Abstract. The high spatio-temporal variability of precipitation is often difficult to characterise due to limited measurements. The available low-resolution global reanalysis datasets inadequately represent the spatio-temporal variability of precipitation relevant to catchment hydrology. The Bureau of Meteorology Atmospheric high-resolution Regional Reanalysis for Australia (BARRA) provides a high-resolution atmospheric reanalysis dataset across the Australasian region. For hydrometeorological applications, however, it is essential to properly evaluate the sub-daily precipitation from this reanalysis. In this regard, this paper evaluates the sub-daily precipitation from BARRA for a period of 6 years (2010-2015) over Australia against point observations and blended radar products. We utilise a range of existing and bespoke metrics for evaluation at point and spatial scales. We examine bias in quantile estimates and spatial displacement of sub-daily rainfall at a point scale. At a spatial scale, we use the Fractions Skill Score as a spatial evaluation metric. The results show that the performance of BARRA precipitation depends on spatial location with poorer performance in tropical relative to temperate regions. A possible spatial displacement during large rainfall is also found at point locations. This displacement, evaluated by comparing the distribution of rainfall within a day, could be quantified by considering the neighbourhood grids. On spatial evaluation, hourly precipitation from BARRA are found to be skilful at a spatial scale of less than 100km (150km) for a threshold of 75th percentile (90th percentile) at most of the locations. The performance across all the metrics improves significantly at time resolutions higher than 3 h. Our evaluations illustrate that the BARRA precipitation, despite discernible spatial displacements, serves as a useful dataset for Australia, especially at sub-daily resolutions. Users of BARRA are recommended to properly account for possible spatio-temporal displacement errors, especially for applications where the spatial and temporal characteristics of rainfall are deemed very important.

1 Introduction

Precipitation is highly variable across both space and time, especially at spatial and temporal scales relevant to catchment hydrology (Michaelides et al., 2009). An understanding of the spatio-temporal pattern of precipitation is vital for many scientific and operational applications such as hydro-climatic modelling and the forecasting of floods (Golding et al., 2016; Kucera et al., 2013; Paschalis et al., 2014). This understanding relies on access to high-resolution precipitation datasets. However, the availability of fine-scale precipitation products (e.g. spatial resolution less than around 0.25° at hourly time scale) are limited.

25   The general sources of precipitation data are gauge measurements, ground-based radars, satellites and atmospheric reanalysis models (Michaelides et al., 2009). Gauge measurements, which are localised in nature, are hindered by the sparse and uneven distribution of gauge network, whereas the coverage of ground-based radars is limited. Global reanalysis datasets (e.g. NCEP-CFSR, Saha et al., 2010; ERA-Interim, Dee et al., 2011; JRA-55, Kobayashi et al., 2015) and satellite products (e.g. TMPA, Huffman et al., 2007; IMERG, Huffman et al., 2018) provide a continuous and consistent estimate at varying spatial ($0.05°$ to

30    $2.5°$) and temporal resolution (hourly to daily).

An atmospheric reanalysis merges observations and models to provide a four-dimensional earth system data at a regular spatial and temporal resolution over long time period, often years and decades (Parker, 2016). The variables in the reanalysis (such as precipitation, cloud and soil moisture) are related to one another through modelled physical relations and with the analysed observations. By undertaking modelling over a limited area, a regional atmospheric reanalysis can provide precip-

35   itation estimates at finer spatial and temporal scale than a global reanalysis. It can incorporate more observations at a finer scale to better constrain the evolution of a higher-resolution model, and thus can account for the effects of mountains, coastlines, and mesoscale atmospheric circulations in greater detail. Such analyses can thereby provide precipitation estimates with greater spatial relevance to local fine-scale studies than coarser-scale models. BARRA (Bureau of Meteorology atmospheric high-resolution regional reanalysis for Australia) is one such high-resolution (~12 km) regional reanalysis (BARRA-R). It is

40   driven with initial and boundary conditions from the global ERA-Interim reanalysis (~79 km) and provides estimates over the Australasian region from 1990 to 2018 (Jakob et al., 2017; Su et al., 2019).

BARRA-R (referred to here as simply BARRA) provides hourly precipitation estimates at 12 km horizontal resolution (Jakob et al., 2017; Su et al., 2019). Rainfall observations are not assimilated in this reanalysis and precipitation is estimated by model physics and parameterisation. Evaluating its suitability for scientific studies and its use in hydrological applications

45   can be facilitated by identifying its strengths and limitations through a quantitative assessment. An initial assessment of daily precipitation from BARRA showed that it was able to reproduce the precipitation statistics and large precipitation amounts at point (gauged locations) and grid scale of 5 km (Acharya et al., 2019; Su et al., 2019). However, precipitation data at sub-daily temporal resolutions are essential to support the application of flood modelling (Chiaravalloti et al., 2018) and analysis of precipitation extremes in convective systems. Therefore, it is useful to assess the performance of BARRA at sub-daily

50   resolution along with its ability to represent the spatial structure of rainfall events.

The performance of BARRA at a daily scale was summarised using continuous metrics and categorical metrics at both point and grid scales (Acharya et al., 2019). However, at sub-daily scales, such one-on-one evaluations can be misleading for several reasons (Jermey and Renshaw, 2016). First, sub-daily precipitation is dominated by zero values and has a highly skewed distribution, which makes it difficult to interpret the correlation statistics. In addition, these metrics doubly penalise

55   a modelled rainfall field that is displaced in space or time: once as a missed observation, and again as a false alarm. This situation is popularly known as "double-penalty problem" (Rossa et al., 2008), and to mitigate this issue it is necessary to adopt an evaluation approach which considers likely displacements in space and time (Gilleland et al., 2009; Jermey and Renshaw, 2016; Thiemig et al., 2012). For example, when evaluating heavy rainfall events at point scale, Thiemig et al. (2012) adopted an error metric that explicitly considers possible time-lags in the gridded dataset. Similarly, Jermey and Renshaw (2016)

considered temporal displacement while evaluating the precipitation by grouping the events into seven synthetic categories with varying temporal shift and bias structure. Besides these methods which look at temporal displacement, a possible shift across space can be considered when evaluating high-resolution precipitation datasets. However, such evaluations may be limited by the availability of suitable gridded observation data for comparison, and it is thus preferable to undertake assessments using multiple evaluation techniques (Jermey and Renshaw, 2016).

The metrics used to undertake the evaluation need to match the prospective use of the dataset. For example, it may be sufficient for some urban and stormwater design problems to only evaluate the non-conditional frequency distribution of precipitation at a point. However, for most hydrological modelling purposes, it is necessary to evaluate the representation of spatio-temporal characteristics of rainfall events over the catchment of interest. The spatial and temporal resolution of the prospective applications also play a critical role in selection of the performance measures, so it is useful to assess the efficacy of the reanalysis over a range of different temporal and spatial accumulations.

The objective of this paper is to present an evaluation of sub-daily BARRA precipitation over temporal and spatial resolutions that are relevant to catchment hydrology applications. The evaluation is undertaken using ground measurements and radar-based rainfall observations across Australia over a six-year period spanning 2010-2015. Following the assessment of BARRA at daily scale (Acharya et al., 2019), this study further explores BARRA precipitation at different time accumulations ranging from hourly to daily. In addition, we compare the temporal distribution of gauged rainfalls with neighbouring grids, specifically for large rainfall events. We also employ a spatial evaluation metric (Roberts and Lean, 2008) to evaluate the ability of the reanalysis dataset to represent the spatial distribution of rainfalls against a gauge-corrected radar dataset. Overall, our aim is to assess the ability of BARRA to capture the behaviour of sub-daily precipitation at the catchment scale, particularly for large events. To this end, we use a combination of existing and bespoke metrics to evaluate performance over different temporal and spatial accumulations in different climatic zones.

2 Study area and data sources

The primary sources of reference data used to evaluate the performance of BARRA data were derived from pluviometer gauges and radar-based products. Ground-based observations are not assimilated in BARRA and thus these data serve as an independent dataset for evaluation. The pluviometer observations in this study encompass three of the broad climatic zones across Australia, namely tropical, temperate and arid (Fig. 1). Rainfall in Australia is highly variable across space and time. Rainfall is concentrated during summer in the tropical north, whereas rainfall is more prevalent during winter in the temperate south and southwest. The southeast region experiences a more consistent rainfall throughout the year. The central arid region receives the least total rainfall, and the eastern coast the highest average rainfall. The spatial evaluation across the whole of Australia is impeded by the availability of high-resolution observation-based dataset. Therefore, the spatial evaluation is undertaken by using radar-based datasets at four city-centred regions (Brisbane, Darwin, Melbourne and Sydney). These study areas are located in the tropical and temperate zones with varying rainfall climates.

Hourly rainfall observations from pluviometer gauges were obtained from the Australian Bureau of Meteorology. Observations from a total of 441 gauges were selected, covering a common period of record between 2010 and 2015 (Fig. 1). The observed rainfall is used to approximate precipitation as most precipitation in Australia is in the form of rainfall.

95   The blended radar precipitation dataset was also obtained from the Australian Bureau of Meteorology for regions surrounding the four city centres (Fig. 1). The spatial resolution of the radar data is 1.5 km, and it is only available from 2014. The radar fields have been blended with the observed rainfall using conditional merging (Sinclair and Pegram, 2005). The approach is in principle close to a copula-based approach, which exhibits less bias and yields a smaller error metric compared to non-parametric radar rainfall estimation (Hasan et al., 2016). The blended radar estimates are still likely to be erroneous and

100   biased due to reasons that include: errors in reflectivity measurement (e.g., radar beam overshoot, terrain blocking, clutter), inaccurate radar reflectivity and rain rate relationship, tendency of the radar to underestimate rainfall at distance, and quality control algorithms rejecting gauge data used for bias adjustment (Chumchean et al., 2006; Seo et al., 2010). Further, there is a fundamental difference in representativity between radar measurements and modelled precipitation, where radar infers precipitations at height over a cubic kilometre in size. However, we follow prior studies (e.g. Mittermaier et al., 2013; Roberts and

105   Lean, 2008) and use radar rainfall to compare spatial rainfall at sub-daily time steps assuming that the spatial distribution of rainfall is preserved. In addition, we apply quantile-based thresholds in order to remove the potential bias in the daily rainfall totals, although we note the strategy remains limited by the fact that the bias is spatially varying.

BARRA utilises the Unified Model (UM, Davies et al., 2005) and its 4D variational data assimilation system (4D Var). BARRA extends spatially over $65.0°$ to $196.9°$ east, $-65.0°$ to $19.4°$ north at a spatial resolution of $0.11°$ (approximately 12

110   km) and with 70 levels up to 80 km into the atmosphere. The model includes a comprehensive set of parametrisations, including a modified boundary layer scheme, mixed phase cloud microphysics, a mass flux convection scheme, and a radiation scheme. The model parameterisation in BARRA is mainly inherited from the UKMO Global Atmosphere (GA) 6.0 configurations as described in Walters et al. (2017). Observations from land surface stations, ships, buoys, aircrafts, radiosondes, and satellites are assimilated in BARRA, conducted 4 times a day with a 6-hour analysis window centred at time t_0 = 0, 6, 12 and 18

115   UTC. Surface and satellite rainfall observations are not assimilated, and the precipitation fields are determined by the modelled dynamics. In particular, they are estimated from the 12-hour (h) forecast runs of the UM from $t_0 - 3h$, using the microphysics scheme based on Wilson and Ballard (1999) and the mass flux convective parameterisation scheme of Gregory and Rowntree (1990) . The former describes the atmospheric processes that transfer water between the various states of water to remove moisture resolved on the grid scale. At 12 km horizontal resolution, BARRA requires the convection scheme to model sub-

120   grid scale convection using an ensemble of cumulus clouds as a single entraining-detraining plume (Clark et al., 2016). The scheme prevents unstable growth of cloud structures on the grid and explicit vertical circulations, and can only predict an area-average rainfall instead of a spectrum of rainfall rates. This parameterisation scheme adopted for sub-grid convection is limiting in resolving convective rainfall and affects the locations dominated by such rainfall (especially tropics). Further details on parameterisation and assimilation schemes in BARRA are provided by (Su et al., 2019).

3   Methodology

Hourly BARRA precipitation estimates at 12 km resolution are evaluated at varying spatial and temporal scales. A range of point-to-grid and grid-to-grid evaluations are undertaken using gauged rainfall and blended radar estimates over various temporal and spatial scales.

3.1   Frequency distribution of sub-daily rainfall

A point-to-grid analysis is undertaken to evaluate the sub-daily frequency distribution of BARRA precipitation. At each gauge location as shown in Fig. 1, corresponding BARRA estimates are obtained using the nearest neighbour interpolation. The basis of comparison requires some thought as the fraction of zero values in sub-daily rainfall data is high (the 95% quantiles at hourly temporal resolution are zero). This issue could be addressed by selecting suitable conditional thresholds, though different thresholds would need to be adopted for each temporal accumulation. For example, a threshold of 0.1mm/h could be adopted for hourly data and 1 mm/day for daily. However, the slight problem with this approach is that any trends in the performance metric with temporal accumulation will be confounded by the somewhat arbitrary choice of thresholds for intermediate temporal accumulations (3h, 6h, and 12h). Accordingly, we derived quantiles for sub-daily rainfalls that occurred only on the rain days for each dataset individually, where, a "rain day" is defined based on a threshold of $1\,\mathrm{mm\,d^{-1}}$ (Ebert et al., 2007).

In investigating the frequency of rainfall, we compute the various quantiles (80, 90, 95, 99%) at different time accumulations (1h, 3h, 6h, 12h and 24h). The analysis of frequencies corresponding to different accumulations (up to 24 h) is selected to be of relevance for design rainfall applications. We then estimate percentage bias using $(m-o)/o*100$, where m and o denote the reanalysis and observed precipitation corresponding to the selected quantiles. This evaluation is further stratified across three broad climatic zones (arid, tropical, and temperate) as defined by the Köppen-Geiger classification (Peel et al.,2007 ; Fig. 1). It is worth noting that comparisons of point (gauged) and areal (gridded) rainfall are generally biased as the average precipitation over a grid cell is lower than rainfall recorded at a particular point. It would also be expected that sub-daily point rainfalls are more variable than those averaged over a grid cell area.

3.2   Neighbourhood-based sub-daily patterns at point locations

A direct comparison of precipitation, especially in higher resolution datasets, is difficult as the conventional metrics are not able to penalise intensity and location errors in a desirable manner (Rossa et al., 2008). Performance metrics which compare point observations with model estimates averaged over a grid cell are heavily influenced by errors in the spatial pattern and location of rainfall events, even if the average rainfall depths over the local domain are the same. This is particularly the case with high-resolution precipitation datasets, and with the analysis of sub-daily periods.

To mitigate this problem in a gauge-based evaluation, we adopt an approach that allows for possible timing and displacement differences in rainfall occurrence. The approach is similar to the neighbourhood (or "fuzzy") approach used with single observation-neighbourhood forecasts (Ebert, 2008), in which gridded observations were evaluated against gridded forecasts.

This method accounts for situations where an event defined on the basis of gauge measurements may miss the nearby grid cell resulting in spatial error, and/or appear non-coincident at the nearby grid cell signifying a temporal error. For the former case, an evaluation that considers neighbouring grid cells can account for spatial errors. For cases involving a time displacement, a moving storm may appear at a neighbouring grid cell at the time-step under consideration, approaching towards the nearby grid cell.

To account for these different types of errors, we employ an analysis that explicitly considers the occurrence and timing of rainfalls at neighbouring grid cells. This evaluation is undertaken by selecting large rainfall events (greater than 10mm/day) in the gauge dataset. The cumulative fraction of rainfall over the day is computed for the gauge and the nearest neighbouring grid (Eq. 1). The squared difference in the fraction of cumulative rainfall occurring in each hour between the gauge and reanalysis rainfalls is then averaged to provide an error score (Eq. 2).

$$F_h = \sum_{i=1}^{h} f_i, \quad 1 \leq h \leq 24 \tag{1}$$

where, f_i is the fraction of daily rainfall occurring at ith hour.

$$errorscore = \frac{1}{23} \sum_{h=1}^{23} (F_{h,model} - F_{h,gauge})^2 \tag{2}$$

Note that 23 is used in the denominator as $F_{24,model} = F_{24,gauge} = 1$ and are not included in the computation of the error score. The temporal error is considered by using cumulative precipitation at a daily scale, which penalises large temporal errors more than small ones. Similarly, to account for possible spatial displacement, we analyse the temporal distribution of precipitation by searching over neighbourhood space to find the best performing grid cell. The error score is computed for both the nearest grid and the neighbourhood grid cells equidistant from the nearest grid. The minimum error score is selected and then averaged across all rainfall events at a location.

The average error score varies between 0 and 1. A score of 1 represents the worse possible situation in which rainfall occurs in the first hour in one dataset and the last hour in the other. Conversely, a score of 0 indicates a perfect match between observations and model estimates. Scores between 0 and 1 indicate differing degrees of temporal error, where for example, a score of 0.33 indicates that rainfall occurs in either the first or last hour in one data set and is distributed uniformly throughout the day in the other.

3.3 Neighbourhood-based spatial evaluation

Finally, a spatial evaluation of reanalysis precipitation against blended radar estimates is undertaken. For each spatial domain, the largest 25 rainfall events to have occurred over the 3-year period are selected based on domain-averaged daily precipitation. Radar precipitation, which is available as 30-minute accumulations, is aggregated to hourly to match the temporal resolution of BARRA. Similarly, a common spatial resolution is adopted. The precipitation from BARRA (~12km) is re-gridded to the

6

resolution of the radar grid (~1.5km) using area-weighted re-gridding, which means that single BARRA precipitation estimates are distributed over 8×8 radar grid cells.

Different metrics have been developed for undertaking spatially variable evaluations (Ebert, 2008, 2009). This study adopts the FSS from Roberts and Lean (2008), as it measures the variation of skill across increasing spatial scales and hence indicates the minimum spatial scale at which the model is skilful.

The FSS metric is based on the likelihood that rainfall over a given threshold occurs somewhere within the neighbouring window of grid cells. A common threshold rainfall rate is selected for both the observed and modelled grid cells. An increasing window of size $n*n$ centred on a particular grid is selected (which yields N windows over the whole domain). For each window i, a fraction of grid points exceeding the threshold in observed rainfall ($p_{o,i}$) and modelled rainfall ($p_{m,i}$) are computed. Then, the FSS is calculated as:

$$FSS = 1 - \frac{\frac{1}{N}\sum_{i=1}^{N}(p_{m,i} - p_{o,i})^2}{\frac{1}{N}\sum_{i=1}^{N}p_{m,i}^2 + \frac{1}{N}\sum_{i=1}^{N}p_{o,i}^2} \tag{3}$$

The FSS score varies between 0 and 1. A score of 0 represents a complete mismatch between two rainfall fields and a score of 1 represents a perfect match. Usually, FSS is computed for varying size of spatial windows and results are plotted as a function of window size. A random score (FSS_{random}) is the FSS that would be achieved, on average, by a random field with the same fraction of observed events (p_o) over the domain. A benchmark score, a target or 'uniform' skill ($FSS_{uniform}$), is given to a uniform field with a probability of occurrence equal to po at each grid cell (Roberts and Lean, 2008). $FSS_{uniform}$ is expressed as $0.5 + po/2$, which is halfway between a perfect score (1) and a random score ($FSS_{random} = p_o$). This $FSS_{uniform}$ can be approximated to 0.5 when p_o is small, as in the case of larger precipitation thresholds.

The thresholds used to calculate FSS are based on rainfall quantiles in observed and reanalysis data which are derived for each time step. A rainfall intensity greater than $0.2\,\mathrm{mm\,h^{-1}}$ is used as a threshold to define a rainy grid cell for which quantile-based thresholds are computed. This ensures that the model and observed rainfall fields have an identical fraction of rain events for each threshold value. The application of quantile based thresholds aims to remove the impact of any bias in rainfall amount and focus solely on spatial accuracy of modelled precipitation (Mittermaier et al., 2013; Roberts and Lean, 2008; Skok and Roberts, 2018). It is worth noting that FSS metric only provides information on variation of performance with increasing spatial scale. The timing errors at finer temporal scales can be indirectly discerned by analysing variation of FSS with time accumulations. Therefore, the FSS is evaluated at temporal aggregations of 3h and 6h.

4 Results

4.1 Frequency distribution of sub-daily rainfall

Fig. 2 illustrates the spatial distribution of quantile bias and its summary across climatic zones. Overall, the spatial distribution of bias across all time accumulations and quantiles exhibit a similar pattern. The biases in the northern region are higher and

spatially more variable than those in the southern region. The variation in bias across quantiles is the highest for hourly rainfall, especially in arid and tropical climatic zones. For the 80% quantile of hourly rainfalls, all stations in the arid and tropical zones exhibit a higher positive bias than those in the temperate zone. This difference is partly due to the tendency of BARRA to overestimate light rain events (Su et al., 2019). Despite considering wet days only in comparing quantiles, hourly rainfall at 80% quantile for arid and tropical region dominated by small precipitation amount which results in a high positive bias. At higher quantiles, the BARRA estimates are all lower than the gauged point rainfalls. This negative bias is largest in the tropical zone, followed by the arid zone. Although the nature of the high hourly bias varies with location, a step reduction in bias is observed when the accumulation time periods increase from 1 to 3 and 6 hours. This is partly due to reduced inherent bias arising from the adoption of longer temporal accumulations which reduces the potential for differences in timing between observations and model estimates.

The spatial distribution of biases associated with the different quantiles exhibits a similar pattern for all temporal accumulations considered. At shorter accumulations (up to 3 hours), the biases change from positive to negative and gradually increase in magnitude with increasing quantile. At higher accumulations (6, 12 and 24 hours), the bias is negative but decreases in magnitude with increasing quantiles. At higher quantiles (95% and 99%), the bias is the least at the temperate zone. The BARRA estimates are under-predicted at all time accumulations, but this improves with increasing temporal accumulations.

4.2 Neighbourhood-based sub-daily patterns at point locations

Figure 3 shows how the minimum error score changes with varying neighbourhood grid size. It is seen that the error score decreases significantly when a neighbourhood of 3×3 grid cells (about 35×35 km) is considered instead of a single nearest neighbour only. The error score continues to decrease slightly as the size of the neighbourhood increases, though the adoption of a larger neighbourhood increases the likelihood that rainfall events unrelated to the gauge observations are being considered. The results show that the temporal distribution of the BARRA precipitation estimates within a wet day are representative yet displaced in terms of location. The error scores are all less than 0.33, which indicates that the temporal distribution of sub-daily BARRA precipitation is on average superior to a uniform distribution of estimates derived by simply disaggregating daily rainfalls over a day.

4.3 Neighbourhood-based spatial evaluation

Fig. 4 shows the hourly precipitation rates corresponding to different quantile thresholds in the Brisbane, Darwin, Melbourne, and Sydney regions, for the largest 25 events that occurred between 2014 to 2016. The Melbourne and Sydney regions are similar than other domains in terms of the frequency distribution of hourly precipitation and the discrepancy between radar and BARRA precipitation.

Overall, the rainfall magnitude corresponding to quantiles is higher for the radar estimates than for BARRA, and this can be attributed to the difference in spatial scale and the area-weighted re-gridding scheme. The difference between the two datasets is greater at higher quantiles. However, at around 99% quantiles, the precipitation from BARRA is close to or greater than radar precipitation.

FSS is calculated for varying quantile thresholds (50, 75, 90, 95, and 99%) at different accumulations across time (1h, 3h and 6h) and presented in Fig. 5. As expected, FSS increases with increasing neighbourhood size and decreases with increasing threshold. If there is no frequency bias, then the FSS curve is expected to asymptote to 1 as the neighbourhood size is increased. In Fig. 5, the maximum FSS of 1 is not achieved even at the neighbourhood size of 300 km, which signifies a frequency bias in BARRA.

The FSS scores vary with location, where the regions in increasing order of performance are: Darwin, Brisbane, Melbourne, and Sydney. The results for hourly precipitation and 75% quantile threshold suggest that the skilful spatial scale L ($FSS > 0.5+p_o/2$) is less than 100 km for all the locations except Darwin. The skilful spatial scale for 90% and 95% quantile thresholds increases to 150 km. For the 99% quantile threshold, BARRA estimates only exhibit useful skill over spatial scales larger than around 250 km.

The FSS metric only provides information on how performance varies with increasing spatial scale. It does not account for timing errors associated with events that might be initiated at different times and/or evolve at different rates. An indication of such timing errors may be discerned by assessing how the FSS varies with increasing time accumulations. The results shown in Figure 5 indicate that FSS improves with increasing time accumulations. For example, at Darwin, BARRA is able to provide skilful estimates of 50% threshold of hourly rainfalls only at a scale of 200 km; however, at 3h and 6h accumulations, the corresponding spatial scale reduces to 125 km and 100 km, respectively. The accuracy of the BARRA estimates decreases with increasing rainfall severity, and even at the longest time accumulations, the spatial scale at which rainfalls above the 99% quantiles are skilful extends out to 300 km.

5 Discussion

To understand the performance of BARRA precipitation at sub-daily scales, a range of evaluation methods are employed to ascertain its spatial and temporal characteristics. Key insights arising from the results are discussed below.

5.1 Performance based on wet day quantiles

The unconditional evaluation of precipitation frequency in terms of wet day quantiles examines the representativeness of sub-daily climatology (Fig. 2). The minimum bias across all time accumulations and quantiles in the temperate zone suggests that BARRA provides unbiased estimates of temperate rainfalls over the observed range of events. In addition, an improved performance is observed across all regions when temporal accumulations are considered. This includes the arid and tropical zones where BARRA performs poorly at an hourly scale. A slight negative bias is observed across all locations in most of the quantiles. This underestimation is however expected due to the mismatch in spatial scale between point observations and grid average precipitation Maraun (2013). The point precipitation, in general, is expected to be higher than areal rainfall at 12 km spatial scale.

5.2 Spatio-temporal representation of rainfall

280 A potential displacement of precipitation field in space and time is expected when evaluating high-resolution precipitation datasets, especially when performance is assessed at an hourly timescale and at a point (or single grid cell) location (Rossa et al., 2008). The BARRA estimates exhibit such displacement errors, as evidenced by improved performance at neighbourhood analysis and FSS analysis. An assessment of hourly temporal patterns shows an improvement when neighbourhood grid cells are considered (Fig. 3). This suggests that when using precipitation from BARRA, users could benefit from considering spatial

285 and temporal displacement in the precipitation field, especially during large events. This further suggests an opportunity to utilise hourly distribution of rainfall for disaggregating daily totals.

At the catchment scale, the accuracy of the spatial distribution of rainfall is important for flood modelling. The evaluation of the spatial performance of BARRA against radar data for selected large events showed a mixed result between locations. BARRA rainfalls for 90% quantile at 3h accumulation achieves the target FSS at a spatial scale of range 100-140 km for all

290 domains except Darwin (250 km) (Fig. 5). Achieving useful skill only at a large spatial scale can be partly attributed to the spatial error in the precipitation fields. The higher quantile thresholds are related to small-scale features which are even more likely to be subject to spatial error. Therefore, it is difficult to achieve a skilful spatial scale for these more extreme rainfalls. This has also been pointed out by Roberts and Lean (2008) based on the skill of NWP model outputs at various quantile thresholds (75, 90, 95 and 99%). The nature of such spatial displacement errors should be considered if BARRA estimates of

295 precipitation are intended to be used for hydrological modelling.

This spatial evaluation is conducted at selected locations to take advantage of the availability of high-resolution blended radar datasets. Across the whole Australian continent there is a dearth of such high-resolution observations of precipitation, and BARRA could be relied upon to provide estimates of sub-daily precipitation at selected spatial scales in regions where there is a paucity of gauging data.

5.3 Performance dependence on spatial location

The overall performance of BARRA varies with location, and this similar trend was evident across all evaluation methods. Both the bias analysis of quantiles and the FSS evaluation show that the performance of BARRA gradually improves as we move from northern to southern regions (Figs. 2 and 5). This variation in performance can partly be attributed to the different rainfall climate in these regions. The convective precipitation during summer season is dominant at northern (low) latitudes,

305 whereas winter (or uniform) frontal rainfall are dominant at southern (high) latitudes. The poorer performance in the tropics, where convective precipitation is dominant, reflects the limitations of the parameterisation scheme to describe sub-grid scale rainfall (Su et al., 2019). This is consistent with the finding of (Ebert et al., 2007) that focuses on general performance of numerical weather prediction models. The variation in performance of sub-daily BARRA precipitation across spatial location and different climatologies is consistent with the daily evaluation performed in Acharya et al. (2019).

5.4 Performance as a function of temporal resolution

Availability of hourly rainfall observations (based on both pluviometer and radar products) enable BARRA estimates of hourly rainfalls to be evaluated. The uneven and sparse distribution of pluviometer gauges across Australia and the limited availability of radar products is not sufficient for an overall assessment of sub-daily precipitation across the whole of Australia, yet given the wide range of climatologies considered, the analyses provide a comprehensive evaluation of BARRA. Our unconditional (Fig. 2) and direct comparison (Fig. 5) both illustrate a similar dependency of performance on temporal resolution. The performance shows a significant improvement when estimates are accumulated from 1h to 3h. The increased performance for coarser temporal resolution can also be linked to the smoothing effect of rainfall at larger accumulation times and reduction of inherent bias.

The trade-off between performance and temporal resolution needs to be considered in combination with the objectives to which the precipitation estimates are used. However, in general terms the increased performance at 3 h and 6 h accumulation suggests that it is better to use these accumulations from BARRA. Given that the performance of BARRA does vary with location, it is expected that shorter (3h) accumulations may be appropriate for use in temperate locations and longer accumulations (6h) in the tropical and arid regions.

6 Conclusions

An accurate representation of spatial and sub-daily temporal characteristics of precipitation fields is important for many hydro-meteorological applications. BARRA is a regional reanalysis dataset that provides long-term high-resolution estimates of atmospheric variables over the Australian continent. In this study, the spatio-temporal characteristics of sub-daily BARRA precipitation estimates are assessed using various metrics to evaluate its performance at various spatial and temporal scales. Based on the results, we conclude:

1. Sub-daily precipitation from BARRA exhibits negative bias at higher quantiles. The magnitude of bias varies with event severity and temporal accumulation.

2. There is some tendency for BARRA reanalysis precipitation to exhibit spatial displacement, and this is more pronounced for rainfall corresponding to higher quantiles.

3. The performance of BARRA precipitation depends on spatial location with poorer performance in tropical relative to temperate regions. These spatial trends are consistent across evaluations undertaken using both gauged point rainfalls and blended radar observations.

4. Bias in BARRA precipitation quantiles at point scale and spatial displacement errors at spatial scale decrease with increasing time aggregation and the performance is reasonably skilful at most of the locations for temporal accumulations of 3h and greater.

11

340   One of the limitations of this study is that the spatial assessment of BARRA is restricted to a few locations where radar-based datasets are available and the performance of BARRA across Australia is generalised based on evaluation at those locations. Currently, the lack of high-quality and high-resolution benchmark datasets limits our ability to fully understand the performance of BARRA across the entire continent. However, a more detailed spatial assessment of BARRA would be possible once such benchmark datasets are available.

345   A natural interest of the users of BARRA is the potential application of the data in hydro-meteorology. Information on sub-daily rainfalls across the Australian continent is limited due to sparse gauge measurements, the availability of radar at only few locations, spatially coarser global reanalysis products, and few satellite products (~25km, going back to only 1998). BARRA stands out as one of few available datasets at hourly temporal resolution. In that respect, it serves as a useful dataset for the applications requiring sub-daily precipitation. Further, it can be used to help characterise rainfall behaviour in regions
350   where gauges are sparse or non-existent. One of the potential applications of BARRA is for deriving probabilistic design rainfall events for engineering applications, which utilise information on the relationship between rainfall magnitude and its exceedance probability either at a point or over an area. Such applications are probabilistic in nature and are less sensitive to spatial and temporal errors of the individual events. For applications in flood modelling, where the spatial and temporal distribution of precipitation is important, a proper account needs to be given to the likely spatio-temporal displacement errors
355   in the BARRA precipitation.

    The strength of BARRA dataset is that it provides estimates of sub-daily areal rainfall which can be used across diverse hydrological applications that require such estimates. In addition to providing absolute estimates of precipitation, BARRA would also appear well suited to providing information on sub-daily patterns of areal rainfalls which can be used as a means of disaggregating daily rainfalls obtained from more reliable sources. The extent to which such estimates might provide a better
360   representation of areal sub-daily rainfall for design and hydrological modelling warrants further investigation.
