Abstract. The US and Canada have entered negotiations to modernize the Columbia River Treaty, signed in 1961. Key priorities are balancing flood risk, hydropower production, and improving aquatic ecosystem function while incorporating projected effects of climate change. In support of the US effort, Chegwidden et al. (2017) developed a large-ensemble dataset of past and future daily streamflows at 396 sites throughout the Columbia River Basin (CRB) and select other watersheds in western Washington and Oregon, using state-of-the art climate and hydrologic models. In this study, we use that dataset to present new analyses of the effects of future climate change on flooding using water year maximum daily streamflows. For each simulation, flood statistics are estimated from Generalized Extreme Value distributions fit to simulated water year maximum daily streamflows for 50-year windows of the past (1950-1999) and future (2050-2099) periods. Our results contrast with previous findings: we find that the vast majority of locations in the CRB are estimated to experience an increase in future streamflow magnitudes. The near-ubiquity of increases is all the more remarkable in that our approach explores a larger set of methodological variation than previous studies; however, like previous studies, our modeling system was not calibrated to minimize error in maximum daily streamflow, and may be affected by unquantifiable errors. We show that on the Columbia and Willamette rivers, increases in streamflow magnitudes are smallest downstream and grow larger moving upstream. For the Snake River, however, the pattern is reversed, with increases in streamflow magnitudes growing larger moving downstream to the confluence with the Salmon River tributary, and then abruptly dropping. We decompose the variation in results attributable to variability in climate and hydrologic factors across the ensemble, finding that climate contributes more variation in larger basins while hydrologic contributes more in smaller basins. Equally important for practical applications like flood control rule

28 curves, the seasonal timing of flooding shifts dramatically on some rivers (e.g., on the Snake, 20th century floods
29 occur exclusively in late spring, but by the end of the 21st century some floods occur as early as December) and
30 not at all on others (e.g. the Willamette).
31

32 **1 Introduction**

33 Among natural disasters in the Northwest, flooding ranks second behind fire in federal disaster declarations¹ since
34 1953 despite extensive flood prevention infrastructure. The largest flood in modern times on the Columbia
35 occurred in late spring (May-June) 1948, and obliterated the town of Vanport which lay on an island between
36 Portland, OR and Vancouver, WA, permanently displacing its 18,500 residents². Other disruptive floods in the
37 region include the Heppner flood in 1903, one of the deadliest flash floods in US history (Byrd, 2014); floods on
38 the Chehalis River in both December 2007³ and January 2009⁴ that closed Interstate 5, the main north-south
39 transportation corridor through the Northwest, for several days each time at a cost of several \$m per day to freight
40 movement alone; and floods on the Willamette River in February 1996 and April 2019. The timing of typical
41 floods varies widely across the region: low-elevation basins in western Washington and Oregon typically flood
42 in November through February, whereas the snow-dominant basins east of the Cascades more typically flood in
43 spring, sometimes as late as June (Berghuis et al. 2016).
44

45 The Columbia River drains much of the Northwest, with the fourth largest annual streamflow volume in the US
46 and a drainage that includes portions of seven states plus the Canadian province of British Columbia (BC), an
47 area of 668,000 km² (Fig. 1). Its numerous federal and nonfederal dams provide flood protection, hydropower
48 production, navigation, irrigation, and recreation services. A treaty between the US and Canada, signed in 1961,
49 codified joint management of the river's reservoirs (and funded construction of new reservoirs in BC) primarily
50 to provide flood protection and hydropower production⁵. The US and Canada have entered negotiations to update

51 the treaty; the USA's "key objectives include continued, careful management of flood risk; ensuring a reliable
52 and economical power supply; and improving the ecosystem in a modernized Treaty regime." (*ibid.*) Both
53 countries have expressed an intention to include the effects of climate change on streamflows, and clearly a key
54 aspect of hydrologic change is to inform the treaty negotiations of the influence of climate change on the
55 magnitude of flooding.

56
57 While rising temperatures potentially affect all parts of the hydrologic cycle, in a snowmelt-dominated hydrologic
58 system such as many of the Northwest's river basins, warming directly affects snow accumulation and melt (e.g.,
59 Hamlet et al. 2005). Observational studies have shown consistent changes toward lower spring snowpack (Mote
60 et al. 2018), earlier spring streamflow (Stewart et al. 2005), and lower summer streamflow (Fritze et al. 2011)
61 since the mid-20th century. Observations of trends in flooding in the US have generally failed to find any
62 consistent trends (Lins and Slack 1999; Douglass et al. 2000; Sharma et al. 2018). Sharma et al. (2018) offer
63 several possible explanations, chiefly "decreases in antecedent soil moisture, decreasing storm extent, and
64 decreases in snowmelt". The detection of trends in floods is complicated by the interaction of extreme events and
65 nonstationarity (Serinaldi and Kilsby, 2015). Moreover, as a result of the substantial alteration of rivers to prevent
66 flooding (e.g., by the construction of dams and levees) during the observational period, the best long-term records
67 - i.e., on streams with the least modifications - are on rivers that were not producing sufficiently disruptive floods
68 to lead decision-makers to construct flood protection structures. That is, as flooding of settlements, infrastructure,
69 or other assets led to the investments in flood protection structures on most rivers, thereby altering the streamflow
70 regime and dividing any gauged records into pre- and post- modification, the ones that were left unmodified
71 tended to be small and/or remote.

72
73 To interpret the ambiguous results from observed trends, Hamlet and Lettenmaier (2007) used the Variable
74 Infiltration Capacity (VIC) hydrologic model forced twice with detrended observed daily weather for the period
75 1916-2003, with about 1°C of temperature difference between the two. They then compared 20- and 100-year
76 flood quantiles for basins at varying sizes in the western US and found a wide range of changes in flood magnitude
77 ranging from large decreases to large increases (+/- 30%). Broadly, the responses depended somewhat on basin
78 winter temperature, with the coldest basins (<-6°C) showing reductions in flood magnitude owing to reduced
79 snowpack, basins with moderate temperatures exhibiting a wide range of changes, and rain-dominant (>5°C)
80 basins showing little change, though the warm basins in coastal areas of Washington, Oregon, and California
81 showed increased flood magnitude.

82

83 Modeling work using state-of-the-art hydrologic models has been applied to understand where and how flood
84 magnitudes may change in the future. Tohver et al (2014) found widespread increases in flood magnitudes,
85 especially in temperature-sensitive basins (mainly on the west side of the Cascades), but their approach used
86 monthly GCM output so changes in daily precipitation would not be represented. Salathé et al. (2014) used a
87 single global climate model (GCM), the ECHAM5, linked to a regional climate model to obtain high-resolution
88 (in space and time) driving data for VIC over the period 1970-2069. As did Hamlet and Lettenmaier (2007), they
89 compared the ratio of flood change (2050s vs 1980s) against mean historical winter temperature and found a
90 majority of locations with a higher 100-year flood, in some cases by a factor of 2 or more; while they projected
91 increases in every one of the warmer basins ($>0^{\circ}\text{C}$), a substantial fraction of colder locations had decreases in
92 flood magnitude.

93

94 Chegwiddden et al. (2019) describe the process used to generate the streamflow ensemble used here. In addition,
95 they used analysis of variance (ANOVA) to analyze the different influences of choices of emissions scenario (as
96 a Representative Concentration Pathway - RCP), GCM, internal (unforced) climate variability, downscaling
97 method, and hydrologic model, and how those influences varied spatially across the domain and also seasonally
98 and by hydrologic variable. They found that the RCP and GCM had the largest influence on the range of annual
99 streamflow volume and timing, and hydrologic model had the largest influence on low streamflows. The
100 hydrologic variables they considered were snowpack (maximum snow water equivalent and date of maximum
101 SWE), annual streamflow volume, centroid timing (the date at which half the water year's streamflow has passed),
102 and seasonal streamflow volume; primary focus was on centroid timing, annual volume, and minimum 7-day
103 streamflow. They did not examine high-flow extremes that can lead to flooding. The purpose of this paper is to
104 address this important gap in our understanding of the future Northwest hydrology; to do so, we use the largest
105 available ensemble of climate-hydrology scenarios. By using a large ensemble, we ensure a reasonable breadth of
106 climatic and hydrological futures in order to better describe the range of possible future flooding and how it varies
107 across the region with its diverse hydroclimates. We also note possible shortcomings associated with modeling
108 future flooding.

109 **2 Methods**

110 **2.1 Hydrologic modeling data set**

111 To assess changing flood magnitudes under climate change, we analyzed changes in water year maximum daily
112 streamflows in a large ensemble of streamflow simulations at 396 locations in the CRB (Figure 1) and select
113 watersheds in western Oregon and Washington (Chegwidden et al., 2017). The simulations were constructed from
114 permutations of modeling decisions on forcing datasets and hydrologic modeling. Specifically, choices included
115 two RCPs (RCP4.5 and RCP8.5), ten GCMs, two methods of downscaling the climate model output to the
116 resolution of the hydrologic models, and four hydrologic model implementations, for a total of 160 permutations.
117 For our analysis, we extracted a more tractable dataset of 40 simulations per location, by only considering
118 simulations with RCP 8.5 and the Multivariate Adaptive Constructed Analogs (MACA) downscaling method
119 (Abatzoglou and Brown, 2012).

120

121 The rationale for using a subset of the available data is as follows. First, the time-dependent set of greenhouse gas
122 concentrations in RCP4.5 is fully included in RCP8.5, so any concentration of greenhouse gases on the RCP4.5
123 path can be converted to a point on RCP8.5 (at a different time). We analyzed results for both RCP8.5 and RCP4.5,
124 and found that to first order the changes in flood magnitude in RCP4.5 were approximately 2/3 those in RCP8.5,
125 which is also roughly the ratio of global temperature change over the period considered (IPCC Summary for
126 Policymakers, 2014). For clarity we show only the results for RCP8.5. Second, we considered only simulations
127 using the MACA downscaling method because of the method's ability to capture the daily GCM-simulated
128 meteorology critical for assessing changes in extremes and its skill in topographically complex regions (Lute et
129 al., 2015). The other downscaling approach used by Chegwidden et al. (2019), the Bias Correction and Statistical
130 Downscaling (BCSD) method (Wood et al. 2004), produces probability distributions of daily precipitation
131 inconsistent with the GCM response to forcings because the method stochastically disaggregates monthly data to
132 daily data based on historical statistical properties of the daily data. This statistical property limits the ability of
133 BCSD to reproduce changes in storm frequency in the future, making it a less attractive choice for daily extreme
134 streamflow analysis (Hamlet et al. 2010; Guttman et al. 2014).

135

136 Model output used in this study came from the following ten GCMs: CanESM2, CCSM4, CNRM-CM5, CSIRO-
137 Mk3-6-0, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, Inmcm4, IPSL-CM5A-MR, and MIROC5. These ten
138 GCMs were chosen primarily for their ability to accurately reproduce observed climate metrics during the

139 historical period mainly of the Northwest US but also at sub-continental and larger scales as assessed in Rupp et
140 al. (2013) and RMJOC (2018). The four hydrologic model implementations originated from two distinct
141 hydrologic models: the Variable Infiltration Capacity (VIC; Liang et al., 1994) model and the Precipitation Runoff
142 Modeling System (PRMS; Leavesley et al., 1983). VIC and PRMS are process-based, energy balance models and
143 were both run on the same 1/16th degree grid with output saved at a daily time step for the period 1950 to 2099.
144 VIC is a macroscale semi-distributed hydrologic model that solves full water and energy balances, and in these
145 simulations it also included a glacier model (Hamman & Nijssen, 2015). Three unique implementations of VIC
146 were used with independently derived parameter sets (P1, P2, P3) marked by differences in calibrated parameters,
147 calibration methodology, and meteorological and streamflow reference sets. PRMS is a distributed, deterministic
148 hydrologic model which, in contrast to VIC, does not allow for subgrid heterogeneity; see Chegwidden et al
149 (2019) for details. It is important to note that these hydrologic simulations and calibrations do not include reservoir
150 models and have not been calibrated for daily, let alone maximum daily, flows, and these shortcomings may affect
151 the results.

152 **2.2 Flood magnitude**

153 We assessed changes in flood magnitude in the Columbia River Basin by comparing water year maximum daily
154 streamflows over a 150-year period (1950-2100). We estimated the 10, 5, 2, and 1% probability of occurrence
155 (commonly referred to as the 10-, 20-, 50-, and 100-year flood, respectively) by fitting generalized extreme value
156 (GEV) probability distributions to simulated water year maximum daily streamflows for 50-year windows of the
157 past (1950-1999) and future (2050-2099) periods; see Figure 2 for an example. (We also looked at 30- and 75-
158 year windows, choosing 50 years as a balance between sample size favoring longer periods, and nonstationarity
159 considerations favoring shorter periods.) We used Python's `scipy.stats.genextreme` module (Jones et al., 2001) to
160 fit a Gumbel distribution and estimate flood magnitudes for each return period. We assessed change in flood
161 magnitude as the "discharge ratio" of the estimated future to past floods for a given return period; a ratio greater
162 than 1 indicates an increase in flood magnitudes while a ratio less than 1 indicates a decrease.

163

164 We describe how changes in flood magnitude vary by climatic zone across the PNW by using an efficient and
165 internally consistent proxy for climatic zone: the centroid of timing – the day in the water year that half the annual
166 volume of water has passed the stream location. The centroid of timing is a metric of snow dominance (e.g.,
167 Stewart et al. 2005) which is related to the spatial distribution of temperature and tends to decrease downstream.
168 This temporal proxy of a hydrologic characteristic is effective in the Columbia Basin where most of the

169 precipitation occurs in winter and the relative magnitude and timing of the freshet from the spring thaw is a good
170 indicator of importance of snowmelt to streamflow. An early centroid indicates that rain, which falls
171 predominantly during the cooler, earlier part of the year, is the driver of the peak streamflows at the location,
172 while a late centroid indicates that snowmelt during later spring months is the prime hydrological driver. We
173 computed the centroid using the 1950-79 simulated years. Note that Chegwiddden et al. (2019) also used the *change*
174 in centroid as a hydrologic variable of interest; below, we discuss our results in the context of their findings.

175

176 **2.3 Model evaluation**

177 Comparing directly between gauged flows and modeled flows is inadvisable since the observed streamflows are
178 substantially altered by regulation, which is not accounted for in the hydrological model. However, a set of
179 streamflows called No Reservoirs No Irrigation (NRNI; RMJOC 2017) has been developed by federal agencies
180 to support practical analysis. The NRNI dataset exists at ~190 sites across the Columbia River Basin for the years
181 1928-2008, and streamflows are adjusted to correct for reservoir management and the diversions and evaporation
182 associated with both the reservoirs and with irrigated agriculture. This dataset is suitable for comparisons with
183 our modeling setup, and we have computed return period curves using GEV fits at all the NRNI locations (not
184 shown) for the period common to both NRNI and our ensemble, viz., 1950-2008. From these fits we have
185 estimated the 10-year and 100-year values (Figure 3). On the lower mainstem Columbia (Figs 3a and d), the return
186 period curves are very close to those computed from NRNI and the means of simulations are almost all within 8%
187 of the NRNI values. Individual hydrologic model configurations are not consistently biased across the basin nor
188 across return periods; despite its different provenance, PRMS generally lies within the return period streamflows
189 of the three VIC configurations rather than being consistently different from all VIC configurations, although the
190 lowest values are from PRMS. On the Snake River, the mean of modeled high streamflows range from 5% above
191 NRNI at Little Goose to 24% above at Oxbow for 10-year floods (and 14% to 41% for 100-year) but again no
192 hydrologic model stands out as strongly biased. On the Willamette, however, the modeled 10-year and 100-year
193 flood magnitudes lie almost entirely below NRNI and the means are too low by from 30% (T. W. Sullivan, 10-
194 year) to 50% (Hills Creek, 100-year). PRMS and the P2 calibration of VIC are consistently closer to NRNI on the
195 Willamette. In general, the simulated flood statistics are least biased on larger river reaches where the hydrographs
196 are less flashy. For the Columbia mainstem, modeled extreme high streamflows agree well with the NRNI dataset.

197

198 We also examined the ensemble performance for 1950-2008 in the distribution of timing of peak daily streamflow
199 for 28 locations along the Columbia, Snake, and Willamette (a subset is shown in Figure 4). At all locations we

200 examined, the median date (as well as earliest and latest quartiles) of annual maximum daily streamflow in the
201 ensemble is within 10 days of the observed, from NRNI. The modeled distribution is shifted slightly later than
202 NRNI on the lower Columbia and slightly earlier than NRNI on the Willamette. As with magnitudes, the
203 agreement in timing suggests a robust modeling set-up since the comparison tests the ability of the combined
204 climate-hydrologic modeling system to match observed, constrained only by the broad physics of the climate
205 system and by meteorological bias correction (which cannot substantially change the timing of the day of the year
206 most conducive to high streamflows). Although the modeled streamflows are calibrated, the statistical approach
207 to calibrations is not sensitive to the extreme maximum daily streamflow studied here.

208

209 It is worth stressing that these results compare outputs of hydrologic models in which the inputs are simulated
210 daily weather (which is then bias-corrected) rather than observed daily weather, and that the hydrologic models
211 are calibrated to 7-day means rather than the daily values relevant here. In other words, we are evaluating the
212 ability of the *combination* of simulations of weather and hydrologic response. The weaknesses evident in Figure
213 4 pose a note of caution in interpreting our results, but a full diagnosis of the causes of the shortcomings (especially
214 on the Willamette) is beyond the scope of this paper, as is the evaluation of our modeling system's performance
215 at other locations besides these rivers.

216 **3 Results**

217 **3.1 Regional changes in flood ratio**

218 Figure 5 shows the changes in maximum daily discharge for all of the 396 streamflow locations for different
219 return periods. The horizontal position of each circle represents the centroid of timing. The circles are semi-opaque
220 so overlapping circles lead to a deeper saturation. Points on the same river are ordered from more to less snow
221 dominant (i.e., right to left) traveling downstream; strings of circles in a smooth pattern usually indicate one of
222 the larger rivers, highlighted in Figure 6. Each circle in Figures 5 and 6 represents an average of 40 simulations:
223 10 GCMs and 4 hydrologic model configurations.

224

225 A striking result in Figure 5 is that, in contrast to the results of Tohver et al. (2014), the flood magnitude increases
226 (i.e., the discharge ratio exceeds one) at nearly every streamflow location and return period (though not for every
227 individual climate scenario, as shown in Figure 7). Broadly, the patterns are similar across all return periods
228 though with slightly higher ratios for longer return periods, and subsequent figures will show only the 10- and

229 100-year floods. For the streamflow locations with centroid <125 or so (i.e. February 2), flood ratios are fairly
230 concentrated about 1.25 for all return periods. For mixed rain-snow basins, roughly delineated by centroids
231 between 125 and 160 (March 8 most years), flood ratios range widely from just below 1 to about 2.4 for the 10-
232 year and 3.2 for 50- and 100-year floods. For the longer return intervals, there is a wide range of projected changes
233 in daily flood at many locations (indicated by the red coloring). This is undoubtedly partly due to the GEV fit
234 extrapolating from 50 to 100 years. Finally, for the basins with streamflow centroid >160, the ratios have a smaller
235 range, from slightly greater than 1 to a maximum that increases from about 2 for the 10-year, to about 2.75 for
236 100-year. Tohver et al. (2014) distinguished basins by their DJF temperature, a rough proxy for our snow
237 dominance metric, and found a substantial number of locations where the flood ratio for both 20-year and 100-
238 year flood was as much as 20% lower for the 2040s compared with a historical period. We return to this point in
239 the conclusions.

240
241 To understand better how flood magnitude changes along the length of a river, we focus (Figure 6) on a handful
242 of significant rivers in the region: the mainstem Columbia, Willamette (along with major tributaries the McKenzie
243 and Middle Fork Willamette), and Snake, and also on the Chehalis in southwest Washington (see Introduction).
244 Flow locations and select numerical results are listed in Table 1. Many of the larger tributaries also have
245 streamflow points in our dataset, so we can infer the role of tributaries in changing the flood magnitudes in the
246 future, as discussed below. The Columbia River includes the most snow-dominant basins, with a centroid of >190
247 days (early to mid April) in the Canadian portion of the basin. The flood ratio decreases almost uniformly along
248 the length of the river, from 1.3 for the 10-year and >1.5 for the 100-year in the Canadian portion to just above 1
249 at the last few points along the river (The Dalles, Bonneville, and Portland). Past flood events on the mainstem
250 Columbia are exclusively associated with large spring snowmelt, and the large tributaries (the Yakima, Snake,
251 and Willamette) contribute annual streamflow volume but rarely contribute peak streamflow at the same time; as
252 shown below, the future flood timing changes but flood magnitudes change little in the lower Columbia owing to
253 the fact that the Columbia integrates such diverse hydroclimates. Like the Columbia, the Willamette also has
254 flood ratios that decrease along the length of the river as it integrates more diverse hydroclimates, from 1.7 to 1.35
255 for both return periods. The McKenzie River (points 15-17), one of the three tributaries that converge at Eugene
256 to form the Willamette, is a highly spring-fed river with higher baseflow than is represented in the hydrologic
257 models, though it is unclear how that difference would manifest in the flood statistics. Nonetheless, the
258 combination of an important unrepresented process and the large errors in flood magnitudes relative to NRNI
259 (Figure 3) are potentially problematic for simulating future changes in flooding.

260

261 In contrast to the Columbia and the Willamette, the Snake behaves oppositely: flood ratio increases downstream
262 along the length of the river, until the confluence with the Salmon River, which drains a large mountainous area
263 of central Idaho. On parts of the Snake the ratios are as high as 1.4 for 10-year and 1.6 for 100-year. Then after
264 the confluence with the Salmon River, which has much lower change in discharge ratio, the ratios on the Snake
265 drop to about 1.2 for 10-year and about 1.3 for the 100-year. Our hypothesis is that in the Snake above the Salmon
266 River, the tributaries shift from snow-dominant to rain-dominant, so that a single storm can drive large rainfall-
267 driven increases (possibly with a snowmelt component) leading to larger synchronous discharges. The Salmon
268 and Clearwater rivers retain less exposure to such shifts, and dilute the effects of single large storms on flooding.
269

270 Each circle in Figures 5 and 6 represents an average of 40 simulations: 10 GCMs and 4 hydrologic model
271 configurations. To better understand the range in results, Figure 7 shows the discharge ratio for all 40 simulations
272 at each point on the mainstem Columbia. Although the mean flood ratio at the lowest two points is only barely
273 above 1, several ensemble members have ratios less than one, and a few have ratios >1.5 . Moving upstream, the
274 range in results increases, as shown also by the color of the dots.

275 **3.2 Dependence of results on modeling choices**

276 As in Chegwiddden et al (2019), we separate the results - here for the three largest rivers - into variations across
277 GCM (Figure 8) and variations across hydrologic model configurations (Figure 9). The ranking of flood ratios by
278 GCM changes substantially between basins and even within a basin, and does not correspond to the changes in
279 seasonal precipitation. For the upper Columbia River, the models with the least warming - inmcm4 and GFDL-
280 ESM2M (Rupp et al 2017) - have almost no change in flood magnitude, but the HadGEM2-ES which warms
281 considerably in summer produces a large decrease in flood magnitude. In the Willamette and Snake Rivers, the
282 range of projected flood changes by different GCMs remains large from the headwaters to the mouth of the river,
283 whereas for the Columbia the range diminishes considerably as one moves downriver.

284

285 The variation of results depends less on hydrologic model than on GCM (Figure 9), though the differences across
286 hydrological models are still substantial. For the Willamette, lower Snake, and both upper and lower Columbia,
287 the PRMS model predicts substantially larger increases in flooding than the three calibrations of the VIC model.
288 For the upper Snake, it predicts substantially smaller change than any VIC calibration. While it is perhaps not
289 surprising that the three calibrations of VIC are close to each other, it is striking just how different are the

290 projections from PRMS at most locations on these three rivers. Chegwidden et al. (2019) found that the main
291 contributors to differences in hydrologic variables (except low streamflows) generally were the climate scenarios
292 (GCM and RCP), consistent with our findings here. (The order of models is similar in the equivalent figure for
293 the 100-year return period, but we elected to show the 10-year figure since the 100-year figure is more difficult
294 to decipher because the symbols overlap with those from other rivers.)

295

296 To parse the contributions of climate factors (represented by the GCMs) and hydrologic factors (represented by
297 the hydrologic models), we perform ANOVA on the 40 discharge ratios. The pie charts in Figure 10 show the
298 proportion of the total variance explained by climate factors and hydrologic factors at different locations. For the
299 Willamette River, the portion of uncertainty connected to the climate grows more important and the portion of
300 uncertainty connected to the hydrologic variability less important going from the confluence of the three major
301 tributaries at Eugene to the mouth. For the Snake and Columbia rivers, climate is responsible for virtually all of
302 the variance in projections in the upper reaches, but only about half at the lowest point, similar to the Willamette.
303 The Willamette basin is much smaller, and a large storm can affect the entire basin on the same day (Parker and
304 Abatzoglou, 2016), whereas storms typically take a couple of days to move across the Snake and Columbia (and
305 generally move upstream). With larger and more diverse contributing areas, differences in the rates with which
306 the hydrological models transfer precipitation to the point of interest become more important. Unlike Chegwidden
307 et al. (2019), we did not attempt to isolate the response to anthropogenic forcing from internal climate
308 variability. Though several techniques for separating these two factors have been used (e.g., Hawkins and Sutton,
309 2009; Rupp et al., 2017; Chegwidden et al., 2019), these techniques are either infeasible with our dataset or we
310 question their suitability for the application to changes in extreme river flows.

311

312 **3.3 Change in timing**

313 Although in a broad hydrologic sense a flood is a flood regardless of what time of year it occurs, there are
314 potentially significant ecological differences depending on time of year; for example, scouring the river bottom
315 causing significant loss of salmon eggs (Goode et al. 2013). Moreover, water management policies are strongly
316 linked to the calendar year (see Discussion). We computed the probability of flooding for (all 40) past and future
317 simulations at all the points on the three rivers (Figure 6) as a function of day of year (Figure 11). For the
318 Willamette, no significant change in timing occurs; however, for the upper Willamette, a single peak in likelihood
319 in February becomes more diffuse. For the Snake, all locations see a shift toward earlier floods, consistent with

320 the transition to less snow-dominant and more rain-dominant. Whereas floods were historically concentrated in
321 the period of mid-May to mid-July, the projected future flooding period spans December to June. For the
322 Columbia, the mode in the flood timing shifts earlier by half a month in the upper Columbia to about a month in
323 the lower Columbia. The distribution also broadens with an elongated tail towards winter such that there is low,
324 but non-negligible, probability of floods occurring as early as January. The magnitudes of the 10- and 100-year
325 flood events in the lower Columbia are not projected to increase substantially (Figures 6-9). However, the window
326 during which a major flood could occur expands, with the likelihood of major flooding in May or April (or even
327 as early as February) increasing.

328 **4 Discussion and conclusions**

329 Our study joins a small number of others in examining high-flow extremes using a large hydroclimate ensemble.
330 Gangrade et al. (2020) used a similar ensemble approach analyzing hydrological projections for the Alabama-
331 Coosa-Tallapoosa River Basin with 11 dynamically downscaled and bias corrected GCMs (10 of which our
332 studies share) and 3 hydrologic models (including VIC and PRMS). While they did not examine extreme daily
333 streamflows, they did calculate changes in the 95th percentile of daily streamflow (Q95). Perhaps because of the
334 hydroclimatic uniformity of that basin, they found very small differences in Q95 across hydrologic models, which
335 contrasts with our results showing changes in flood magnitudes varying by watershed and distance downstream.
336 Thober et al. (2018) conducted a similar study in some European river basins, but rather than using a climate
337 ensemble they simply imposed uniform warming scenarios on a hydrologic model (i.e. a more straightforward
338 temperature sensitivity analysis rather than an exploration of the range of future climate scenarios). Other, smaller
339 ensemble studies of floods in different basins include Huang et al. (2018), with 4 GCMs and 3 hydrology models,
340 and Vormoor et al (2015) with several parameterizations of one hydrology model.

341
342 Returning to the Northwest, our findings contrast with earlier work. Salathe et al. (2014) found decreases in flood
343 magnitude at a substantial number of sites, but our results show increases in flood magnitude at nearly every
344 return period and location, which includes about 100 locations not included in their study. They also noted that
345 directly downscaling the GCM outputs leads to a smaller range of results than when running the regional model
346 as an intermediate step, so we infer that if we had had access to RCM simulations driven by all 20 of our RCP-
347 GCM combinations, our range of results might have been larger. Another important difference may be in the
348 spatiotemporal coherence of extreme precipitation, which in the RCM would be generated directly by the

349 interaction of synoptic-scale storms, topography, and to a small extent by surface water and energy balance; and
350 in our study, by the interaction of the GCM-scale synoptic storms and constructed analogs derived from
351 observations. A large ensemble would reduce the magnitude of that effect. In our study, the MACA statistical
352 downscaling approach preserves much of the daily variability from the GCM, so the primary reason for the
353 difference between our results and theirs is probably the fact that we analyzed 40 scenarios. Some locations, for
354 example the points on the lower Columbia river, had a handful of ensemble members with decreasing flood
355 magnitude. But averaging the entire ensemble nearly always resulted in an increase in flood magnitude. It is
356 possible therefore that their study, repeated with a larger ensemble of hydrologic-climate model combinations,
357 might have found ubiquitous increases in flood magnitude as ours did.

358
359 Prior results (Hamlet and Lettenmaier 2007, Tohver et al. 2014, Salathe et al. 2014) suggested a decrease in flood
360 magnitude in snowmelt-dominated basins like the Columbia, since reduced snowpack reduces the store of water
361 available to be released quickly in a spring flood (like the May-June 1948 Vanport flood). In a subbasin of the
362 Willamette, Surfleet and Tullos (2013) projected decreases in flood magnitude for return periods > 10 years in the
363 Santiam River basin under a high-emissions scenario (SRES A1B, 2070-2099 vs. 1960-2010; 8 GCMs),
364 attributing the decreases to fewer large rain-on-snow events. Our results for the Santiam River show an *increase*
365 of 40% for both 10- and 100-year floods; this result includes rain-on-snow events, since they are represented in
366 VIC, which computes the accumulation of water in the snowpack and determines whether sufficient energy has
367 been provided to create a melt event. Our results point to ubiquitous increases in magnitude throughout the basin,
368 even on the lower mainstem Columbia. We also project some large increases in flood magnitude in the coldest
369 basins, including the headwaters of the Columbia, suggesting that the former results were missing some key
370 details. It seems likely that any reduction in flood magnitude originating from the warming-induced reduction in
371 spring snowpack is offset by other factors. While there is evidence that warmer future temperatures could
372 engender slower melt rates (Musselman et al. 2017), the effect on high streamflow events is less clear. For
373 example, Chegwiddden et al (2020) showed that magnitudes of both rain- and snowmelt-driven floods are likely
374 to increase across headwater basins in the Pacific Northwest through the 21st century. These results emphasize
375 the necessity of revisiting reservoir rule curves, which are strongly tied to historical hydrographs, and also
376 emphasize that changes in the seasonality of flooding can be dramatically different from the changes in the mean
377 hydrograph. In particular, in the lower Snake and lower Columbia, changes in magnitude of flooding are modest
378 but changes in timing of the earliest quartile of flood events is much larger than the 0.5-1 month shift in the mean
379 hydrograph.

380

381 The evaluation of the modeling system in section 2.3 raises some concerns about the reliability of our results,
382 especially as to flood magnitude on the Willamette mainstem, and also in smaller basins where we have not
383 performed an evaluation. While this is a concern in an absolute sense, in a relative sense our results are probably
384 more robust than those of earlier studies in the Northwest, for several reasons. First, previous studies have rarely
385 provided the sort of evaluation of flood statistics that we show in section 2.3. Second, we used more
386 methodological variations, which tend to broaden, not narrow, the spread of results, and yet we still obtained a
387 narrowing of the spread of results to almost ubiquitous increases. Third, our use of a large ensemble samples a
388 wide climate space by using GCMs as opposed to RCMs. Conventional wisdom and evidence from the weather
389 and seasonal climate forecasting realms illustrate the utility of considering ensembles, and that generally the true
390 outcome of a prediction lies near the middle of the ensemble. Our ANOVA analysis (Figure 10) shows that climate
391 scenarios contribute a majority of the variation among results for most of the basin. Consequently, it is of great
392 importance to sample the climate scenarios broadly, which currently only GCMs can do. Large ensembles of
393 RCMs are rare; the 12-member NARCCAP ensemble (6 RCMs, 4 GCMs; Mearns et al. 2013), some of whose
394 model runs were completed a decade ago, remains the largest, but has a spatial resolution of only 50km. CORDEX
395 North America, similarly now has a comparable-size ensemble, but mostly still at 50 km (some at 0.22°), and was
396 not available in such large numbers when we began our hydrologic simulations. At such spatial resolutions, RCMs
397 would still have to be further downscaled and bias corrected to use in our hydrologic models (~6km spatial
398 resolution). In the tradeoff between breadth of climate scenarios and spatial resolution, these ensembles offer
399 insufficient improvement in spatial resolution relative to our GCM ensemble to justify sacrificing the breadth in
400 climate scenarios represented by choosing just 4 GCMs. While RCMs certainly have their place in such work and
401 were used in some previous studies, using GCMs in this study allowed for a larger climate space to be sampled,
402 thus adding to the robustness of our results.

403

404

405 Although the likeliest outcome, as shown in Figure 7, is for smaller changes in flood magnitude in the lower
406 Columbia than elsewhere, a prudent risk management strategy would consider the range of possibilities. The
407 validation (Figures 3 and 4) provides no *a priori* basis for excluding or under-weighting the projections from any
408 hydrologic model. On the Willamette, a rain-dominant basin, our hydrologic simulations of flood magnitudes are
409 biased low; possible causes for the low bias originate both in the climate and hydrological models. For example,
410 a low bias in extreme daily precipitation may lead to an underestimation of the hydrologic response. We also note

411 that the hydrologic models were calibrated to 7-day means rather than daily values and may underestimate the
412 daily response in smaller basins. Nevertheless, three physical processes contribute directly to the increase in
413 magnitude: an increase in seasonal precipitation affecting soil saturation, an increase in extreme daily
414 precipitation, and a warming-induced reduction in the snow-covered area in the wet season. In our results for the
415 Willamette this reduction in snow-covered area reduces the buffering effect of snow accumulation during storms
416 and more than offsets an increase in melt from rain-on-snow events. This mechanism is supported by Chegwidien
417 et al (2020) who, using the same underlying dataset as our study, project a growth in both prevalence and
418 magnitude of rain-driven floods at the expense of floods from snowmelt and rain-on-snow events.

419
420 Our findings provide an initial indication of how existing flood risk management could respond to a warming
421 climate. Reservoir management is guided by rule curves which are intended to reflect the changing priorities and
422 risks during the year. For example, reservoirs used for flood control have rule curves that require reservoir levels
423 to be lowered when approaching the time of year when flood likelihood increases, and reservoir levels may be
424 raised as the likelihood decreases. For the Willamette, we found little change in the distribution of timing of flood
425 events, which indicate that with the state of the science today, reservoir rule curves may need to be altered as to
426 magnitude of flooding (which our results indicate will increase by 30-40%) but not timing; a reservoir model,
427 along with further investigation of the low bias in observed flood magnitudes (Figure 3e and 3f) would be required
428 for complete understanding of how flood risk (magnitude and timing) will actually change. For the Snake, larger
429 shifts in the timing imply a need to completely re-evaluate the existing rule curves. For the Columbia, the mode
430 in flood timing shifts earlier by half a month in the upper Columbia to about a month in the lower Columbia. The
431 distribution also broadens, with an elongated tail towards winter such that there is low, but non-negligible,
432 probability of floods occurring as early as January. These changes in timing imply a need for moderate alteration
433 of rule curves for reservoirs in the Canadian portion of the Columbia Basin.

434
435 Our results should not be taken as a precise prediction of flood magnitude change but rather as the best available
436 projections given the current state of the science. Two important factors need to be considered when interpreting
437 our results: first, in using RCP8.5, we selected the most extreme scenario of rising anthropogenic greenhouse gas
438 concentrations. If efforts to stabilize the climate before 2050 are successful, the flood magnitudes shown here will
439 undoubtedly be smaller (our analysis suggests most of the locations would see a change in flood magnitude about
440 1/3 smaller, for RCP4.5; e.g., a ratio of 1.3 (30% increase) for RCP8.5 would correspond to a ratio of 1.2 for
441 RCP4.5).

442

443 The second important factor in interpreting our results is that the actual river system in the Northwest includes
444 many dams, a majority of which have flood control as a primary (or at least a top) objective. As a result, actual
445 streamflows (and the changes in streamflow) at a given point in the river would be altered by reservoir
446 management. Translating these changes in flood magnitude into actual changes would require a reservoir model
447 for the basin or subbasin of relevance. One could then compute optimal rule curves for the major flood control
448 reservoirs (perhaps time-evolving every couple of decades, to reflect the likely changes in scientific understanding
449 and emissions trajectory). Even without that additional analysis, however, our results stress that the magnitude
450 and/or timing of flood events will change throughout the basin. In other words, what worked for flood control in
451 the past will not work as well in the future.

452

453 This study may have some utility in framing and quantifying the possible changes in flood risk as the Columbia
454 River Treaty is in renegotiation, but further work would be needed to assign probabilities to future flood
455 magnitude. Such work includes (a) a deeper understanding of the underlying model differences to explain
456 differences in model sensitivities (our analysis in section 2.3 shows that PRMS performs about as well as the three
457 calibrations of VIC for simulating past peak streamflows, but more work would be needed to understand the
458 reasons for divergence in future projections), (b) applying different statistical and/or dynamical downscaling
459 methods, and (c) using a more sophisticated approach to evaluating extremes in a nonstationary climate (as
460 advocated by Serinaldi and Kilsby, 2015). The mechanisms of flooding in the upper Columbia and elsewhere are
461 also a key question arising from this work; this and other work is needed to decipher the cause of the discharge
462 ratio patterns we found along the major rivers. Furthermore, a new generation of GCM outputs (CMIP6, Eyring
463 et al. 2016) already has data available from over 25 GCMs; in the near future, it would be feasible to apply a
464 newer multi-model hydrologic modeling approaches (e.g., Clark et al., 2015) to the new generation of GCMs,
465 though perhaps no significant changes would result.

466

467 Nonetheless, with current knowledge the fact that very few locations would see a decrease in flood risk under any
468 climate/hydrologic scenario is a strong statement of the need to update all aspects of flood preparation: the
469 definition of N-year (especially 100-year) return period streamflows, flood plain mapping, and reservoir rule
470 curves, to name a few. Moreover, the challenges that the renegotiated Columbia River Treaty faces in accounting
471 for climate change now appear to include the necessity of incorporating the likely increase in flood risk throughout
472 the region.

473

474 Generally, this study shows how complex the spatial and temporal patterns of change can be in a mixed rain-and-
475 snow basin. Basins of similar size and hydrological response to warming exist on most continents, so our results
476 provide a warning against using a small number of climate scenarios or a single hydrologic model to estimate
477 changes in flood risk in other basins.

616 **Figure captions.**

617

618 **Figure 1.** Domain of hydrologic simulations used in this paper, with colors indicating elevation of each grid cell,
619 major rivers highlighted in blue, and numbers indicating locations of streamflow points highlighted in Figures 6-
620 11, and Table 1. See Chegwiddden et al. (2017, 2019) for all streamflow locations plotted in Figure 5.

621 **Figure 2.** Generalized Extreme Value fit of annual maximum daily streamflow from 50 years of simulation using
622 output from one GCM (HadGEM2-ES), one hydrologic model (PRMS), for the Willamette River at Portland. Red
623 and blue dots/ lines indicate the annual values and GEV fit for the 1950-99 ‘past’ and 2050-99 ‘future’ periods.
624

625 **Figure 3.** Comparison of 10-year (a, b, c) and 100-year (d, e, f) flood magnitudes from the observationally derived
626 NRNI and the 40 climate-hydrologic model simulations, for 1950-2008, for select locations on the rivers as shown.
627

628 **Figure 4.** Statistical representations of the variation through the water year of the timing of flood events, 1950-
629 2008, for NRNI (blue) and the 40 simulations of 1950-2008 with the climate-hydrology modeling system (green).
630 To create each curve, the dates of the 5 highest streamflows in the period of record are tallied, and the resulting
631 distributions smoothed. Long dashed lines indicate median date, short dashed lines the lowest and highest
632 quartiles. MCD= Mica Dam (upper Columbia), TDA= The Dalles (lower Columbia, between the confluences of
633 the Snake and Willamette), LGS = Little Goose (lower Snake), BRN=Brownlee, SVN=T. W. Sullivan (lower
634 Willamette near Portland), DEX=Dexter (middle fork Willamette).
635

636 **Figure 5.** Discharge ratios (future:past) versus centroid of timing (day on which 50% of water-year streamflow
637 has passed, an indicator of snow dominance) for all 396 locations and four return periods. For each location, the
638 average of 40 ensemble member ratios calculated from GEV distribution fitting from 50-year windows for the
639 future (2050-2099) and past (1950-1999) time periods is shown. Points are sized by average daily streamflow
640 and colored by the coefficient of variation of the 40 ratios.
641

642 **Figure 6.** As in Figure 5 but only for points on the indicated rivers. Dashed lines indicate tributaries: 9-12 are on
643 the Middle Fork Willamette, 15-17 on the McKenzie; tributaries of the Snake are the Grand Ronde (14),
644 Clearwater (17) and Salmon (24). In the lower panel, the Grand Ronde and Salmon are clearly distinguished by a
645 black circle around their perimeter. Table 1 translates the codes in the legend into named locations and shows the

646 numerical values represented in the figure. As is evident from both snow-dominance and size, locations are
647 ordered downstream to upstream from left to right for each river.

648

649 **Figure 7.** Averaged (large circles) and individual ensemble member (small colored circles) discharge ratios for
650 simulated streamflow locations along the mainstem Columbia River for the 10-year (top) and 100-year (bottom)
651 return periods. As shown in the legend, the color of the dots distinguishes results by hydrologic model setup.

652

653 **Figure 8.** Average ratios of all 40 ensemble members (large circles) and the average of 4 hydrologic model
654 results for each GCM (symbols), shown for simulated streamflow locations along the Willamette (top), Snake
655 (middle), and the mainstem Columbia (bottom) for 100-year return periods. GCMs are ordered in the legend
656 by their ranking in Rupp et al. (2017), representing their ability to simulate Northwest climate.

657

658 **Figure 9.** As in Figure 8 but averaged by hydrologic model, for 10-year return period, and combined into one
659 panel.

660

661 **Figure 10.** ANOVA results for select locations on the indicated rivers, for climate and hydrologic factors (and
662 the residual). Charts are numbered to correspond with their location in Figure 6, with the most-downstream
663 location at the top.

664

665 **Figure 11.** Statistical representations of the variation through the water year of the timing of flood events. For
666 each of the 40 simulations, the dates of the 5 highest streamflows in the 50-year past (blue) and future (green)
667 windows are tallied, and the resulting distributions smoothed. Long dashed lines indicate median date, short
668 dashed lines the lowest and highest quartiles.
