result is determined by simple averaging. One merit of RF algorithm is its
285 capability of handling complicated nonlinear problems and high dimensional data (Xu et al., 2018).
286 For the RF product used in this study, multiple explanatory variables including enhanced
287 vegetation index, fAPAR, leaf area index, daytime and nighttime land surface temperature,
288 incoming radiation, top of atmosphere potential radiation, index of water availability and relative
289 humidity were used to train regression trees (Bodesheim et al., 2018).

290 The fourteen LSMs-derived ET products were from the Trends and Drivers of the Regional Scale
291 Sources and Sinks of Carbon Dioxide (TRENDY) Project (including CABLE, CLASS-CTEM,
292 CLM45, DLEM, ISAM, JSBACH, JULES, LPJ-GUESS, LPJ-wsl, LPX-Bern, O-CN,
293 ORCHIDEE, ORCHIDEE-MICT and VISIT). Daily gridded meteorological reanalyses from the
294 CRU-NCEPv8 dataset (temperature, precipitation, long- and short-wave incoming radiation, wind-
295 speed, humidity, air pressure) were used to drive the LSMs. The TRENDY simulations were
296 performed in year 2017 and contributed to the Global Carbon Budget reported in Le Quéré et al.
297 (2018). We used the results of S3 experiment of TRENDYv6 (with changing CO₂, climate and

298 land use) over the period 1982-2011, a time period consistent with other products derived from
299 remote sensing-based physical models and machine-learning algorithms.

300 **2.3 Description of other datasets**

301 To quantify the contributions of vegetation greening to terrestrial ET variations, we used the LAI
302 of TRENDYv6 S3 experiment. We also used the newest version of the Global Inventory Modeling
303 and Mapping Studies LAI data (GIMMS LAI3gV1) as satellite-derived LAI. GIMMS LAI3gV1
304 was generated from AVHRR GIMMS NDVI3g using an Artificial Neural Network (ANN) derived
305 model (Zhu et al., 2013). It covers the period 1982 to 2016 with bimonthly frequency and has a
306 $1/12^\circ$ spatial resolution. To achieve a uniform resolution, all data were resampled to $1/2^\circ$ using the
307 nearest neighbour method. Following Pan et al. (2018a), grids with an annual mean NDVI <0.1
308 were assumed to be non-vegetated regions and were therefore masked out. NDVI data are from
309 GIMMS NDVI3gV1 dataset. Temperature, precipitation and radiation are from CRU-NCEPv8.

310 **2.4 Statistical analysis**

311 The significance of ET trends is analyzed using the Mann-Kendall (MK) test (Kendall, 1955;
312 Mann, 1945). It is a rank-based non-parametric method that has been widely applied for detecting
313 a trend in hydro-climatic time series (Sayemuzzaman and Jha, 2014; Yue et al., 2002). The Theil-
314 Sen estimator was applied to estimate the magnitude of the slope. The advantage of this method
315 over ordinary least squares estimator is that it limits the influence of the outliers on the slope (Sen,
316 1968).

317 Terrestrial ET IAV is mainly controlled by variations in temperature, precipitation, and shortwave
318 solar radiation (Zeng et al., 2018b; Zhang et al., 2015). In this study, we performed partial
319 correlation analyses between ET and these three climatic variables at an annual scale for each grid

320 cell to explore climatic controls on ET IAV. Variability caused by climatic variables was assessed
 321 through the square of partial correlation coefficients between ET and temperature, precipitation,
 322 and radiation. We chose partial correlation analysis because it can quantify the linkage between
 323 ET and a single environmental driving factor while controlling the effects of other remaining
 324 environmental factors. Partial correlation analysis is a widely applied statistical tool to isolate the
 325 relationship between two variables from the confounding effects of many correlated variables
 326 (Anav et al., 2015; Jung et al., 2017; Peng et al., 2013). All variables were first detrended in the
 327 statistical correlation analysis since we focus on the inter-annual relationship. The study period is
 328 from 1982 to 2011 for all models except MODIS and Rand Forest whose temporal coverage is
 329 limited to 2001-2011 because of data availability.

330 To quantify the contribution of vegetation greening to terrestrial ET, we separated the trend in
 331 terrestrial ET into four components induced by climatic variables and vegetation dynamics by
 332 establishing a multiple linear regression model between global ET and temperature, precipitation,
 333 shortwave radiation, and LAI (Eq. 3-4):

$$334 \quad \delta(ET) = \frac{\partial(ET)}{\partial(LAI)} \delta(LAI) + \frac{\partial(ET)}{\partial T} \delta(T) + \frac{\partial(ET)}{\partial(P)} \delta(P) + \frac{\partial(ET)}{\partial R} \delta(R) + \varepsilon \quad (3)$$

$$335 \quad \delta(ET) = \gamma_{ET}^{LAI} \delta LAI + \gamma_{ET}^T \delta T + \gamma_{ET}^P \delta P + + \gamma_{ET}^R \delta R + \varepsilon \quad (4)$$

336 γ_{ET}^{LAI} , γ_{ET}^T , γ_{ET}^P , γ_{ET}^R are the sensitivities of ET to leaf area index (LAI), air temperature (T),
 337 precipitation (P), and radiation (R), respectively. ε is the residual, representing the impacts of other
 338 factors.

339 After calculating γ_{ET}^{LAI} , γ_{ET}^T , γ_{ET}^P , γ_{ET}^R , the contribution of trend in factor i ($Trend(i)$) to the trend
 340 in ET ($Trend(ET)$) can be quantified as follows:

$$341 \quad Contri(i) = (\gamma_{ET}^i \times Trend(i)) / Trend(ET) \quad (5)$$

342 In performing multiple linear regression, we used GIMMS LAI for both remote sensing-based
 343 physical models and machine learning methods, and individual TRENDYv6 LAI for each
 344 TRENDY model. The gridded data of temperature, precipitation and radiation are from CRU-
 345 NCEPv8

346 3. Results

347 3.1 The ET magnitude estimated by multiple models

348
 349 **Figure 1.** Average annual global terrestrial ET estimated by each model during the period 2001-
 350 2011. Error bars represent the standard deviation of each model. The four lines indicate the mean
 351 value of each category.

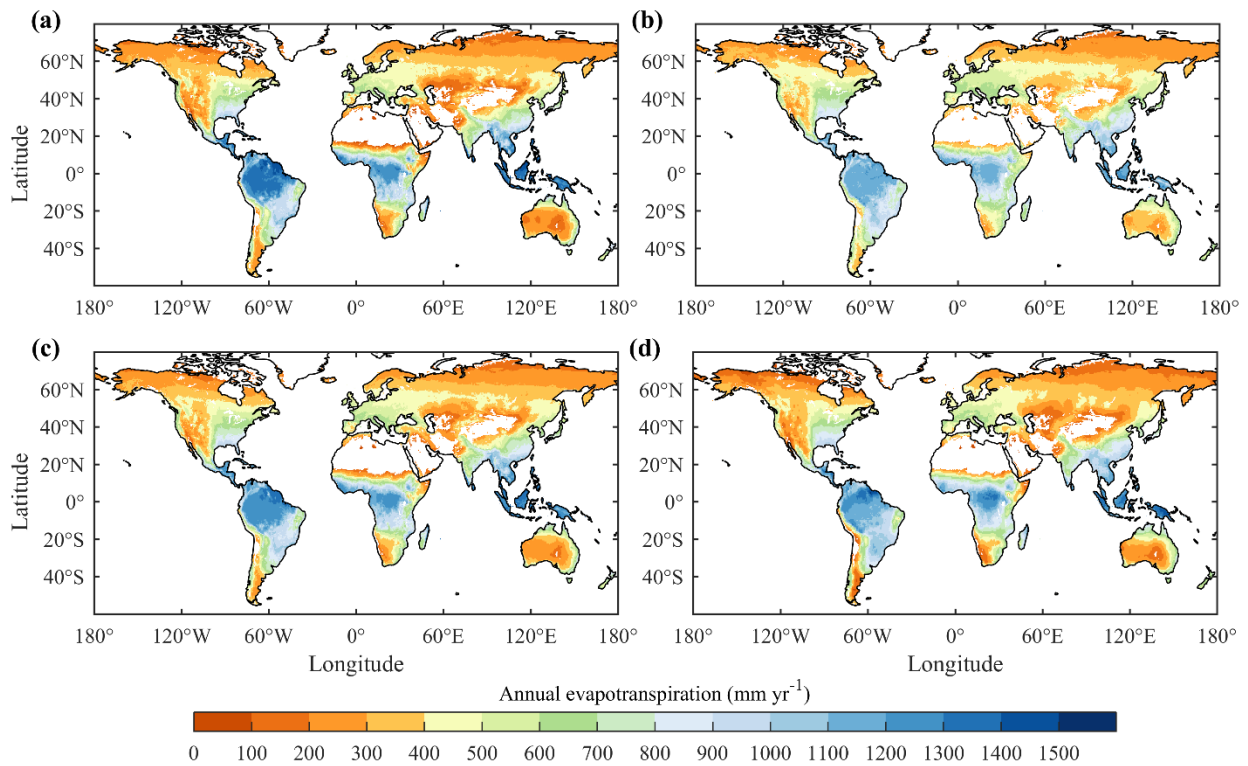

352 The multi-year ensemble mean of annual global terrestrial ET during 2001-2011 derived by the
 353 machine learning methods, remote sensing-based physical models and TRENDY models agreed

354 well, ranging from 589.6 mm yr⁻¹ to 617.1 mm yr⁻¹. However, substantial differences existed
355 among individual models (Fig. 1). LPJ-wsl (455.3 mm yr⁻¹) and LPX-Bern (453.7 mm yr⁻¹)
356 estimated significantly lower ET than other models, even in comparison with most previous studies
357 focusing on earlier periods (Table S1). In contrary, JULES gave the largest ET estimate (697.3
358 mm yr⁻¹, equals to 7.57×10⁴ km³ yr⁻¹) among all models, and showed an obvious increase of ET
359 compared to its estimation during 1950-2000 (6.5×10⁴ km³ yr⁻¹, Table S1).

360 **3.2 Spatial patterns of global terrestrial ET**

361 As shown in Fig. 2, the spatial patterns of multi-year average annual ET of different categories
362 were similar. ET was the highest in the tropics and low in northern high latitudes and arid regions
363 such as Australia, central Asia, western U.S., and Sahel. Compared to remote sensing-based
364 physical models and LSMs, machine-learning methods obtained a smaller spatial gradient. In
365 general, latitudinal profiles of ET estimated by different approaches were also consistent (Fig. 3).
366 However, machine-learning methods gave higher ET estimate at high latitudes and lower ET in
367 the tropics compared to other approaches. In the tropics, LSMs have significant larger uncertainties
368 than benchmark products, and the standard deviation of LSMs is about two times as large as that
369 of benchmark products (Fig. 3). In other latitudes, LSMs and benchmark ET products have
370 generally comparable uncertainties. The largest difference in ET of different categories was found
371 in the Amazon Basin (Fig. 2). In most regions of the Amazon Basin, the mean ET of remote sensing
372 physical models are more than 200mm yr⁻¹ higher than the mean ET of LSMs and machine-
373 learning methods. For individual ET estimates, the largest uncertainty was also found in the
374 Amazon Basin. MODIS, VISIT and CLASS-CTEM estimated that annual ET was larger than 1300
375 mm in the majority of Amazon, whereas JSBACH and LPJ-wsl estimated ET of smaller than 800
376 mm yr⁻¹ (Fig. S1). As is shown in Fig. S2, the difference in ET estimates among TRENDY models

377 were larger than those among benchmark estimates for tropical and humid regions. The uncertainty
 378 of ET estimates by LSMs is particularly large in the Amazon Basin where the standard deviation
 379 of LSMs estimates is more than two times as large as that of benchmark estimates. It is noteworthy
 380 that, in arid and semi-arid regions such as western Australia, central Asia, northern China and
 381 western US, the difference in ET estimates among LSMs is significantly smaller than those among
 382 remote sensing models and machine learning algorithms.

383
 384 **Figure 2.** Spatial distributions of mean annual ET derived from (a) remote sensing-based physical
 385 models, (b) machine-learning algorithms, (c) benchmark datasets and (d) TRENDY LSMs
 386 ensemble mean, respectively.

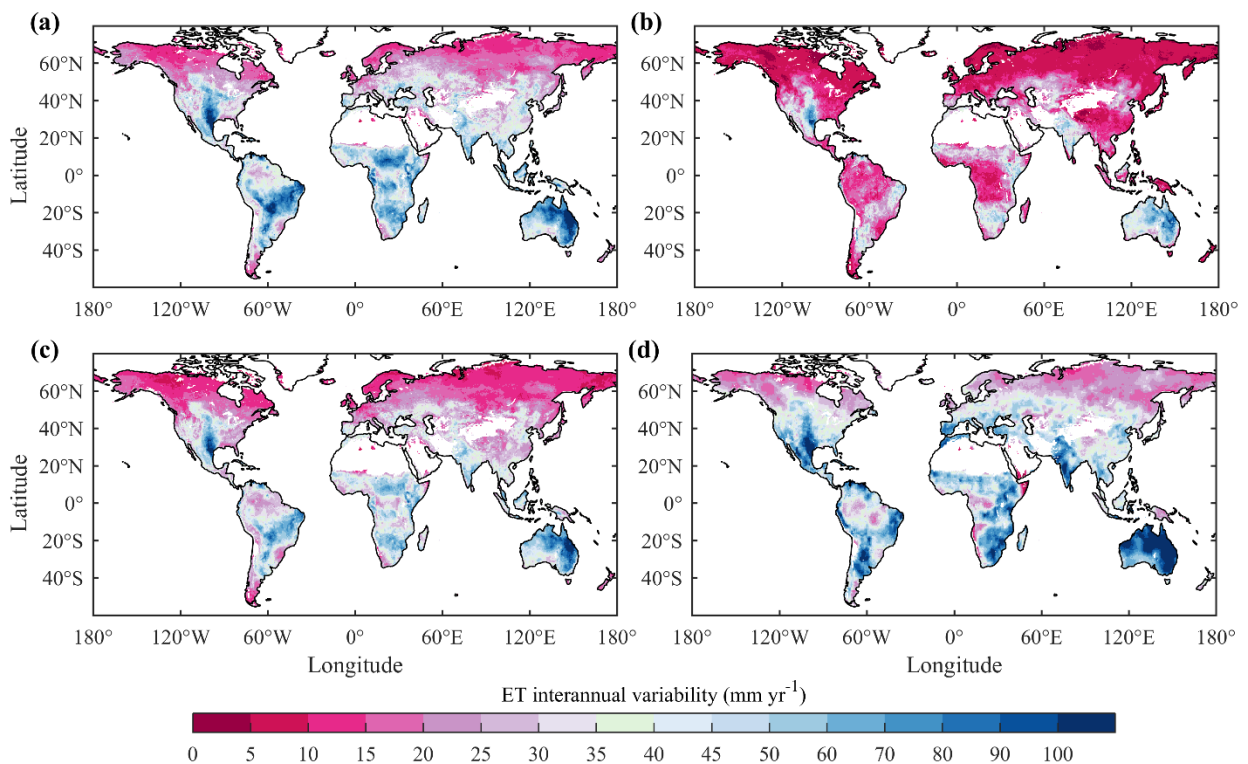

387
 388 **Figure 3.** Latitudinal profiles of mean annual ET for different categories of models. Each line
 389 represents the mean value of the corresponding category and the shading represents the interval of
 390 one standard deviation.

391 **3.3 Inter-annual variations in global terrestrial ET**

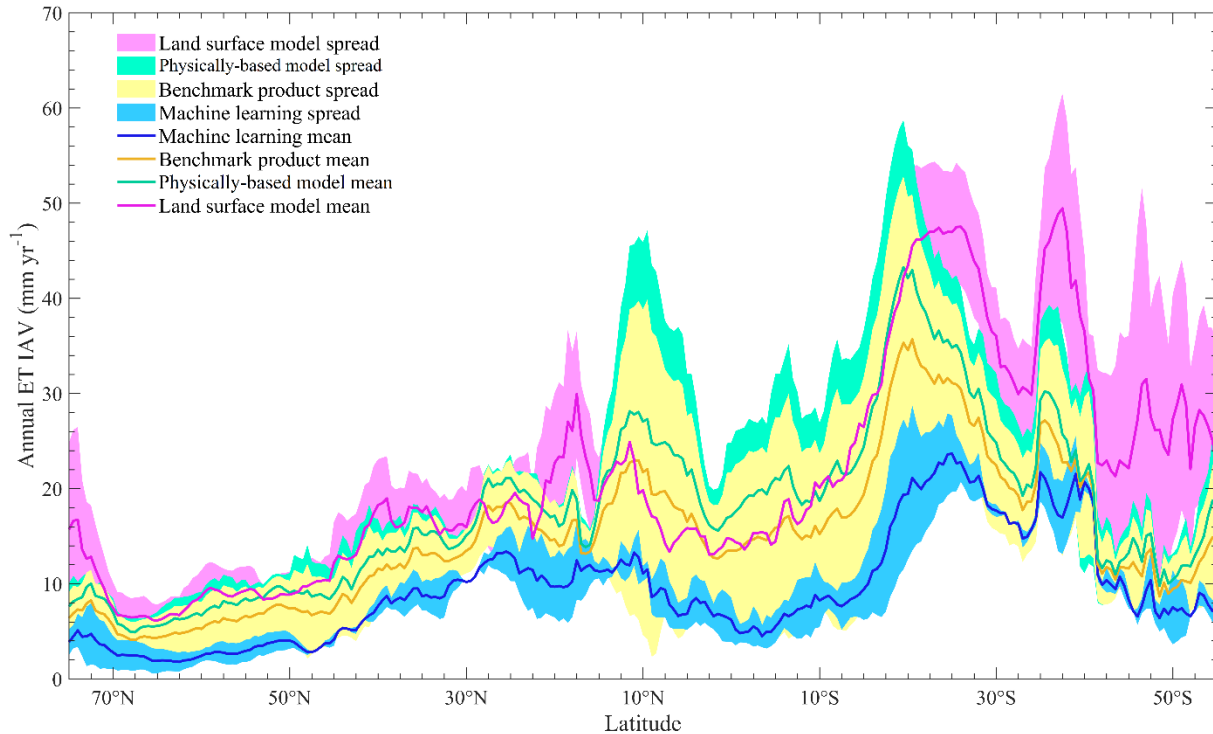

392 The ensemble mean inter-annual variability (IAV) of remote sensing ET estimates and LSMs ET
 393 estimates showed similar spatial patterns (Fig. 4). Both remote sensing physical models and LSMs
 394 presented low IAV in ET in northern high latitudes but high IAV in ET in southwestern U.S, India,
 395 south Sahara Africa, Amazon and Australia. In contrast, IAV of machine-learning based ET was
 396 much weaker. In most regions, IAV of machine learning ET is smaller than 40% of IAV of remote
 397 sensing physical ET and LSMs ET, and this phenomenon is especially pronounced in tropical
 398 regions. Further investigation into the spatial patterns of ET IAV for individual model showed that
 399 the two machine-learning methods performed equally in estimating spatial patterns of ET IAV

400 (Fig. S4). In contrast, differences in ET IAV among remote sensing physical estimates and LSMs
 401 estimates were much larger. LSMs showed the largest differences in IAV of ET in tropical regions.
 402 For example, CABLE and JULES obtained an ET IAV of smaller than 15 mm yr⁻¹ in most regions
 403 of the Amazon Basin, while LPJ-GUESS predicted an ET IAV of larger than 60 mm yr⁻¹. Figure
 404 5 showed that, in the north of 20°S, remote sensing physical ET and LSMs ET had comparable
 405 IAV, but IAV of the machine learning based ET was much smaller. In the region south of 20°S,
 406 TRENDY ET showed the largest IAV, followed by those of remote sensing physical ET and
 407 machine learning estimates. The three approaches agreed on that ET IAV in the Southern
 408 Hemisphere was generally larger than that in the Northern Hemisphere.

409
 410 **Figure 4.** Spatial distributions of the inter-annual variability in ET derived from (a) remote
 411 sensing-based physical models, (b) machine learning algorithms, (c) benchmark datasets, and (d)

412 TRENDY LSMs ensemble mean, respectively. The study period used in this study for inter-annual
413 variability analysis is from 1982 to 2011.

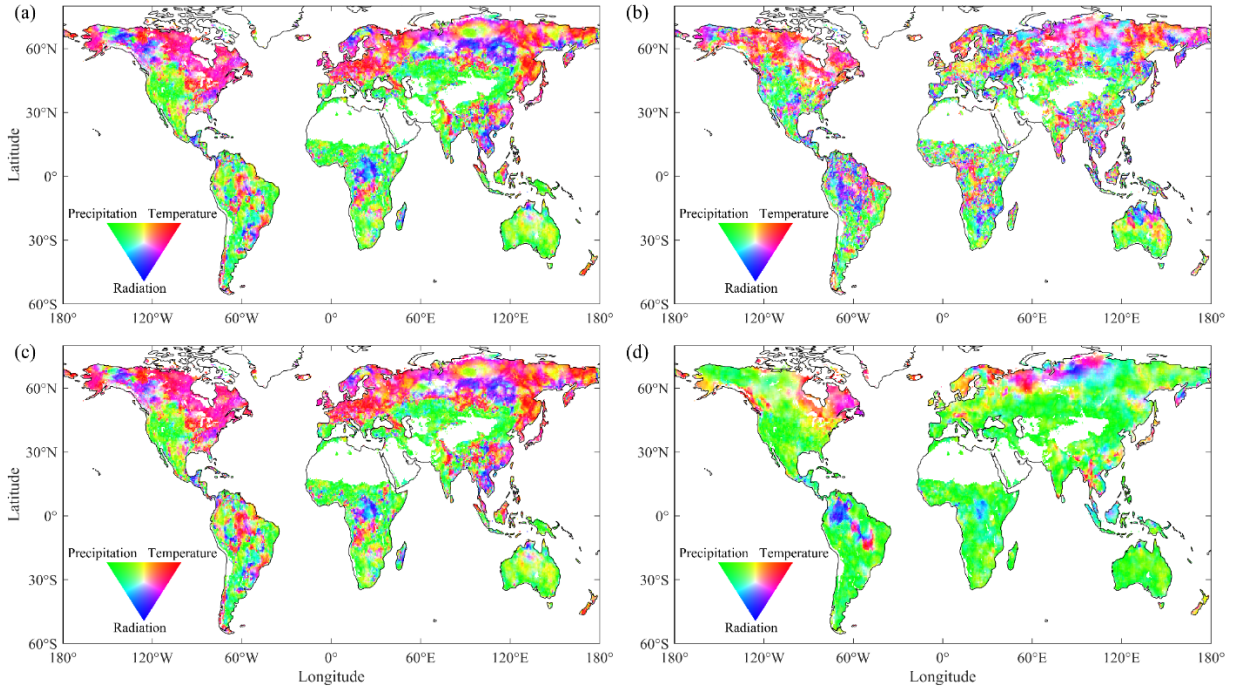

414
415 **Figure 5.** Latitudinal profiles of ET IAV for different categories of models. Each line represents
416 the mean value of the corresponding category and the shading represents the interval of one
417 standard deviation.

418 3.4 Climatic controls on ET

419 According to the ensemble remote sensing models, temperature and radiation dominated ET IAV
420 in northern Eurasia, northern and eastern North America, southern China, the Congo River Basin
421 and the southern Amazon River Basin, while precipitation dominated ET IAV in arid regions and
422 semi-arid regions (Fig. 6a). The ensemble machine-learning algorithms had a similar pattern, but
423 suggested a stronger control of radiation in the Amazon Basin and a weaker control of precipitation

424 in several arid regions such as central Asia and northern Australia (Fig. 6b). In comparison, the
425 ensemble LSMs suggested the strongest control of precipitation on ET IAV (Fig. 6). According to
426 the ensemble LSMs, ET IAV was dominated by precipitation IAV in most regions of the Southern
427 Hemisphere and northern low latitudes. Temperature and radiation only controlled northern
428 Eurasia, eastern Canada and part of the Amazon Basin (Fig. 6d). As is shown in Fig. S6, the
429 majority of LSMs agreed on the dominant role of precipitation in controlling ET in regions south
430 of 40°N. However, the pattern of climatic controls in the ORCHIDEE-MICT model is quite unique
431 and different from all other LSMs. According to the ORCHIDEE-MICT model, radiation and
432 temperature dominate ET IAVs in more regions, and precipitation only controls ET IAVs in
433 eastern Brazil, northern Russia, central Europe and a part of tropical Africa. Since ORCHIDEE-
434 MICT was developed from ORCHIDEE, the dynamic root parameterization in ORCHIDEE-MICT
435 may explain why ET is less driven by precipitation compared to ORCHIDEE (Haverd et al., 2018).
436 It is noted that two machine learning algorithms MTE and RF had significant discrepancies in the
437 spatial pattern of dominant climatic factors. According to the result of MTE, temperature
438 controlled ET IAV in regions north of 45°N, eastern US, southern China and the Amazon basin
439 (Fig. S6e). By contrast, RF suggested that precipitation and radiation dominated ET IAV in these
440 regions (Fig. S6f).

441

442
 443 **Figure 6.** Spatial distributions of climatic controls on inter-annual variation of ET derived from
 444 the ensemble means of remote sensing-based physical models (a), machine learning algorithms
 445 (b), benchmark data (c), and TRENDY LSMs (d). (red: temperature; green: precipitation; and blue:
 446 radiation).

447 **3.5 Long-term trends in global terrestrial ET**

448 All approaches suggested an overall increasing trend in global ET during the period 1982-2011
 449 (Fig. 7), although ET decreased over 1998-2009. This result is consistent with previous studies
 450 (Jung et al., 2010; Lian et al., 2018; Zhang et al., 2015). Remote sensing physical models indicated
 451 the largest increase in ET (0.62 mm yr^{-2}), followed by the machine-learning method (0.38 mm yr^{-2}),
 452 and land surface models (0.23 mm yr^{-2}). Mean ET of all categories except LSMs significantly
 453 increased during the study period ($p < 0.05$). It is noted that the ensemble mean ET of different
 454 categories are statistically correlated with each other ($p < 0.001$), even if the driving forces of
 455 different ET approaches are different.

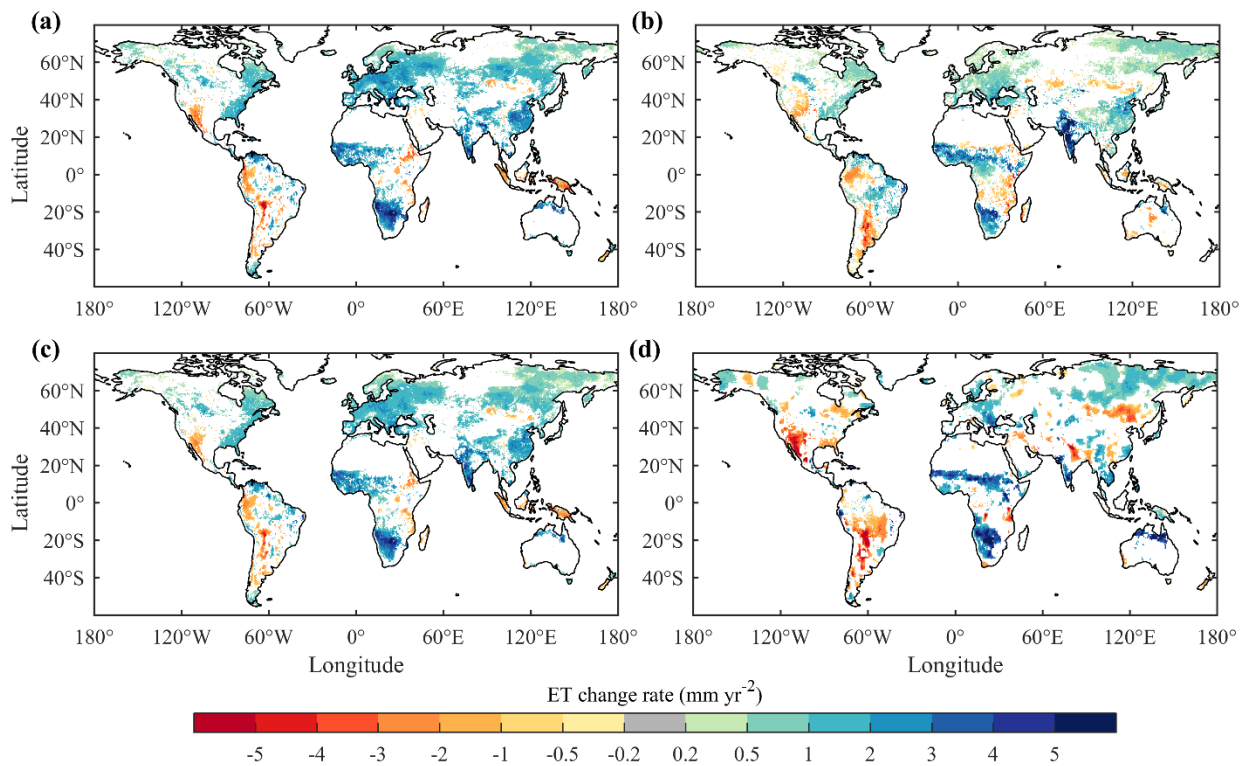

456

457 **Figure 7.** Inter-annual variations in global terrestrial ET estimated by different categories of
 458 approaches.

459 All remote sensing and machine learning estimates indicate a significant increasing trend in ET
 460 during the study period ($p < 0.05$), although the increase rate of P-LSH (1.07 mm yr^{-2}) is more than
 461 three times as large as that of GLEAM (0.33 mm yr^{-2}). Nevertheless, there is a larger discrepancy
 462 among LSMs in terms of ET trend. The majority of LSMs (10 of 14) suggest an increasing trend
 463 with the average trend of 0.34 mm yr^{-2} ($p < 0.05$), and eight of them are statistically significant (see
 464 Table 2). However, four LSMs (JSBACH, JULES, ORCHIDEE and ORCHIDEE-MICT) suggest
 465 a decreasing trend with the average trend of -0.12 mm yr^{-2} ($p > 0.05$). Among the four decreasing
 466 trends, only the trend of ORCHIDEE-MICT (-0.34 mm yr^{-2}) is statistically significant ($p < 0.05$).

467 According to Fig. 8, the ensemble means of all the three approaches showed increasing trends of
 468 ET over western and southern Africa, western Indian, and northern Australia, and decreasing ET
 469 over western United States, southern South America and Mongolia. Discrepancies in ET trends
 470 mainly appeared in East Europe, eastern India and central China. LSMs also suggested larger area
 471 of decreasing ET in both North America and South America. Although the differences in ET trends
 472 among individual models were larger than those among the ensemble means of different
 473 approaches, the majority of models agreed that ET increased in western and southern Africa, and
 474 decreased in western United States and southern South America (Fig. S2). For both remote sensing
 475 estimates and LSMs estimates, ET trends in Amazon Basin had large uncertainty. P-LSH, CLM-
 476 45 and VISIT suggested large area of increasing ET, in contrast, GLEAM, JSBACH and
 477 ORCHIDEE suggested a large area of decreasing ET.

478

479 **Figure 8.** Spatial distributions of ET trends during the period 1982-2011 derived from (a) remote
480 sensing-based physical models, (b) machine learning algorithm, (c) benchmark datasets, and (d)
481 TRENDY LSMs ensemble mean, respectively. Regions with non-significant trends were
482 excluded.

483 **3.6 Impacts of vegetation changes on ET variations**

484 During the period 1982-2011, global LAI trends estimated from remote sensing data and from the
485 ensemble LSMs are $2.51 \times 10^{-3} \text{ m}^2 \text{ m}^{-2} \text{ yr}^{-1}$ ($p < 0.01$) and $4.63 \times 10^{-3} \text{ m}^2 \text{ m}^{-2} \text{ yr}^{-1}$ ($p < 0.01$), respectively
486 (Table 2). All LSMs suggested a significant increasing trend in global LAI (greening). It was found
487 that, for both benchmark estimates and LSMs estimates, the spatial pattern of trends in ET matched
488 well with that of trends in LAI (Fig. 8c-d and Fig. S5a-b), indicating significant effects of
489 vegetation dynamics on ET variations. According to the results of multiple linear regression, all
490 models agreed that greening of the Earth since the early 1980s intensified terrestrial ET (Table 2),
491 although there was a significant discrepancy in the magnitude of ET intensification which varied
492 from 0.04 mm yr^{-2} to 0.70 mm yr^{-2} . The ensemble LSMs suggested a smaller ET increase (0.23 mm
493 yr^{-2}) than the ensemble remote sensing physical models (0.62 mm yr^{-2}) and machine-learning
494 algorithm (0.38 mm yr^{-2}). Nevertheless, the greening-induced ET intensification estimated by
495 LSMs (0.37 mm yr^{-2}) is larger than that estimated by remote sensing models (0.28 mm yr^{-2}) and
496 machine-learning algorithms (0.09 mm yr^{-2}) because LSMs suggested a stronger greening trend
497 than remote sensing models. The contribution of vegetation greening to ET intensification
498 estimated by the ensemble LSMs is larger than 100% while the contributions estimated by the
499 ensemble remote sensing physical models (0.62 mm yr^{-2}) and machine-learning algorithm are
500 smaller than 50%. Although TRENDY LSMs were driven by the same climate data and remote
501 sensing physical models were driven by varied climate data, TRENDY LSMs still showed a larger

502 discrepancy in terms of the effect of vegetation greening on terrestrial ET than remote sensing
503 physical models because of the significant differences in both LAI trends ($1.74\text{-}13.63 \times 10^{-3} \text{ m}^2 \text{ m}^{-1}$
504 yr^{-1}) and the sensitivities of ET to LAI ($4.04\text{-}217.39 \text{ mm yr}^{-2} \text{ per m}^2 \text{ m}^{-2}$). In comparison, remote
505 sensing physical models had smaller discrepancies in terms of the sensitivity of ET to LAI (55.78-
506 $143.43 \text{ mm yr}^{-2} \text{ per m}^2 \text{ m}^{-2}$).

507 **4. Discussion and perspectives**

508 **4.1 Sources of uncertainty**

509 **4.1.1 Uncertainty in the ET estimation of Amazon Basin**

510 LSMs show large discrepancies in the magnitude and trend of ET in the Amazon Basin (Fig. 3 and
511 Fig. S3). However, it is challenging to identify the uncertainty sources. Given that the TRENDY
512 LSMs used uniform meteorological inputs, the discrepancies in ET estimates among the
513 participating models mainly arise from the differences in underlying model structures and
514 parameters. One potential source of uncertainty is the parameterization of root water uptake. In the
515 Amazon Basin, large root depth was confirmed by field measurements (Nepstad et al., 2004).
516 However, many LSMs have an unrealistically small rooting depth (generally less than 2 m),
517 neglecting the existence and significance of deep roots. The incorrect root distributions enlarge the
518 differences in plant available water and root water uptake, producing large uncertainties in ET. In
519 addition, differences in the parameterization of other key processes pertinent to ET such as LAI
520 dynamics (Fig. S5), canopy conductance variations (Table 1), water movements in the soil
521 (Abramopoulos et al., 1988; Clark et al., 2015; Noilhan and Mahfouf, 1996) and soil moisture's
522 control on transpiration (Purdy et al., 2018; Szutu and Papuga, 2019) also increase the uncertainty
523 in ET. The above-mentioned processes are not independent of each other but interact in complex
524 ways to produce the end result.

525 4.1.2 Uncertainty in the ET estimation of arid and semi-arid regions

526 In arid and semi-arid regions, benchmark products show much larger differences in the magnitude
527 of ET than LSMs (Fig. S2). One cause of this phenomenon is the difference in meteorological
528 forcing. Remote sensing and machine learning datasets used different forcing data. For
529 precipitation, RF used the CRUNCEPv6 dataset, MTE used the Global Precipitation Climatology
530 Centre (GPCC) dataset, MODIS used the Global Modeling and Assimilation Office (GMAO)
531 dataset, GLEAM used the Multi-Source Weighted-Ensemble Precipitation (MSWEP) dataset,
532 PML-CSIRO used the Princeton Global Forcing (PGF) and the WATCH Forcing Data ERA-
533 Interim (WFDEI) datasets, and P-LSH used data derived from four independent sources. Since
534 precipitation is the key climatic factor controlling ET in arid and semi-arid regions (Fig. 6),
535 discrepancies between different forcing precipitation (Sun et al., 2018) may be the main source of
536 large uncertainty there. In comparison, the uniform forcing data reduced the inter-model range in
537 ET estimates of TRENDY LSMs. Nevertheless, it is noted that the congruence across LSMs ET
538 estimates doesn't necessarily mean they are the correct representation of ET. The narrower inter-
539 model range may suggest shared biases. All remote sensing models and machine learning
540 algorithms except GLEAM do not explicitly take the effects of soil moisture into account (Table
541 S1). Given that soil moisture is pivotal to both canopy conductance and soil evaporation in arid
542 and semi-arid regions (A et al., 2019; De Kauwe et al., 2015; Medlyn et al., 2015; Purdy et al.,
543 2018), the lack of soil moisture information also increases the bias in ET estimation. In addition,
544 the accuracy of remotely-sensing data itself is also an uncertainty source. The retrieval of key land
545 surface variables, such as leaf area index and surface temperature, is influenced by vegetation
546 architecture, solar zenith angle and satellite observational angle, particularly over heterogeneous
547 surface (Norman and Becker, 1995).

548 **4.1.3 Uncertainty in the ET IAV in the Southern Hemisphere**

549 In regions south of 20°S (including Australia, southern Africa and southern South America), the
550 ET IAVs of remote sensing models and machine learning algorithms are smaller than that of LSMs
551 (Fig. 4 and 5), although their spatial patterns are similar. In these regions, GLEAM, the only remote
552 sensing model that explicitly considers the effects of soil moisture, has larger ET IAVs than other
553 remote sensing models and has similar ET IAVs with LSMs (Fig. S4). This could imply that most
554 existing remote sensing models may underestimate ET IAVs in the Southern Hemisphere because
555 the effects of soil moisture are not explicitly considered. Machine learning algorithms show much
556 smaller IAVs than other models (Fig. 4 and S4). The main reason is that ET inter-annual variability
557 is partly neglected in the training process because the magnitude of ET inter-annual variability is
558 usually smaller than the spatial and seasonal variability (Anav et al., 2015; Jung et al., 2019).
559 Moreover, the IAV of satellite-based key land surface variables such as LAI, fAPAR and surface
560 temperature may be not reliable because of the effects of clouds, which also affects the estimation
561 of IAV of satellite-based ET. It is noted that LSMs ET IAVs show large differences in latitudes
562 south of 20°S (Fig. 5). This divergence in ET IAV indicates that LSMs need better representation
563 of ET response to climate in the Southern Hemisphere.

564 **4.1.4 Uncertainty in global ET trend**

565 All the three categories of ET models detected an overall increasing trend in global terrestrial ET
566 since the early 1980s, which is in agreement with previous studies (Mao et al., 2015; Miralles et
567 al., 2014; Zeng et al., 2018a; Zeng et al., 2018b; Zeng et al., 2014; Zhang et al., 2015; Zhang et
568 al., 2016b). Benchmark products generally suggested stronger ET intensification than LSMs. The
569 weaker ET intensification in LSMs may be induced by the response of stomatal conductance to
570 increasing atmospheric CO₂ concentration. The increasing CO₂ affects ET in two ways. On one

571 hand, increasing CO₂ can effectively reduce stomatal conductance and thus decrease transpiration
572 (Heijmans et al., 2001; Leipprand and Gerten, 2006; Swann et al., 2016); on the other hand, it can
573 increase vegetation productivity and thus increase LAI. For benchmarks, the second effect could
574 be captured by remotely sensed LAI, NDVI or fAPAR, while the first effect was neglected by all
575 models except P-LSH (Zhang et al., 2015). In contrast, both effects were modeled in all TRENDY
576 LSMs.

577 LAI dynamics have significant influences on ET. The increased LAI trend (greening) since the
578 early 1980s was reported by previous studies (Mao et al., 2016; Zhu et al., 2016) and is also
579 confirmed by remote sensing data and all TRENDY LSMs used in this study (Table 2 and Fig.
580 S5). Zhang et al. (2015) found that the increasing trend of global terrestrial ET over 1982-2013
581 was mainly driven by an increase in LAI and the enhanced atmosphere water demand. Using a
582 land-atmosphere coupled global climate model (GCM), Zeng et al. (2018b) further estimated that
583 global LAI increased about 8%, resulting in an increase of $0.40 \pm 0.08 \text{ mm yr}^{-2}$ in global ET
584 (contributing to $55\% \pm 25\%$ of the ET increase). This number is close to the estimates of ensemble
585 LSMs ($0.37 \pm 0.18 \text{ mm yr}^{-2}$). In comparison, remote sensing models and machine learning
586 algorithms used in this study suggested smaller greening-induced ET increases. It is noted that
587 TRENDY LSMs still showed a larger discrepancy in terms of the effect of vegetation greening on
588 terrestrial ET than remote sensing physical models (Table 2) because of the significant differences
589 in LAI trend ($1.74\text{-}13.63 \times 10^{-3} \text{ m}^2 \text{ m}^{-2} \text{ yr}^{-1}$) and in the sensitivity of ET to LAI ($4.04\text{-}217.39 \text{ mm}$
590 yr^{-2} per $\text{m}^2 \text{ m}^{-2}$). Uncertainties in LAI trend may arise from inappropriate carbon allocations and
591 deficits in responding to water deficits (Anav et al., 2013; Hu et al., 2018; Murray-Tortarolo et al.,
592 2013; Restrepo-Coupe et al., 2017). Additionally, for machine-learning algorithms, the results

593 from insufficient long-term in situ measurements and sparse observations in tropical, boreal and
594 arid regions imply that there likely are deficiencies in representing the temporal variations.

595 **4.1.5 Lack of knowledge of the effects of irrigation**

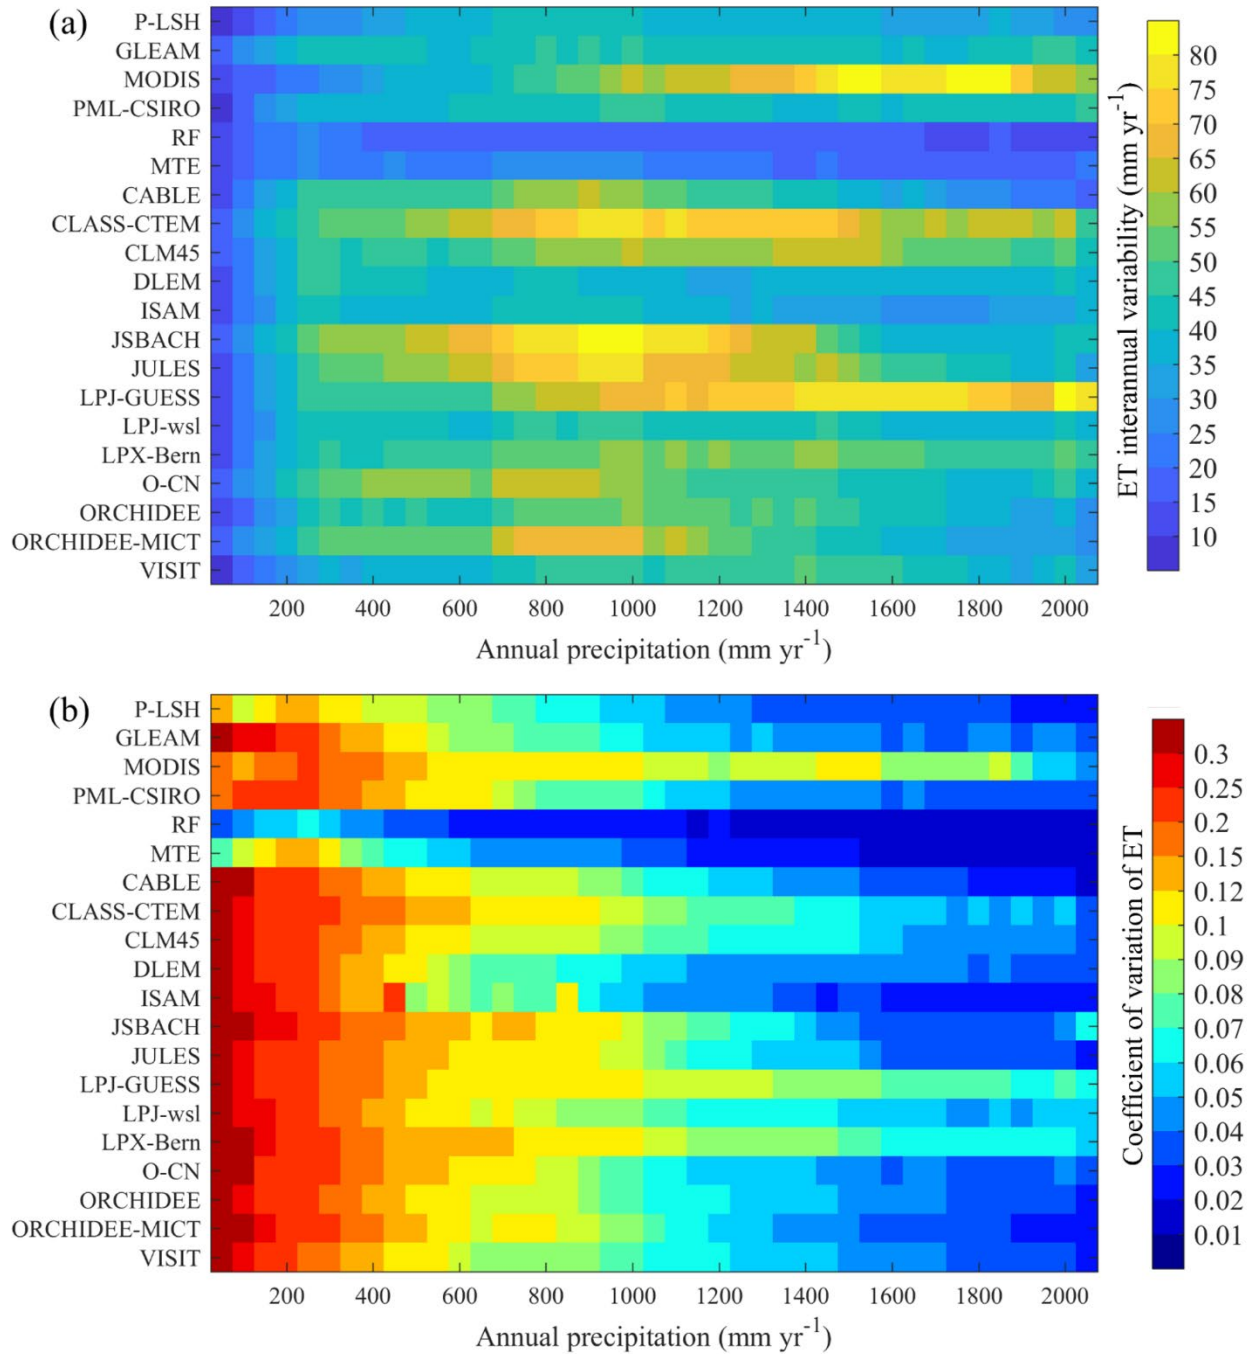

596 Irrigation accounts for about 90% of human consumptive water use and largely affects ET in
597 irrigated croplands (Siebert et al., 2010). Global water withdrawals for irrigation were estimated
598 to be within the range of 1161-3800 km³ yr⁻¹ around the year 2000, and largely increased during
599 the period 2000-2014 (Chen et al., 2019). However, none of the remote sensing-based physical
600 models and machine-learning algorithms explicitly accounted for the effects of irrigation on ET,
601 although these effects could be taken into account to some extent by using observed LAI, NDVI,
602 or fAPAR to drive the models (Zhang et al., 2015). Considering that annual ET may surpass annual
603 precipitation in cropland, Zhang et al. (2016b) used the Budyko hydrometeorological model to
604 constrain PML-CSIRO model only in grids covered by non-crop vegetation. But the process of
605 irrigation affecting evaporation was still not taken into consideration. For TRENDY LSMs, only
606 2 of 14 models (DLEM and ISAM) included the irrigation processes (Le Quéré et al., 2018).
607 Therefore, the effects of irrigation are largely neglected in existing global ET datasets, which
608 reduces the accuracy of local ET estimates in regions with a large proportion of irrigated cropland.

609 **4.1.6 ET variability across precipitation gradient and its planetary boundary**

610 Precipitation is the source of terrestrial evapotranspiration. According to Fig. 9a, the vast majority
611 of models agree that ET has the largest IAV in regions with annual precipitation between 700 mm
612 and 1000 mm, although the magnitude of ET IAV has substantial discrepancies among different
613 models. The low ET IAV in arid and semi-arid regions doesn't mean ET is stable in these regions.
614 In fact, ET has the largest coefficient of variation (CoV, the ratio of ET standard deviation to ET
615 mean value) in arid regions, and all models show a clear negative trend of CoV with increasing

616 precipitation (Fig. 9b). This is mainly caused by the large CoV of precipitation in arid regions
617 (Fatichi et al., 2012).

618 In comparison, terrestrial ET shows a much smaller IAV at the global scale (Table 2), ranging
619 from 4.8 to 12.2 mm yr⁻¹ (one standard deviation), which only equals to 1.0-1.8% of global annual
620 mean ET. The model results suggest that global terrestrial ET stabilizes at about 6.74×10^4 km³ yr⁻¹
621 (603 mm yr⁻¹), which is close to previous estimates (Alton et al., 2009; Mueller et al., 2011; Oki
622 and Kanae, 2006; Zeng et al., 2012). The stability of global terrestrial ET is probably based on
623 partitioning the solar constant and suggests that, at a global scale, droughts in one place are
624 balanced by excess rain in other places so it all evens out. It implies that ET also has a potential
625 planetary boundary, a suggestion made by Running (2012) on NPP as a planetary boundary. ET
626 integrates four aspects of the current planetary boundaries defined by Steffen et al. (2015) : climate
627 change, freshwater use, land-system change, and biochemical flows. Given ET's importance in
628 linking terrestrial water, carbon, nutrient and energy cycles, more studies on the ET planetary
629 boundary are needed under the background of intensifying global change and increasing human
630 perturbations on the Earth system.

631

632 **Figure 9. Interannual variability (a) and coefficient of variation (b) of ET in each 50mm**
 633 **interval of mean annual precipitation.**

634 In short, the multi-model inter-comparison indicates that considerable uncertainty exists in both
 635 the temporal and spatial variations in global ET estimates, even though a large portion of models

636 adopt similar ET algorithms (Table 1). The major uncertainty source is different for different types
637 of models and regions. The uncertainty is induced by multiple factors, including problems
638 pertinent to parameterization of land processes, lack of in situ measurements, remote sensing
639 acquisition, scaling effects and meteorological forcing. Based on the results of different
640 approaches, we suggest that global terrestrial ET also has a potential planetary boundary, with the
641 value being about $6.74 \times 10^4 \text{ km}^3 \text{ yr}^{-1}$ (603 mm yr^{-1}), which is consistent with previous estimates.

642 **4.2 Recommendations for future development**

643 **4.2.1 Remote sensing-based physical methods**

644 In the past decades, the development of remote sensing technologies has contributed to the boom
645 of various ET estimating methods. However, there is still a large room for remote sensing
646 technologies to improve (Fisher et al., 2017). Developing new platforms and sensors that have
647 improved global spatiotemporal coverage and using multi-band, multi-source remote sensing data
648 are the key points. Planned or newly launched satellites, such as NASA's GRACE Follow-On
649 (GRACE-FO) mission and ECOSystem Spaceborne Thermal Radiometer Experiment on Space
650 Station (ECOSTRESS) mission, will improve the accuracy of terrestrial ET estimates.
651 ECOSTRESS's thermal infrared (TIR) multispectral scanner is capable of monitoring diurnal
652 temperature patterns at high-resolutions, which gives insights into plant response to water stress
653 and the means to understand sub-daily ET dynamics (Hulley et al.). GRACE Follow-On
654 observations can be used to constrain subsurface lateral water transfers, which helps to correct soil
655 moisture and subsequently improves the accuracy of ET estimates (Rouholahnejad and Martens,
656 2018). Moreover, building integrated methods that fuse different ET estimates or the upstream
657 satellite-based biophysical variables from different platforms and the other forcing data will be

658 helpful to improve the accuracy and spatiotemporal coverage of ET (Ke et al., 2016; Ma et al.,
659 2018; Semmens et al., 2016).

660 The theories and retrieval algorithms of ET and related key biophysical variables also need to be
661 further improved. For example, the method for canopy conductance calculation may be improved
662 by integrating remote sensing based solar-induced chlorophyll fluorescence (SIF) data. SIF data
663 in existing Global Ozone Monitoring Experiment-2 (GOME-2), Orbiting Carbon Observatory-2
664 (OCO-2) and TROPospheric Monitoring Instrument (TROPOMI) and the forthcoming OCO-3
665 and Geostationary Carbon Cycle Observatory (GeoCarb) satellites provide a good opportunity for
666 diagnosing transpiration and for ET partitioning at multiple spatiotemporal scales (Pagán et al.,
667 2019; Stoy et al., 2019; Sun et al., 2017). Theoretical advancements in nonequilibrium
668 thermodynamics and Maximum Entropy Production (MEP) could be incorporated into the
669 classical ET theories (Xu et al., 2019; Zhang et al., 2016a). In addition, quantifying the effects of
670 CO₂ fertilization on stomatal conductance is pivotal for remote sensing models to capture the long-
671 term trend of terrestrial ET.

672 Most existing remote sensing-based ET studies focused on total ET, however, the partitioning of
673 ET between transpiration, soil evaporation, and canopy interception may have significant
674 divergence even though the total ET is accurately estimated (Talsma et al., 2018b). In current
675 remote sensing-based ET models, soil evaporation, which is sensitive to precipitation events and
676 soil moisture, is the part with the largest error (Talsma et al., 2018a). Therefore incorporating the
677 increasing accessible satellite-based precipitation, soil moisture observations and soil property
678 data will contribute to the improvement of soil evaporation estimation. Meanwhile, the
679 consideration of soil evaporation under herbaceous vegetation and canopy will also reduce the
680 errors.

681 **4.2.2 Machine learning methods**

682 It is well known that the capability of machine-learning algorithms in providing accurate ET
683 estimates largely depends on the representativeness of training datasets in describing ecosystem
684 behaviors (Yao et al., 2017). As a result, machine-learning algorithms may not perform well
685 outside the range of the data used for their training. Unfortunately, long-term field observations
686 out of northern temperate regions are still insufficient. This is an important cause of the small
687 spatial gradient and small IAVs of machine-learning ET. Given that remote sensing is capable of
688 providing broad coverage of key biophysical variables at reasonable spatial and temporal
689 resolutions, one way to overcome this challenge is to exclusively use remote sensing observations
690 as training data (Jung et al., 2019; Poon and Kinoshita, 2018). Another simple way to make IAVs
691 of machine-learning ET more realistic is normalizing the yearly anomalies when comparing with
692 ET estimates from LSMs and remote sensing physical models (Jung et al., 2019). New machine-
693 learning techniques, including the extreme learning machine and the adaptive neuro-fuzzy
694 inference system, can be used to improve the accuracy of ET estimation (Gocic et al., 2016; Kişi
695 and Tombul, 2013). The emerging deep learning methods such as recurrent neural network (RNN)
696 and Long Short-Term Memory (LSTM) have large potential to outcompete conventional machine-
697 learning methods in modelling ET time series (Reichstein et al., 2018; Reichstein et al., 2019).
698 Almost all machine-learning datasets used precipitation rather soil moisture as explanatory
699 variable when training. However, soil moisture rather than precipitation directly controls ET. As
700 more and more global remote sensing based soil moisture datasets become available, using soil
701 moisture products as input is expected to improve the accuracy of ET estimates, especially for
702 regions with sparse vegetation coverage (Xu et al., 2018).

703 **4.2.3 Land surface models**

704 In contrast to observation-based methods, LSMs are able to project future changes in ET, and can
705 disentangle the effects of different drivers on ET through factorial analysis. However, results from
706 LSMs are only as good as their parameterizations of complex land surface processes which are
707 limited by our incomplete understanding of physical and biological processes (Niu et al., 2011).
708 Although TRENDY LSMs are the state-of-the-art process-based global land surfaces models,
709 improvements are still needed because several important processes are missing or not being
710 appropriately parameterized. Most of the TRENDY LSMs did not simulate the processes relevant
711 to human management including irrigation (Chen et al., 2019) and application of fertilizers (Mao
712 et al., 2015), and natural disturbances like wildfire (Poon and Kinoshita, 2018). Incorporating these
713 processes into present LSMs is critical, although introduction of new model parameters potentially
714 also leads to an increase in a model's uncertainty.

715 In light of the importance of soil water availability in constraining canopy conductance and
716 dynamics, accurate representation of hydrological processes is a core task for LSMs, particularly
717 in dry regions. Integrating a dynamic root water uptake function and hydraulic redistribution into
718 the LSM can significantly improve its performance of estimating seasonal ET and soil moisture
719 (Li et al., 2012). Moreover, other hydrological processes including groundwater (Decker, 2015),
720 lateral flow (Rouholahnejad and Martens, 2018) and water vapor diffusion at the soil surface
721 (Chang et al., 2018) need to be simulated and correctly represented to reproduce the dynamics of
722 soil water and ET. Since canopy LAI plays an important role in regulating ET, correctly simulating
723 vegetation dynamics is also critical. One way is to correct the initialization, distribution, and
724 parameterization of vegetation phenology in LSMs (Murray-Tortarolo et al., 2013; Zhang et al.,
725 2019). Appropriate carbon allocation scheme and parameterization of vegetation's response to
726 water deficits are also important for reproducing vegetation dynamics (Anav et al., 2013).

727 **5. Conclusion**

728 In this study, we evaluated twenty global terrestrial ET estimates including four from remote
729 sensing-based physical models, two from machine-learning algorithms and fourteen from
730 TRENDY LSMs. The ensemble mean values of global terrestrial ET for the three categories agreed
731 well, ranging from 589.6 mm yr⁻¹ to 617.1 mm yr⁻¹. All the three categories detected an overall
732 increasing trend in global ET during the period 1982-2011 and suggested a positive effect of
733 vegetation greening on ET intensification. However, the multi-model inter-comparison indicates
734 that considerable uncertainties still exist in both temporal and spatial variations in global terrestrial
735 ET estimates. LSMs had significant differences in the ET magnitude in tropical regions, especially
736 the Amazon Basin, while benchmark ET products showed larger inter-model range in arid and
737 semi-arid regions than LSMs. Trends in ET estimates also showed significant discrepancies among
738 LSMs. These uncertainties are induced by parameterization of land processes, meteorological
739 forcings, lack of in-situ measurements, remote sensing acquisition and scaling effects. Model
740 developments and observational improvements provide two parallel pathways towards improving
741 the accuracy of global terrestrial ET estimation.

742 **Code and data availability**

743 TRENDYv6 data are available from S.S. (s.a.sitch@exeter.ac.uk) on reasonable request. MODIS
744 ET data are available from http://files.ntsg.umt.edu/data/NTSG_Products/MOD16/. GLEAM ET
745 are available from <https://www.gleam.eu/>. Both Model Tree Ensemble and Random Forest ET are
746 available from <https://www.bgc-jena.mpg.de/geodb/projects/FileDetails.php>. P-LSH ET are
747 available from http://files.ntsg.umt.edu/data/ET_global_monthly/Global_8kmResolution/.
748 PML-CSIRO ET are from <https://data.csiro.au/dap/landingpage?pid=csiro:17375>. CRU-

749 NCEPv8 data are available from Nicolas Viovy on reasonable request. GIMMS LAI3gV1 data are
750 available from R. B. Myneni on reasonable request. GIMMS NDVI3gV1 data are available from
751 <https://ecocast.arc.nasa.gov/data/pub/gimms/3g.v1/>.

752 **Author contributions**

753 S.P. initiated this research and was responsible for the integrity of the work as a whole. N.P. carried
754 out the analyses. S.P., N.P., H.T. and H.S. wrote the manuscript with contributions from all
755 authors. P.F., S.S., V.K.A., V.H., A.K.J., E.K., S.L., D.L., J.E.M.S.N., C.O., B.P., H.T. and S.Z.
756 contributed to the TRENDY results.

757 **Competing interests**

758 The authors declare that they have no conflict of interest.

759 **Acknowledgements**

760 This study has been supported partially by grants from National Science Foundation (1903722 and
761 1243232), AU-OUC Joint Center Program and Auburn University IGP Program. A.K.J. was
762 support in part by Department of Energy (No. DE-SC0016323) and NSF (NSF AGS 12-43071).
763 D.L. acknowledges funding from the National Institute of Food and Agriculture/US Department
764 of Agriculture (2015- 67003-23489 and 2015-67003-23485). S.L. acknowledges support from EC
765 H2020 (CCiCC; grant no 821003) and SNSF (grant no. 20020_172476). V.H. acknowledges
766 support from the Earth Systems and Climate Change Hub, funded by the Australian Government's
767 National Environmental Science Program. We thank all people who provided data used in this
768 study, in particular, the TRENDY modelling groups. Additional details on funding support for the
769 participating 14 land surface models have been provided in the TRENDY Project.

1200 **Table 1.** Descriptions of models used in this study, including their drivers, adopted algorithms,
1201 key equations, limitations and references

Name	Input	Algorithm	Spatial resolution	Temporal resolution	Key equations	Limitations	References
------	-------	-----------	--------------------	---------------------	---------------	-------------	------------

MTE	Climate: precipitation, temperature, sunshine hour, relative humidity, wet days Vegetation: fAPAR	TRIAL ERROR	+0.5°×0.5°	Monthly	No specific equation	Insufficient observations in tropical regions; with no CO2 effect	fluxJung et al. in(2011)	
RF	enhanced vegetation index, fAPAR, leaf area index, land surface temperature, radiation, potential radiation, index of water availability, relative humidity	Randomized decision tree	0.5°×0.5°	Half-hourly	No specific equation	The same with MTE	Bodesheim et al. (2018)	
P-LSH	Climate: radiation, temperature, vapor pressure, wind speed, CO2 Vegetation: AVHRR NDVI	Modified airPenman–Monteith	0.083°×0.083°	Monthly	$E_v = \frac{\Delta R_n + \rho C_p VPD g_a}{\lambda_v (\Delta + \gamma \left(1 + \frac{g_a}{g_s}\right))}$ $E_s = RH \frac{VPD}{k} \frac{\Delta R_n + \rho C_p VPD g_a}{\lambda_v (\Delta + \gamma \left(1 + \frac{g_a}{g_s}\right))}$	Advantages: more robust physical basis; consider the effects of CO ₂	Zhang et al. (2015)	
GLEAM	Climate: precipitation, net radiation, surface soil moisture, land surface temperature, air temperature, snow depth Vegetation: vegetation optical depth	Modified Priestley–Taylor	0.25°×0.25°	Daily	$E_s = f_s S_s \alpha_s \frac{\Delta}{\lambda_v \rho_w (\Delta + \gamma)} (R_n^s - G_s)$ $E_{sc} = f_{sc} S_{sc} \alpha_{sc} \frac{\Delta}{\lambda_v \rho_w (\Delta + \gamma)} (R_n^{sc} - G_{sc})$ $E_{tc} = f_{tc} S_{tc} \alpha_{tc} \frac{\Delta}{\lambda_v \rho_w (\Delta + \gamma)} (R_n^{tc} - G_{tc}) - \beta E_i$	Limitations: high meteorological forcing requirements; canopy conductance is based on proxies;	Advantages: simple; low requirement for meteorological data; well-suited for remote sensing observable variables; soil moisture is considered	(Miralles et al., 2011)
MODIS	Climate: temperature, shortwave radiation, wind speed, relative humidity, air pressure Vegetation: LAI, fAPAR, albedo	airPenman–Monteith–Leuning	0.05°×0.05°	Monthly	$E_i = f_{wet} f_c \frac{\Delta(R_n - G) + \rho c_p \frac{VPD}{r_a^{wc}}}{\lambda_v \rho_w (\Delta + \gamma \frac{r_s^{wc}}{r_a^{wc}})}$ $E_v = (1 - f_{wet}) f_c \frac{\Delta(R_n - G) + \rho c_p \frac{VPD}{r_a^t}}{\lambda_v \rho_w (\Delta + \gamma \frac{r_s^t}{r_a^t})}$ $E_s = [f_{wet} + \frac{(1 - f_{wet}) h VPD}{\beta}] \frac{(s A_{soil} + \frac{\rho c_p (1 - f_c) VPD}{r_{as}})}{\lambda_v \rho_w (S + \gamma \frac{r_{tot}}{r_{as}})}$	Advantages: more robust physical basis;	Limitations: require many variables that are difficult to observe or not observable with satellites; canopy conductance is based on proxies; do not consider soil moisture but use atmospheric humidity as a surrogate; do not	Mu et al. (2011)

PML-CSIRO	Climate: Penman-Monteith-temperature, vapor pressure, shortwave radiation, longwave radiation, wind speed Vegetation: AVHRR LAI, emissivity and albedo	0.5°×0.5°	Monthly	$E_v = \frac{\Delta R_n + \rho C_p VPD g_a}{\lambda_v (\Delta + \gamma (1 + \frac{g_a}{g_s}))}$ $E_s = \frac{f \Delta A_s}{\Delta + \gamma}$	<p>consider the effects of CO₂</p> <p>Advantages: Zhang et al. (2016b) more robust physical basis (compared to Priestley-Taylor equation); biophysically based estimation of surface conductance</p> <p>Limitations: high meteorological forcing requirements; canopy conductance is based on proxies; do not consider the effects of CO₂</p>
				E _i : an adapted version of Gash rainfall interception model (Van et al., 2001)	

TRENDY LSMs

Advantages: land surface models are process-oriented and physically-based. Given their structure almost all models are capable to allow factorial analysis, where one forcing can be applied at a time. Most models also consider the physiological effect of CO₂ on stomatal closure.

Disadvantages: most models typically do not allow integration/assimilation of observation-based vegetation characteristics. Model parameterizations remain uncertain and a same process is modelled in different ways across models. Model parameters may or may not be physically-based and therefore measurable in the field.

Models participating in the TRENDYv6 comparison were forced by precipitation, air temperature, specific humidity, shortwave radiation, longwave radiation, wind speed based on the CRU-NCEPv8 data as explained in Le Quere et al. 2018. It is very difficult to list all key equations for all land surface models. Here, we just list the stomatal conductance equation for each model.

Name	Algorithm	Spatial resolution	Temporal resolution	Key equations	References
CABLE	Penman-Monteith	0.5°×0.5°	Monthly	$g_s = g_0 + \frac{g_1 f_w A}{c_a - c_p} (1 + \frac{VPD}{VPD_0})^{-1}$	Haverd et al. (2018)

1202 Notes: A: net assimilation rate; A_{dt} : total daytime net photosynthesis; $A_{n,pot}$: unstressed net
1203 assimilation rate; b: soil moisture factor; b_i : stomatal conductance intercept; c_a : atmospheric CO₂
1204 concentration; c_c : critical CO₂ concentration; c_i : internal leaf concentration of CO₂; $c_{i,pot}$: internal
1205 leaf concentration of CO₂ for unstressed conditions; c_s : leaf surface CO₂ concentration; c_p : CO₂
1206 compensation point; e_s : vapor pressure at leaf surface; e_i : saturation vapor pressure inside the leaf;
1207 E_s : soil evaporation; E_c : canopy evapotranspiration; E_{dry} : dry canopy evapotranspiration; E_{wet} : wet
1208 canopy evapotranspiration; E_v : canopy transpiration; E_i : canopy interception; E_{tc} : transpiration
1209 from tall canopy; E_{sc} : transpiration from short canopy; f: fraction of P to equilibrium soil
1210 evaporation; f_s : soil fraction; f_{sc} : short canopy fraction; f_{tc} : tall canopy fraction; f_{vpd} : factor of the
1211 effect of leaf-to-air vapor pressure difference; f_w : a function describing the soil water stress on
1212 stomatal conductance; f_{wet} : relative surface wetness parameter; f_0 : the maximum ratio of internal
1213 to external CO₂; $f(ppdf)$: limiting factor of photosynthetic photo flux density; $f(T_{min})$: limiting factor
1214 of daily minimum temperature; $f(VPD)$: limiting factor of vapor pressure deficit; $f(CO_2)$: limiting
1215 factor of carbon dioxide; G: ground energy flux; g_a : aerodynamic conductance; g_m :
1216 empirical parameter; g_s : stomatal conductance; g_{smax} : maximum stomatal conductance; g_{smin} :
1217 minimum stomatal conductance; g_{soil} : bare soil conductance; g_0 : residual stomatal conductance
1218 when the net assimilation rate is 0; g_1 : sensitivity of stomatal conductance to assimilation, ambient
1219 CO₂ concentration and environmental controls; I: tall canopy interception loss; m: stomatal
1220 conductance slope; P_{atm} : atmospheric pressure; PE_s : potential soil evaporation; PE_{canopy} : potential
1221 canopy evaporation; q_a : specific air humidity; q_c : critical humidity deficit; q_s : specific humidity of
1222 saturated air; r_a : aerodynamic resistance; r_s : stomatal resistance; R_n : net radiation; R_d : day
1223 respiration; RH: relative humidity; T_s : actual surface temperature; VPD: vapor pressure deficit;
1224 VPD_0 : the sensitivity of stomatal conductance to VPD; W: top soil moisture; W_{canopy} : canopy water;
1225 W_{sat} : soil porosity; α : Priestley-Taylor coefficient; α_m : empirical parameter; β : a constant
1226 accounting for the times in which vegetation is wet; β_t : soil water availability factor between 0 and
1227 1; β_w : A scaling factor to account for water stress; β_s : moisture availability function; ρ : air density;
1228 γ : psychrometric constant; λ_v : latent heat of vaporization; λ_c : ratio of intercellular to ambient partial
1229 pressure of CO₂; r_{corr} : correction factor of temperature and air pressure on conductance; Γ^* : CO₂
1230 compensation point when leaf day respiration is zero; θ_1 : parameter of moisture concentration in
1231 the top soil layer; θ_c : parameter of moisture concentration in the spatially varying critical soil
1232 moisture; Δ : slope of the vapor pressure curve.

1233 **Table 2.** Inter-annual variability (IAV, denoted as standard deviation) and trend of global
 1234 terrestrial ET during 1982-2011 and the contribution of vegetation greening to ET trend. * suggests
 1235 significance of the trend at the 95% confidence level ($p < 0.05$).

	Model	ET IAV (mm yr ⁻¹)	ET Trend (mm yr ⁻²)	Greening-induced ET change (mm yr ⁻²)	Sensitivity of ET to LAI trend (10 ⁻³ m ² LAI (mm yr ⁻² per m ² m ⁻²))	(10 ⁻³ m ² m ⁻² yr ⁻¹)
