14 **Abstract**

15

16 Projecting the spatio-temporal changes in water resources under a no-analog future climate
17 requires physically-based integrated hydrologic models, which simulate the transfer of water and
18 energy across the earth's surface. These models show promise in the context of unprecedented
19 climate extremes given their reliance on the underlying physics of the system as opposed to
20 empirical relationships. However, these techniques are plagued by several sources of uncertainty,
21 including the inaccuracy of input datasets such as meteorological forcing. These datasets, usually
22 derived from climate models or satellite-based products, are typically only resolved on the order
23 of tens to hundreds of kilometers, while hydrologic variables of interest (e.g. discharge,
24 groundwater levels) require a resolution at much smaller scales. In this work, a high-resolution
25 hydrologic model is forced with various resolutions of meteorological forcing (0.5 to 40.5 km)
26 generated by a dynamical downscaling analysis from the regional climate model Weather
27 Research and Forecasting (WRF). The Cosumnes watershed, which spans the Sierra Nevada and
28 Central Valley interface of California (USA), exhibits semi-natural flow conditions due to its
29 rare un-dammed river basin and is used here as a testbed to illustrate potential impacts of various
30 resolutions of meteorological forcing on snow accumulation and snowmelt, surface runoff,
31 infiltration, evapotranspiration, and groundwater levels. Results show that the errors in spatial
32 distribution patterns impact land surface processes and can be delayed in time. Localized biases
33 in groundwater levels can be as large as 5-10 m, and 3 m in surface water. Most hydrologic
34 variables reveal that biases are seasonally and spatially-dependent, which can have serious
35 implications for model calibration and ultimately water management decisions.

36 **1. Introduction**

37

38 Understanding water and energy fluxes across the Earth's critical zone, a region spanning
39 from bedrock to vegetation canopy, is important to assess the impacts of climate change on water
40 resources. Integrated hydrologic models, solving water-energy interactions and transfers, across
41 the lower-atmosphere, the land surface, and the subsurface, allow to analyze water resources in
42 both time and space and to project into a no-analog future where empirical models are no longer
43 valid. With the advancement of computing power, these high-fidelity, high-resolution models are
44 becoming widely used (e.g. MIKE-SHE (Abbott et al., 1986), HydroGeoSphere (Panday and
45 Huyakorn, 2004), and ParFlow-CLM (Maxwell and Miller, 2005)). However, their
46 implementation can be plagued by several sources of uncertainty. While the accuracy, the
47 precision, and the uncertainty reduction of hydrologic models are extensively discussed in the
48 literature, more attention is given to the physical representation of the phenomena occurring in
49 the hydrological systems (Beven, 1993; Beven and Binley, 1992; Liu and Gupta, 2007), the
50 reduction of uncertainties related to the hydrodynamic parameters (Gilbert et al., 2016; Janetti et
51 al., 2019; Maina and Guadagnini, 2018; Srivastava et al., 2014), and the numerical resolution of
52 the mathematical equations governing the physics of the environment (Belfort et al., 2009;
53 Bergamaschi and Putti, n.d.; Fahs et al., 2009; Hassane Maina and Ackerer, 2017; Miller et al.,
54 1998; Tocci et al., 1997).

55 Atmospheric dynamics (e.g. precipitation patterns) constitute one of the main drivers of
56 the simulated hydrologic processes. Unfortunately, measuring atmospheric conditions is difficult,
57 and is often only at point locations with stations which are difficult to maintain. Thus, models
58 relying on data assimilation methods that fuse observations at different scales and remote sensing

59 products are commonly used to generate the spatiotemporal distribution of meteorological
60 variables. Furthermore, because integrated hydrologic models require many meteorological
61 variables (i.e. precipitation, temperature, wind speed, solar radiation, air pressure, and relative
62 humidity), synthetic data from climate models are often used due to the scarcity of
63 measurements. In addition, in the context of climate change, only climate models can provide a
64 spatial distribution of future meteorological conditions. Also, integrated hydrologic models
65 require high resolution forcing to ensure fidelity and accuracy and meteorological variables such
66 as precipitation, one of the most important data and key control of hydrological models, are very
67 heterogeneous especially in mountainous areas (Olsson et al., 2014; Prein et al., 2013).

68 Like any model input, meteorological forcing is impacted by several sources of
69 uncertainty, including the fidelity of the physics of the atmospheric model as well as the
70 representativity of the spatial resolution at which they occur. The impact of precipitation
71 resolution on runoff and streamflow is widely documented in the literature with studies relying
72 on (i) empirical hydrologic models with precipitation data coming from measurements (Arnaud
73 et al., 2002; Berne et al., 2004; Lobligois et al., 2014; Nicótina et al., 2008; Schilling, 1991;
74 Shrestha et al., 2006; Tobin et al., 2011), satellite-based products (Koren et al., 1999; Ochoa-
75 Rodriguez et al., 2015; Vergara et al., 2013) and climate models outputs (Dankers et al., 2007;
76 Kleinn et al., 2005) and (ii) physics-based hydrologic models with precipitation data coming
77 from measurements (Elsner et al., 2014; Fu et al., 2011), satellite-based products (Eum et al.,
78 2014; Haddeland et al., 2006) and climate models outputs (Mendoza et al., 2016; Rasmussen et
79 al., 2011). Moreover, Rasmussen et al., (2011) study the impact of meteorological forcing on
80 snow dynamics.

81 Nevertheless, previous studies were mostly focused on runoff and streamflow analysis,
82 lacking a complete analysis of all the hydrodynamic processes occurring at the watershed scale.
83 Moreover, the resolutions of the meteorological data (~km) used remain relatively coarse
84 compared to the scale of resolution of the hydrological models (~m). Hence, the objective of this
85 study is to investigate the impact of the spatial resolution of the meteorological forcing from
86 ~km to ~m on the hydrologic processes occurring at the watershed scale using a physics-based
87 integrated hydrologic model. In other words, we seek to understand how the uncertainties
88 associated with the coarse spatial resolution of meteorological forcing propagate into the high-
89 resolution integrated hydrologic models and affect the output of interest.

90 While in this study we utilize specific models to quantify the impact of meteorological
91 forcing on hydrologic variables, the results generalized for watershed processes and **are** meant to
92 be illustrative of the potential bias with various codes and in various locations. In this work, we
93 use ParFlow-CLM (Kollet and Maxwell, 2006; Maxwell, 2013; Maxwell and Miller, 2005)
94 forced with the Weather Research and Forecasting (WRF) model (Skamarock et al., 2008a;
95 Skamarock and Klemp, 2008). ParFlow simulates subsurface and surface flows (as well as their
96 interaction) by solving the mixed form of the Richards equation (Richards, 1931) and the
97 kinematic wave equation, respectively. The transfer of water and energy from the subsurface and
98 the land surface to the atmosphere is simulated using a coupled version of the Community Land
99 Model (CLM, Dai et al., 2003) to ParFlow. Therefore, the model allows for the spatio-temporal
100 analysis of all the hydrological components of interest such as the distribution of pressure-head
101 which encompasses the information on the water level in the river and the groundwater, the
102 groundwater and surface water storages, the evapotranspiration, the infiltration, and the snow
103 dynamics. WRF is a state-of-the-art, fully compressible, non-hydrostatic, mesoscale numerical

104 weather prediction model that simulates the physics governing the atmospheric dynamics using a
105 nested domain configuration to provide meteorological forcing data at different spatial
106 resolutions for ParFlow-CLM.

107 Our study focuses on the Cosumnes watershed located in Northern California, USA, a
108 region where the effects of climate change have already been observed. The latter are
109 characterized by a fluctuation between extreme droughts (Griffin and Anchukaitis, 2014) and the
110 subsequent occurrence of unprecedented wildfires and periods of intense precipitation mainly
111 caused by atmospheric rivers (Dettinger, 2011). Atmospheric rivers, filaments of concentrated
112 moisture in the atmosphere, generate storms with intensity much higher than the average
113 precipitation events and are sometimes very localized. The Cosumnes hosts one of the last rivers
114 without a dam in California, offering the opportunity to study natural flow. The watershed also
115 spans the Sierra Nevada - Central Valley interface, offering an opportunity to assess the
116 relationship between snowpack dynamics, large-scale river runoff, and aquifer storage. The
117 region is representative of many watersheds in the state, given the strong variations in
118 topography and land cover and land use, but also the snow dynamics given that the majority of
119 the water resources in the state originate from snowmelt (Dettinger and Anderson, 2015). These
120 sharp variations in above and below ground heterogeneities necessitate high-resolution models,
121 making it an excellent candidate to understand the impact of the forcing resolution on hydrology.

122 We study the water year 2017, the wettest water year on California record characterized
123 by several atmospheric rivers (Di Liberto, 2017; SCRIPPS Institution of Oceanography, 2017).
124 As mentioned by Swain et al., (2018), the future climate of California will likely be characterized
125 by extreme wet and dry conditions. It is therefore important to understand the dynamics of these
126 currently end-member conditions. Although exceptional today, these extremes will likely

127 become the “new normal” in the future. Wet conditions are also ideal to conservatively
128 understand the amount of bias an overly coarse meteorological forcing dataset might have on a
129 region’s hydrology. The developed integrated hydrologic model has a spatial resolution of 200 m
130 and we use five different spatial resolutions (40.5, 13.5, 4.5, 1.5 and 0.5 km) of meteorological
131 forcing derived from the WRF dynamical downscaling approach. Our study aims to answer the
132 following questions:

- 133 • What is the effect of meteorological forcing spatial resolution on simulated snow
134 accumulation and melt, evapotranspiration, infiltration and pressure head and/or
135 water table depth? In broader terms, how do meteorological uncertainties
136 propagate into the resolved hydrodynamics and which processes require high-
137 resolution meteorological forcing?
- 138 • At which spatial resolution should the climate models be solved to accurately
139 describe the strong variations in meteorological conditions induced by
140 atmospheric rivers and their effect on the hydrology and therefore water supply?

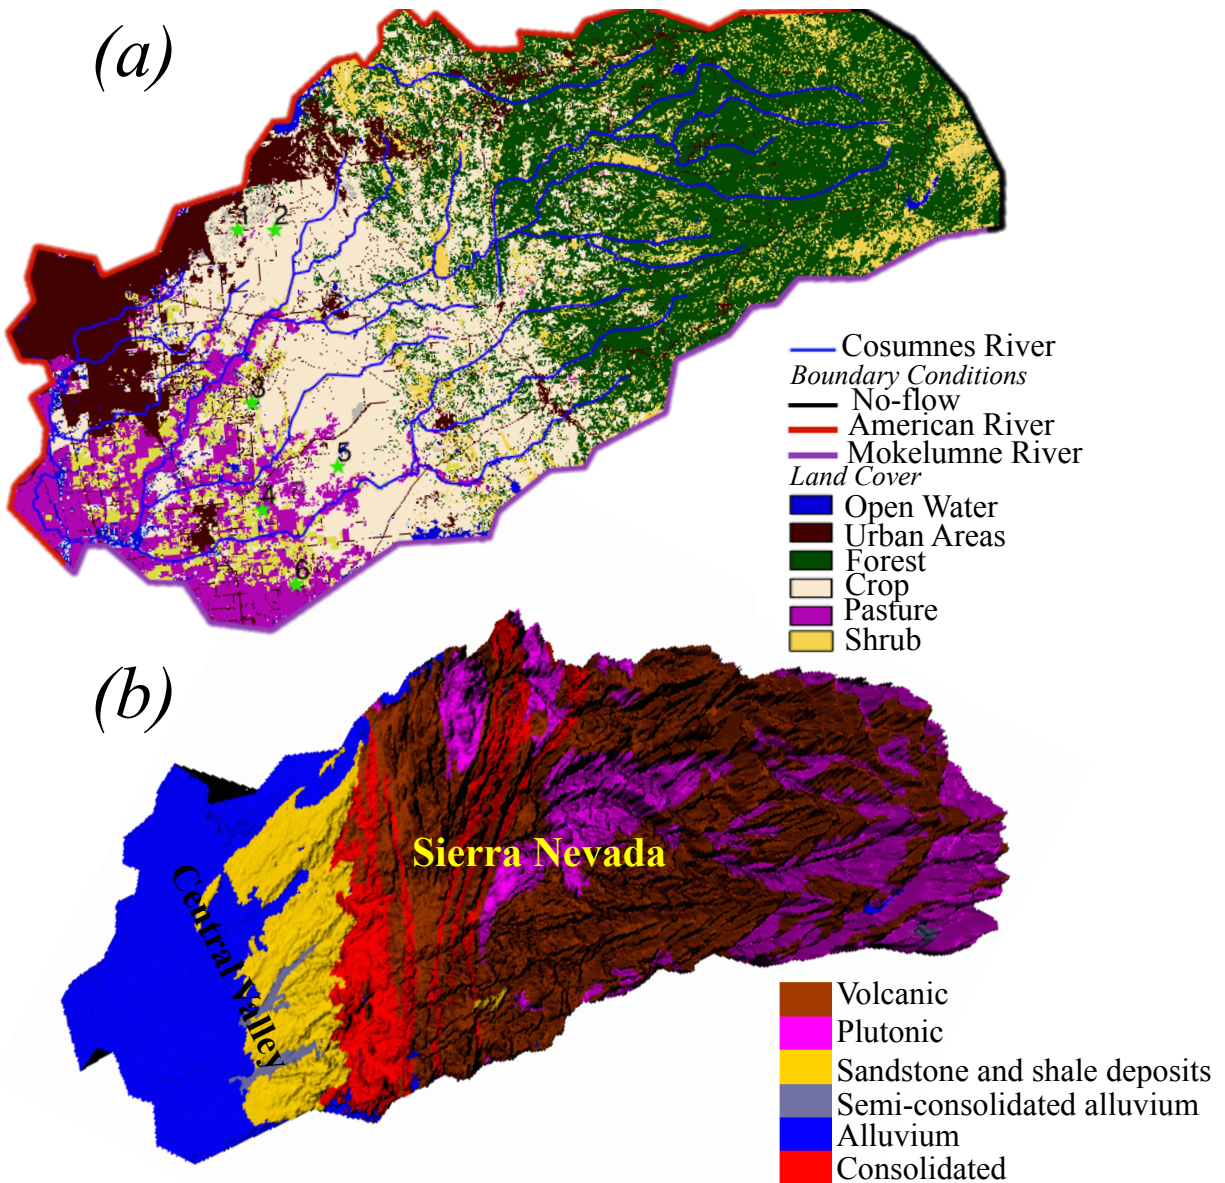

141

142 **2. The Cosumnes watershed model**

143 **a. Study area**

144 The Cosumnes watershed is approximately 7,000 km² in size (Figure 1a) and hosts one of
145 the last rivers in the region without a major dam. Thus, it offers a rare opportunity to study the
146 natural flow conditions. The geologic composition consists of materials ranging from nearly
147 impermeable formations (volcanic and plutonic rocks located mainly in the Sierra Nevada
148 mountains) to highly porous and permeable aquifers in the Central Valley. The agricultural
149 region of Central Valley, subject to seasonal pumping and irrigation, is located in the southwest

150 of the watershed and consists of various crop types, including alfalfa, pasture lands, and
151 vineyards. The Sierra Nevada Mountains are predominately covered by an evergreen forest.
152 Spatial patterns of precipitation are highly heterogeneous across the watershed. On average, the
153 Sierra Nevada Mountains receive three times more precipitation (1500 mm) than the Central
154 Valley (Cosgrove et al., 2003), primarily in the form of snow. The regional climate is considered
155 Mediterranean, with wet and cold winters (with a watershed average temperature equal to 0 °C)
156 and hot and dry summers (with watershed average temperature reaching 25 °C) (Cosgrove et al.,
157 2003).

158

159 Figure 1: (a) Land-use and land-cover (Homer et al., 2015) and (b) geology (Jennings et al.,
 160 1977) and topography (USGS) of the Cosumnes Watershed

161

162 3. Numerical Modeling Methods

163 In this section, we briefly describe the two numerical models that we used in this study:

164 (1) ParFlow-CLM, which simulates interactions as well as the transfer of water and energy

165 between the lower atmosphere, the land surface, and the subsurface, and (2) Weather Research

166 Forecast (WRF), which simulates mesoscale numerical weather prediction, and is used here to
 167 drive the meteorological conditions of the ParFlow-CLM simulations.

168 **3.1. Integrated Hydrologic Model: ParFlow-CLM**

169 ParFlow-CLM (Kollet and Maxwell, 2006; Maxwell, 2013; Maxwell and Miller, 2005)
 170 describes the movement of water in the subsurface by solving the three-dimensional mixed form
 171 of Richards equation (Richards, 1931), given by:

$$172 \quad S_S S_W(\psi_P) \frac{\partial \psi_P}{\partial t} + \phi \frac{\partial S_W(\psi_P)}{\partial t} = \nabla \cdot [k(x) k_r(\psi_P) \nabla(\psi_P - z)] + q_s \quad (1)$$

173 Where S_S is the specific storage (L^{-1}), $S_W(\psi_P)$ is the degree of saturation (-) associated
 174 with the subsurface pressure head ψ_P (L), t is the time, ϕ is the porosity (-), k_r is the relative
 175 permeability (-), z is the depth (L), q_s is the source/sink term (T^{-1}), and $k(x)$ is the saturated
 176 hydraulic conductivity ($L T^{-1}$). The interdependence of variables (i.e. relationships between
 177 saturation and pressure head and between relative permeability and pressure head) is described
 178 by the Van Genuchten model (van Genuchten, 1980). Overland flow is described by the two-
 179 dimensional form of the kinematic wave equation given by:

$$180 \quad -k(x) k_r(\psi_0) \nabla(\psi_0 - z) = \frac{\partial \|\psi_0, 0\|}{\partial t} - \nabla \cdot \vec{v} \|\psi_0, 0\| - q_r(x) \quad (2)$$

181 Where $\|\psi_0, 0\|$ indicates the greater term between ψ_0 the surface pressure-head and 0, \vec{v}
 182 is the depth averaged velocity vector of surface runoff ($L T^{-1}$), q_r represents rainfall and
 183 evaporative fluxes ($L T^{-1}$). The depth of the ponding water at the surface in x direction (v_x) and y
 184 direction (v_y) is calculated by:

$$185 \quad v_x = \frac{\sqrt{S_{f,x}}}{n} \psi_0^{2/3} \text{ and } v_y = \frac{\sqrt{S_{f,y}}}{n} \psi_0^{2/3} \quad (3)$$

186 Where $S_{f,x}$ and $S_{f,y}$ are the friction slopes in the x and y directions (respectively), and n is
 187 the manning coefficient.

188 Solutions of the Richards and kinematic wave equations require the terms q_s and $q_r(x)$
189 respectively. These terms include the land surface processes simulated by CLM, such as
190 evapotranspiration, infiltration, and snow dynamics. To compute these processes, CLM uses soil
191 moisture calculated by ParFlow, vegetation characteristics (the type of land use/land cover as
192 well as its physical properties), and the meteorological forcing calculated by WRF.

193 The Cosumnes ParFlow-CLM model is horizontally resolved at 200 m and varies in
194 vertical discretization from 10 cm at the land surface to 30 m at the bottom of the domain. The
195 total thickness of the domain is 80 m. An analysis of variations in measured groundwater levels
196 showed that this thickness is sufficient to capture water table depth fluctuations and that in
197 general, beyond 50 m below the ground surface the aquifer remains fully saturated. Simulations
198 utilize parallel high-performance computing to accommodate the large number of cells
199 (approximately 1.4 million) that constitute the high-resolution model.

200 The Cosumnes watershed is bounded by the American and Mokelumne rivers and is
201 constrained in the model with the use of weekly-varying values of Dirichlet boundary conditions
202 along these borders. A no-flow (i.e. Neumann) boundary condition is imposed at the eastern,
203 headwater side of the watershed. Hydrodynamic properties (including hydraulic conductivity,
204 specific storage, porosity, Van Genuchten parameters) are derived from a regional geological
205 map (Geologic Map of California, 2015; Jennings et al., 1977) and a literature review of previous
206 studies (Faunt et al., 2010; Faunt and Geological Survey (U.S.), 2009; Flint et al., 2013; Gilbert
207 and Maxwell, 2017; Welch and Allen, 2014). The 2011 National Land Cover (NLCD) map
208 (Homer et al., 2015) is used in CLM to define land use and land cover. Agricultural maps
209 provided by the National Agricultural Statistics Service (NASS) of the US Department of
210 Agriculture's (USDA) Cropland Data Layer (CDL) (Boryan et al., 2011) are used to further

211 delineate specific croplands in the Central Valley. Vegetation parameters are defined by the
212 International Geosphere-Biosphere Programme (IGBP) database (IGBP, 2018). The developed
213 model also accounts for pumping and irrigation occurring in the Central Valley. More details
214 about the model parameterization and validation can be found in [Maina et al., \(2020\)](#) and [Maina
215 and Siirila-Woodburn, \(2020\)](#).

216 A full water year is simulated to demonstrate how different scales of meteorological
217 forcing impact both wet and dry seasons of the year. The water year 2017 (i.e. October 1st, 2016-
218 September 30th, 2017), a particularly wet year, is selected to conservatively demonstrate how
219 forcing scales may impact hydrologic results in a wide range of weather conditions.

220

221 **3.2. Meteorological Model: Weather Research Forecast (WRF)**

222 WRF (Skamarock et al., 2008b; Skamarock and Klemp, 2008) is a state-of-the-art, fully
223 compressible, non-hydrostatic, mesoscale numerical weather prediction model. As shown in
224 Figure 2, we configure WRF version 3.6.1 over four two-way nested domains with a horizontal
225 resolution of 13.5 km (domain 1, d01), 4.5 km (domain 2, d02), 1.5 km (domain 3, d03), and 0.5
226 km (domain 4, d04). Each domain is composed of 30 vertical atmospheric levels. Land cover in
227 WRF matches the one used in ParFlow-CLM. Post-spin-up soil moisture from ParFlow-CLM is
228 used to initialize the WRF model at the beginning of the simulation. Other WRF initial
229 conditions, as well as boundary conditions, are defined based on the NLDAS-2 (Cosgrove et al.,
230 2003) terrestrial and meteorological data. The lateral boundary condition is specified for the
231 coarse grid (d01 in Figure 2) to constrain wind speed and direction, potential temperature,
232 mixing ratio for water vapor, geopotential height, and hydrostatic pressure. The parametrizations
233 that represent physical processes in the configuration of WRF used here include the Dudhia

234 scheme (Dudhia, 1988) for shortwave radiation, the Rapid Radiative Transfer Model (Mlawer et
235 al., 1997) for longwave radiation, the Morrison double-moment scheme (Morrison et al., 2009)
236 for microphysics, University of Washington Boundary Layer Scheme (Bretherton and Park,
237 2009) for the planetary boundary layer, and the Eta Similarity scheme (Monin and Obukhov,
238 1954) for the model surface layer. The Grell-Freitas scheme (Grell and Freitas, 2014) is used for
239 cumulus parameterization in two outer-most domains only (d01 and d02). For domain d03 and
240 d04, the higher-resolutions allow for convection to be resolved explicitly. WRF mass balance
241 validation results are shown in Appendix A1. The described configuration of WRF has been
242 extensively validated against ground observation of meteorological conditions in the California
243 region in previous works (Vahmani et al., 2019; Vahmani and Jones, 2017). These studies show
244 a very good performance for the current configuration of WRF over California, predicting daily
245 mean and maximum air temperatures and evapotranspiration with errors of 1.1 °C, 0.4 °C, and
246 0.74 mm day⁻¹, respectively. We further compare WRF simulations over the Cosumnes
247 watershed with ground measurements (see Appendix A3). Our comparisons indicate a reasonable
248 match between measurements and simulations allowing us to gain confidence in the ability of
249 WRF to reproduce the atmospheric dynamics in this watershed.

250 Using the nested domain configuration of WRF described above, we design a series of
251 simulations to dynamically downscale across the four spatial resolutions. The coarsest scale of
252 forcing at 40.5 km resolution is generated by statistically up-scaling the coarsest of the WRF
253 simulations (13.5 km). WRF simulations are conducted from September 1st, 2016 to September
254 30th, 2017, covering the entire water year 2017 plus one month of spin-up. Spatial distributions
255 of precipitation and temperature at three selected times (characterized by three different storms

256 of varying intensity and duration) obtained with the five spatial resolutions of forcing are shown
257 in Appendix A2.

258
259 Figure 2: Geographical representation of four WRF nested domains with 13.5, 4.5, 1.5, and 0.5
260 km spatial resolutions for d01, d02, d03, and d04, respectively.

261
262 **3.3. Hydrologic variables**

263 Results from the five spatial resolutions are compared for key land surface and
264 subsurface processes. We consider the results obtained with the finest spatial resolution of
265 meteorological forcing (0.5 km, closest to that of the hydrologic model) as the most accurate
266 resolution, and evaluate the differences relative to that of the four remaining resolutions (1.5, 4.5,
267 13.5 and 40.5 km). Comparisons are shown as an absolute error (*AE*) and/or percent error (*PE*)
268 relative to the 0.5 km results via:

269
$$AE_{i,t} = X_{0.5_{i,t}} - X_{R_{i,t}} \tag{5}$$

270 and

271
$$PE_{i,t} = \frac{X_{0.5_{i,t}} - X_{R_{i,t}}}{X_{0.5_{i,t}}} \times 100 \quad (6)$$

272 where X is the model output (ET , I , SWE , or ψ) at a given point in space (i) at a time (t), and R is
 273 the spatial resolution of the forcing (1.5, 4.5, 13.5 or 40.5 km). Snap-shots in time of these errors
 274 highlight the sensitivity of each scale of forcing in space. Global (i.e. domain-wide) differences
 275 are also calculated for select parameters of interest and shown as a function of time.

276 Because large-scale changes in storage are of interest from a water management
 277 perspective, total surface water (SW) storage is calculated via:

278
$$Storage_{SW} = \sum_{i=1}^{n_{SW}} \Delta x_i \times \Delta y_i \times \psi_i \quad (7)$$

279 where n_{SW} is the total number of river cells (-), Δx_i and Δy_i are cell discretizations along
 280 the x and y directions (L), and i indicates the cell. Similarly, total groundwater (GW) storage is
 281 calculated via:

282
$$Storage_{GW} = \sum_{i=1}^{n_{GW}} \Delta x_i \times \Delta y_i \times \Delta z_i \times \psi_i \times (S_{si} / \phi_i) \quad (8)$$

283 where n_{GW} is the total number of subsurface saturated cells (-) and Δz_i is the
 284 discretization along the vertical direction the cell (L).

285

286 **4. Results and discussions**

287 **4.1. Snow Water Equivalent, SWE**

288 Figure 3 shows the domain total SWE obtained with the five resolutions of forcing. Our
 289 results indicate that all four resolutions overestimate the SWE when compared to the results
 290 obtained with 0.5 km forcing. We note that the accumulation of SWE starts at the same time for
 291 all resolutions while the time of snowmelt peak varies considerably from one resolution to
 292 another, the coarser resolutions show a delay in ablation. For example, SWE results obtained
 293 with the 40.5 km resolution forcing exhibits low global error for the first half of the water year,

294 however during peak ablation the differences are very large both in terms of magnitude ($PE = 90$
295 %) and timing (which is delayed by around 40 days). Our results show that an accurate
296 representation of SWE requires forcing data with a resolution close to that of the hydrologic
297 model. This conclusion is somewhat different from that drawn by Rasmussen et al., (2011), who
298 found that the representation of SWE in mountainous systems can be accurate for spatial
299 resolutions of forcing lower than 6 km. A possible explanation for this difference is the
300 resolution of the physics-based model used in this study compared to that of Rasmussen and co-
301 authors, the integrated hydrologic model we used in addition to the climate model, or differences
302 stemming from watershed locations of the two studies.

303

304 Figure 3: Temporal variations of the total Snow Water Equivalent (*SWE*) obtained with
305 meteorological forcing at spatial resolutions of 0.5, 1.5, 4.5, 13.5, and 40.5 km.

306

307 Figure 4a shows the spatial distributions of *SWE* obtained with the five spatial resolutions
308 at two selected days, which correspond to the beginning (January) and peak (March) of snow
309 accumulation. The spatial distribution of *SWE* is more precise for results obtained with the
310 higher resolution meteorological forcing. *SWE* distributions obtained with meteorological forcing
311 of **resolutions** at or above 13.5 km are not well estimated. Figure 4b shows the spatial
312 distribution of the absolute error of *SWE* (AE_{SWE}). Over- and under- estimations of *SWE* with
313 similar magnitudes are observed for all the four resolutions. Errors in *SWE* distribution increase
314 (with *AE* greater than 100 mm) as the resolution of the forcing data decreases. We notice that
315 over- and under- estimations of *SWE* depend both on the topography and the resolution of
316 forcing as snow processes depend not only on the meteorological conditions but also on the slope
317 and aspect of a given hillslope. Depending on the elevation, the orientation of the cell (north and
318 south facing), the energy fluxes are different resulting in very different snow dynamics. This
319 strengthens the conclusions drawn previously stating that the meteorological data should be at a
320 resolution close to the one associated with the input data (e.g. topography) as well as the physics-
321 based model to ensure a good precision and accuracy in the representativity of the snow
322 dynamics. We further note that differences in *SWE* will lead to different snowmelt, *ET*, and
323 infiltration rates which will have implications for other hydrologic variables such as streamflow
324 and groundwtaer levels.

346

Figure 5 shows the temporal variation of the percent error in the domain-average ET (PE_{ET}) flux as calculated with equation (6). We note that the percent error has large values due to the low values of ET ; thus small changes in ET result in large percent errors. While in general, the coarsest spatial resolution of forcing (i.e. 40.5 km) shows the highest errors for some time steps, the percent errors obtained with the second coarsest meteorological forcing (13.5 km) are actually the largest. A possible explanation is the aggregated nature of the domain-average ET . Depending on the time step, the coarser forcing resolutions can lead to either an over or under-estimation of ET . Results do not show a systematic trend with regards to the over- or under-estimation of ET . It is therefore difficult to establish a clear relationship between the spatial resolution of forcing and the directionality of ET error at a watershed scale. Note, however, that these errors do not increase over time. This can be related to the fast-changing nature of ET that is strongly linked to short-lived weather patterns and the diurnal cycle.

347

348 Figure 5: Temporal variation of the percent error of evapotranspiration, PE_{ET} , obtained with
 349 meteorological forcing at spatial resolutions of 1.5, 4.5, 13.5, and 40.5 km relative to the highest
 350 spatial resolution of meteorological forcing (0.5 km)

351

352 Figure 6a shows the spatial distributions of ET for the five resolutions at two selected
 353 time steps characterizing periods with and without precipitation events. Day 0 corresponds to a
 354 dry day in October and day 167 corresponds to a wet day in March. The spatial patterns of ET at
 355 these two time steps are different. Furthermore, spatial patterns between the different scales of
 356 forcing also reveal distinct ET patterns. As expected, the most accurate ET distribution is
 357 obtained with the highest resolution of the meteorological data, the coarser a resolution of
 358 meteorological data is the less accurate the spatial distribution of ET . Because the highest

359 resolution of forcing is close to the resolution of the integrated hydrologic model (and thus the
 360 resolution of input data such as topography, geology, and land use and land cover), it allows us
 361 to better understand the relationships between *ET* and these different characteristics of the
 362 watershed. Such analyses are difficult to undertake for coarser resolutions.

363

366

367 Figure 6: Spatial distributions of (a) the ET obtained with the five spatial resolutions of
 368 meteorological forcing and (b) percent error of ET (PE_{ET}) with respect to the highest spatial
 369 resolution of meteorological forcing (0.5 km). Results are shown at the first day of the simulation
 370 (WY day 0, in October) and during the time at which peak differences are observed (WY day
 371 167, in March).

372

373 Seasonality and location affect the degree to which forcing scales impact ET . Note that
 374 for the spatial distributions of ET associated with the second time step considered (day 167), the
 375 results obtained with the five resolutions are very similar in the Central Valley. At this time
 376 spatial patterns of ET only differ in the Sierra Nevada Mountains and the intrusion. The geology,
 377 as well as, the land cover and the topography are more or less uniform in this valley, whereas
 378 these parameters notably topography vary significantly in the Sierra Nevada Mountains. For the
 379 first time step, the differences observed in the Central Valley are due to the fact that for very
 380 precise resolutions of the forcing, the evolution of the storm is accurate (see Appendix A2) and
 381 so is the ET . Thus, for relatively homogeneous areas such as the Central Valley, high-resolution
 382 forcing data is required only if the storm shows a strong spatial variation within the areas
 383 whereas for highly heterogeneities associated with geology, topography, and land-cover, high-
 384 resolution forcing data are always required if one is interested in analyzing accurately the spatial
 385 distribution of ET .

386 Figure 6b shows the spatial distributions of percent error of ET (PE_{ET}) relative to the
 387 results of the 0.5 km meteorological forcing. Whatever the resolution considered, we note both

388 an over- and under- estimation of *ET* on the same scale of error (+/- 3000%), but with more
389 localized and less wide-scale differences at the finest scale of meteorological forcing. We also
390 observe that error is higher in the Sierra Nevada Mountains characterized by complex
391 topography and geology than in the Central Valley for all resolutions. This reinforces the
392 conclusions drawn previously, namely that for complex environments a precision in the
393 meteorological data is strongly required.

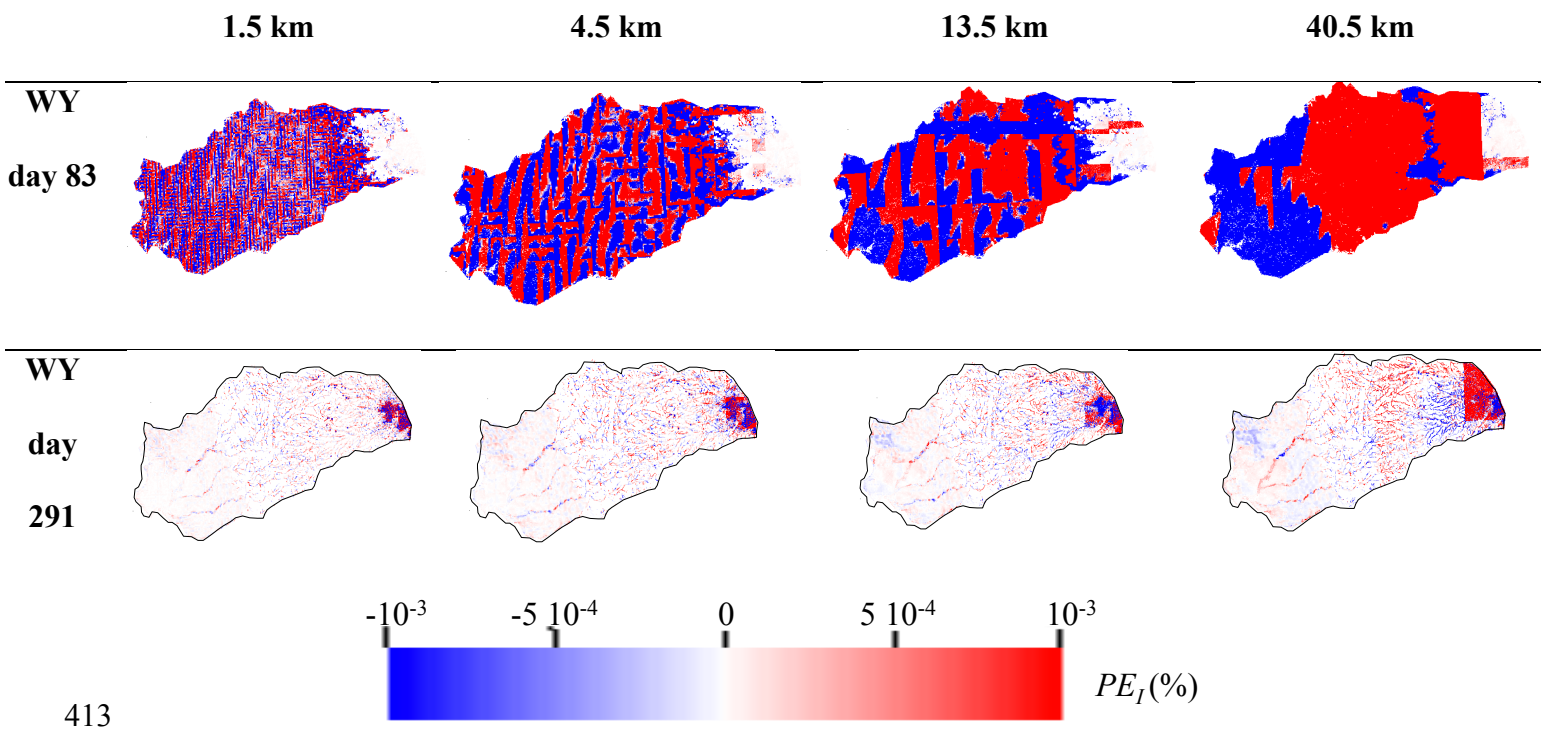

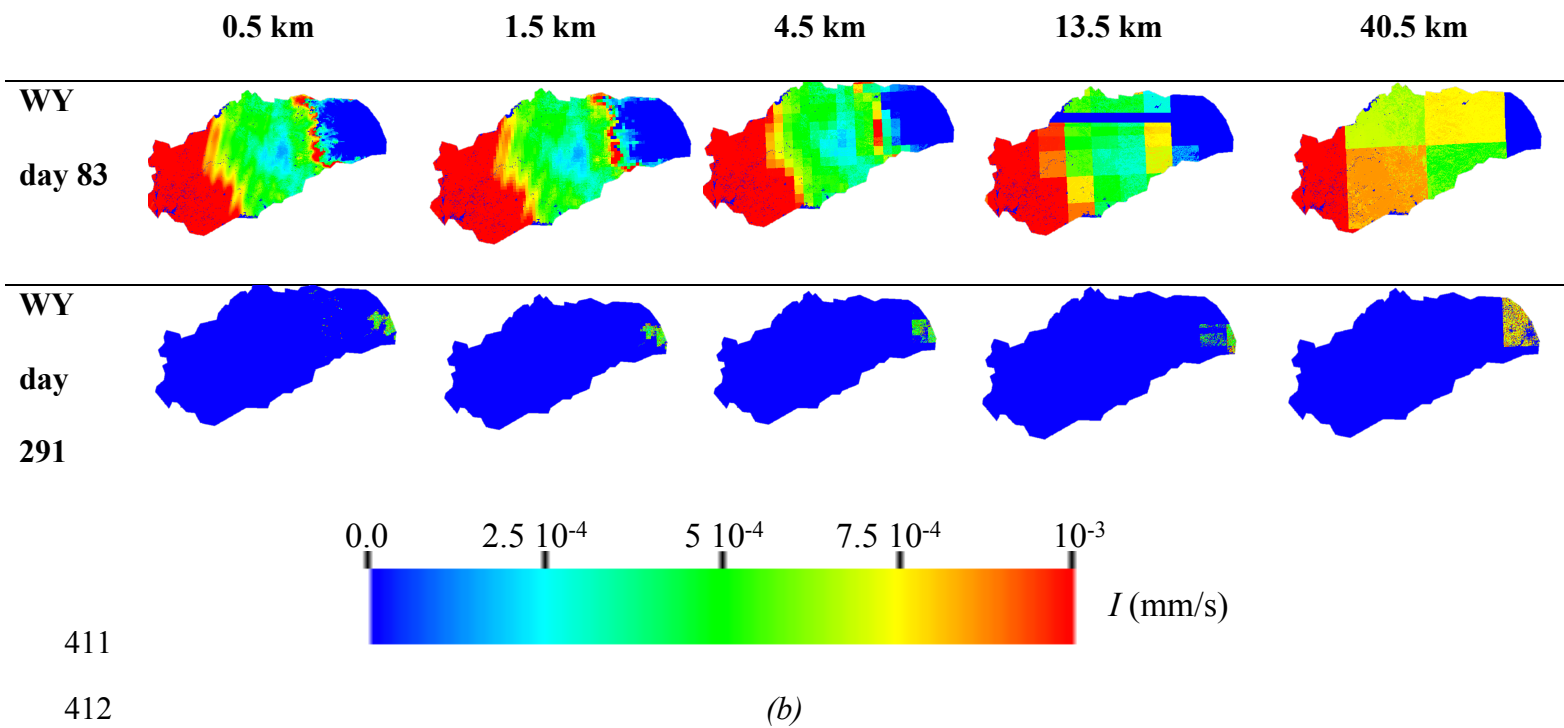

394

395 **4.3.Infiltration**

396 Figure 7 shows the spatial distributions of infiltration obtained with the five spatial
397 resolutions (Figure 7 a) and their corresponding percent errors (Figure 7 b) at two selected times
398 corresponding to winter (WY day 83, December, presence of precipitation event) and summer
399 (WY day 291, June, absence of precipitation event). The first time step corresponds to the snow
400 accumulation period while the second one characterizes the snowmelt period. The spatial
401 resolution of forcing data strongly impacts the spatial distribution of infiltration. Indeed, for
402 coarse resolutions (i.e. 40.5 km), it is almost impossible to determine the position of the storm
403 and its impact on infiltration, the results obtained at this scale are strongly dependent on the
404 resolution of the forcing. However, for more precise resolution (i.e. 0.5 km), we can exactly see
405 the location of the storm, this resolution allows distinguishing areas characterized by a very weak
406 infiltration as the upper part of the catchment corresponding to the Sierra Nevada Mountains.
407 Indeed, in this area, due to the accumulation of snow (precipitation is in the form of snow unlike
408 in the Central Valley), the resulting infiltration is zero. The spatial extension of the area subject
409 to the snow accumulation is only accurate for high-resolution meteorological forcing results.

410

(a)

414 Figure 7: Spatial distributions of (a) infiltration I obtained with the five spatial resolutions of
 415 meteorological and the (b) percent error of infiltration (PE_I) with respect to the highest spatial

416 resolution of meteorological forcing (0.5 km). Results are shown in winter (WY day 83) and
417 summer (WY day 291).

418

419 To better understand how the quality and precision of the spatial distribution of
420 infiltration deteriorates by decreasing the resolution of the input data, Figure 7b shows the spatial
421 distribution of the PE_i of the four resolutions at the same two time steps. For the first time step,
422 the errors are null in the Sierra Mountains which is not the case for the second time step.
423 Whatever the resolution considered, and as previously discussed, we note that depending on the
424 point considered there may be over- and under- estimation of the infiltration with percent error
425 close to 10^{-3} . Note that these differences are observed over the entire watershed except in the
426 Sierra Mountains for the first time step, while for the second time step, these errors are only
427 observed along the river and its tributaries as well as in the Sierra Nevada Mountains. This
428 second time step corresponds to the summer, a snowmelt period and without rain. As such,
429 differences of infiltration in the Sierra Nevada Mountains are due to the snowmelt. As for the
430 differences observed close to the areas subject to the overland flow, these are due to the
431 exchanges between the surface flow and the subsurface. Because the amount of snow
432 accumulated as well as the spatial extent of the area subject to snow dynamics is different for the
433 five resolutions considered, the resulting snowmelt is different. Thus, the runoff controlled by
434 this snowmelt will also be different and so is the infiltration of the quantities of water coming
435 from the overland flow. This indicates that the effects of the spatial resolution of forcing data can
436 be delayed in time.

4.4.1. Surface water storage and river stage

Figure 8 illustrates the percent error of surface water storage PE_{SW} . In general, the percent error of the surface water storage is small ($< 5\%$) regardless of the time of the year, and these differences are almost zero for the results obtained with 1.5 and 4.5 km forcing resolutions for the entire water year. As shown in Figure 9 illustrating the spatial distributions of the absolute error of surface pressure-head (AE_{ψ_s}), the percent error of the total surface water storage at the watershed scale is small because some regions in the domain over-estimate the pressure-head while others under-estimate the pressure-head. In contrast, while the error is negligible at the beginning of the simulation for results obtained with forcing at 13.5 and 40.5 km, the PE_{SW} increases over time, eventually reaching a near-maximum at the end of the water year. This suggests that PE_{SW} may be cumulative and that longer simulations with overly coarse scales of forcing will compound through time. It's interesting to also note that while the results obtained with the 13.5 km resolution forcing overestimates the surface water storage at any time, those obtained with the 40.5 km resolution forcing show over-estimates of PE_{SW} at the beginning of the simulation and under-estimates of PE_{SW} at the end of the simulation. Moreover, the errors obtained with the 13.5 and 40.5 km resolution are of the same order but opposite signs. This suggests that although the total water budget is nearly equivalent for each scale of forcing considered here (see Appendix A1), an inaccurate spatial distribution of forcing can lead to an inaccurate redistribution (and possibly a delay) of water and energy, and hence different signals of surface water storage.

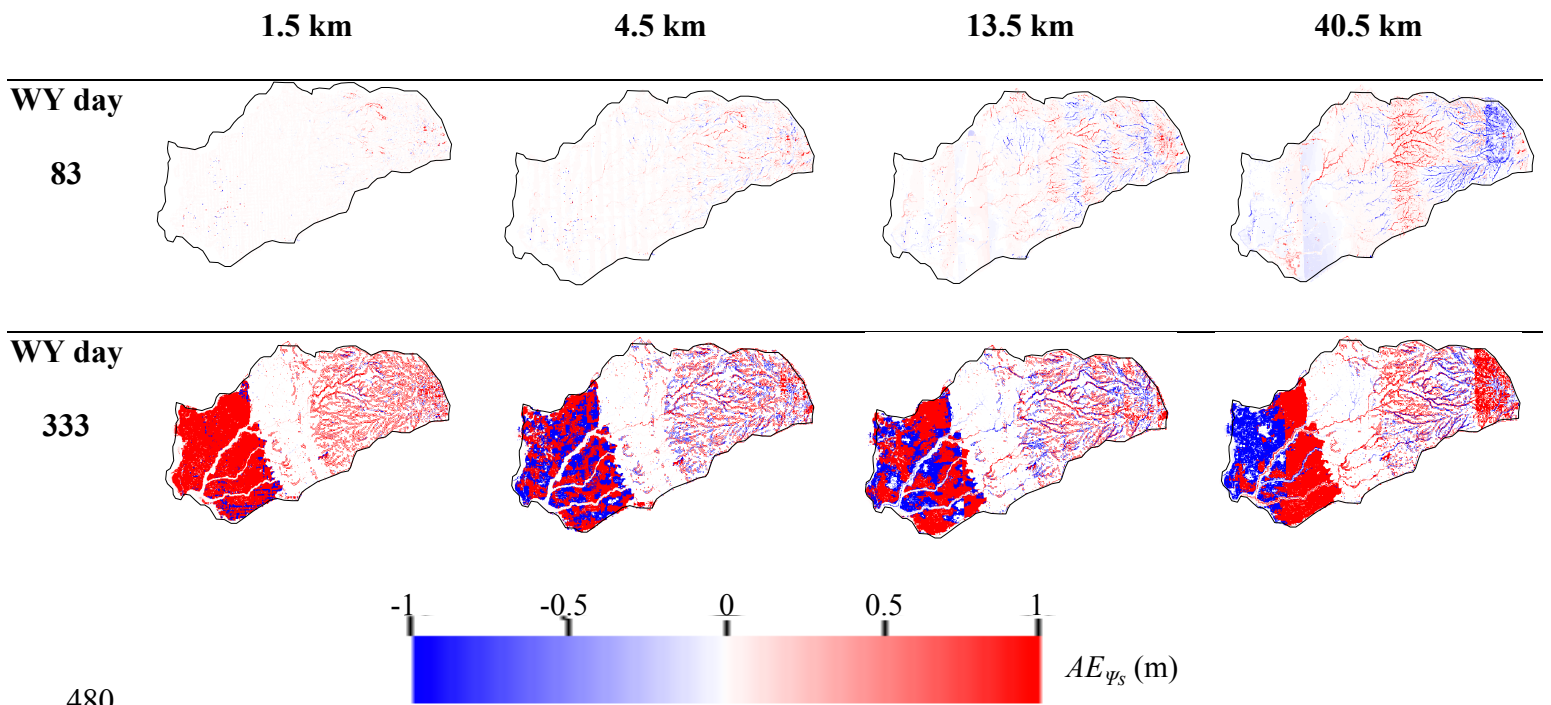

459

460 Figure 8: Temporal variations of the percent error of surface water storage (PE_{SW}) obtained with
 461 meteorological forcing at spatial resolutions of 1.5, 4.5, 13.5, and 40.5 km with respect to the
 462 highest spatial resolution of meteorological forcing (0.5 km)

463

464 Figure 9 shows the spatial distributions of the absolute error of pressure-head for the first
 465 layer (AE_{ψ_s}) at two selected time steps corresponding to winter (WY day 83, in December) and
 466 summer (WY day 333, in August). Similar to PE_{SW} , this error increases with time. In December,
 467 the error is nearly zero for forcing spatial resolutions of 1.5 and 4.5 km whereas it is non-zero
 468 (with values close to 1 m) in August. Although the spatial resolutions of 13.5 and 40.5 km have
 469 non-zero errors at the first time step, the error increases considerably as the simulation proceeds.

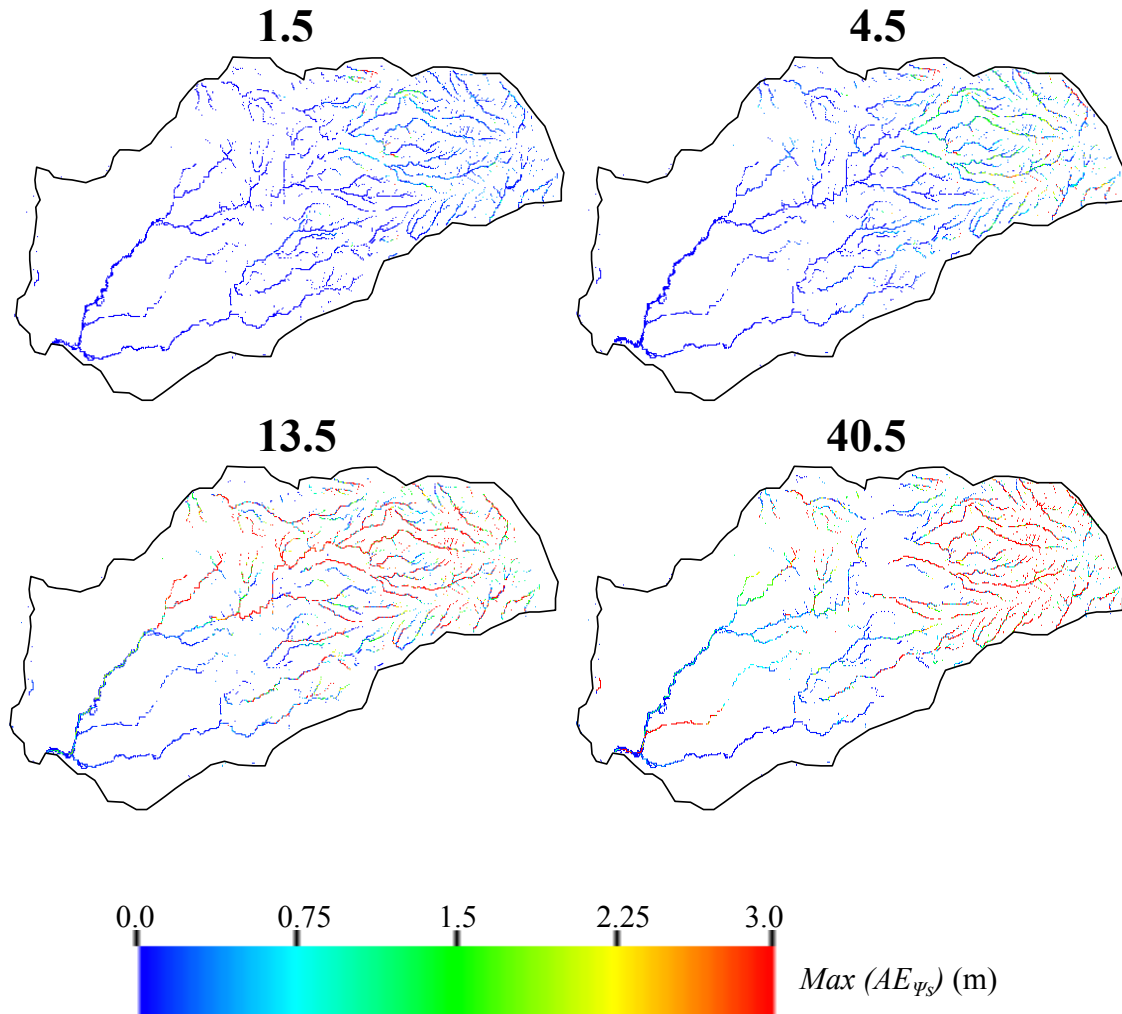

470 We note that the areas sensitive to the spatial resolution of the meteorological forcing data are
 471 approximately the same for all four resolutions. Indeed, the absolute error is null at the intrusion
 472 on contrary to the Central Valley and in the Sierra Nevada Mountains. Interestingly, these two
 473 zones have different areas of influence, in the Central Valley, the errors are non-zero everywhere
 474 except close to the river, which is contrary to the trend observed in the Sierras. This is related to
 475 the geological nature of these environments. Due to the very low permeability and low surface
 476 roughness of Sierra Nevada Mountains, any water from precipitation will quickly contribute to
 477 surface runoff, which is highly sensitive to the spatial resolution of forcing, on contrary to the
 478 Central Valley characterized by high permeability and low manning coefficient and therefore
 479 low overland flow.

480
 481 Figure 9: Absolute error of surface pressure-head (AE_{ψ_s}) with respect to the highest spatial
 482 resolution of meteorological forcing (0.5 km). Results are shown in winter (WY day 83, in
 483 December) and summer (WY day 333, in August).

Within the water year, the maximum absolute error of surface water levels, $\max(AE_{\psi_s})$, is an important metric for understanding where, and to what degree, forcing resolution impacts the prediction of river dynamics. Figure 10 shows the spatial distribution of $\max(AE_{\psi_s})$, which is obtained by an analysis of the maximum difference in surface water levels between the results obtained with the highest spatial resolution of forcing (0.5 km) and the four other resolutions for all time steps. Maximum differences in surface water levels are shown in absolute values (in units of meters) and are at any point in time in the simulated water year. Differences in surface water levels at a given time are as high as 3 m. High values of differences are mainly located in the headwater region of the watershed, although some lower regions of the model such as one tributary of the main stem of the Cosumnes near the river outlet also show $\max(AE_{\psi_s})$ as high as 3 m. These results suggest that although the impact of forcing spatial resolutions on the global (i.e watershed-scale) surface water storage is small to insignificant (see Figure 8), at a given point in space and time, differences may be considerable. This can be especially problematic for calibration and validation purposes where input parameters of the model are adjusted to reproduce the observed surface water levels with the model. In this case, differences between measured and simulated hydrologic variables are assumed to be due to parametric uncertainties, when in reality the source of the error is the scale of the meteorological forcing. Adjusting the model parameters may potentially cause the model to inaccurately simulate the physics of the system.

4.4.2. Groundwater storage and water table depth

510

511

512

Figure 10: Spatial distributions of the maximum of Absolute Error of river height $\max(AE_{\psi_s})$ with respect to the highest spatial resolution of meteorological forcing (0.5 km).

Figure 11 depicts the percent error of groundwater storage PE_{GW} . For the cases considered here, the different spatial resolutions of forcing have very little impact on the total groundwater storage of the watershed.

513
514

515 Figure 11: Temporal variations of the percent error of groundwater storage (PE_{GW})
516 obtained with meteorological forcing at spatial resolutions of 1.5, 4.5, 13.5, and 40.5 km with
517 respect to the highest spatial resolution of meteorological forcing (0.5 km)

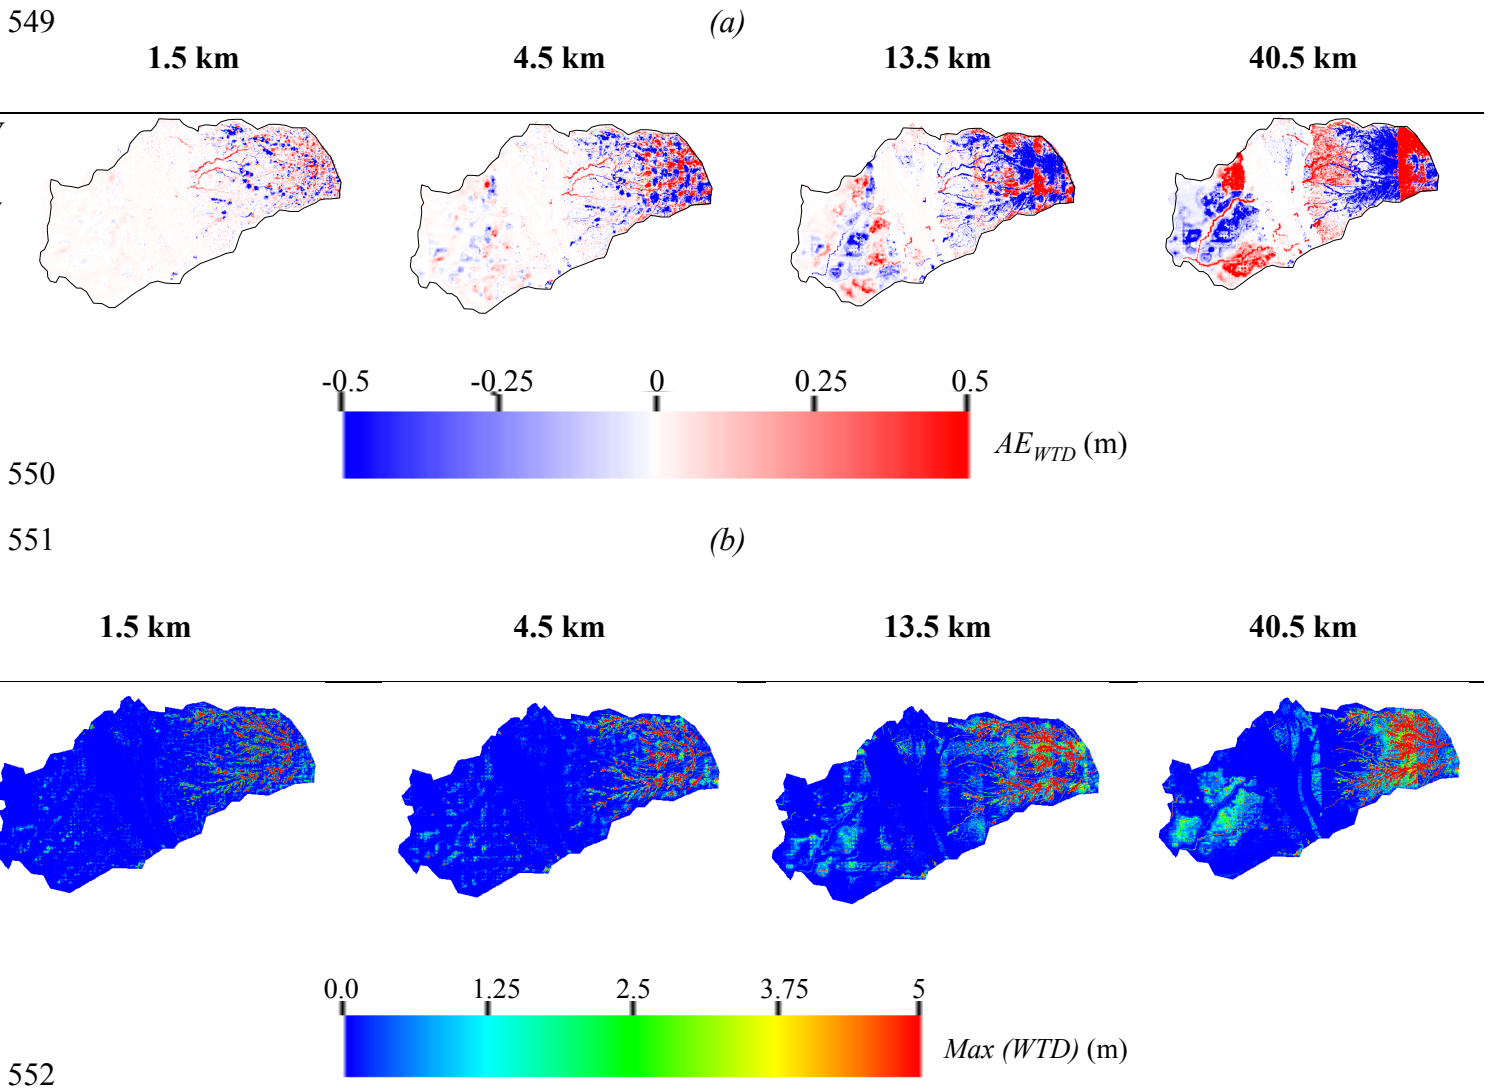

518

519 With the exception of the coarsest scale of forcing resolution towards the end of the
520 simulation, the error in groundwater storage for the different spatial resolutions of forcing yield
521 very similar results. Groundwater storage obtained with a forcing resolution of 13.5 km
522 overestimates the storage, however, this overestimation remains very low, on the order of 1% at
523 most times. In contrast, the groundwater storage results obtained with the 40.5 km forcing

524 resolution are close to the storage obtained with the finest scale of forcing resolution at the
525 beginning of the simulation, yet these errors reach 10% at the end of the simulation.

526 Figure 12a shows the maps of Water Table Depth (WTD) absolute error (AE_{WTD}) for the
527 four scales of forcing resolution relative to the results obtained with the 0.5 km forcing. Water
528 year day 333 (August) corresponding to baseflow conditions is used here because differences in
529 water table depth at the beginning of the simulation are too small for interpretation. Results show
530 both an over- and under- estimation of the water table depth as a function of the forcing
531 resolution (Figure 12a). Thus, while the global groundwater storage error is low as indicated in
532 Figure 11, an examination of the spatial trends shows that this is predominantly due to the
533 counterbalancing of positive and negative error in space. For all the spatial resolutions
534 considered, the Sierra Nevada Mountains are the most sensitive areas to the spatial resolution of
535 meteorological data, while the intrusion remains insensitive with almost zero errors. This is due
536 to the characteristics of the Sierra Nevada Mountains which include strong variations of
537 topography, snow dynamics, and low permeability rocks. The intrusive zone is composed of
538 extremely low permeability materials so it has no groundwater dynamics, as such the errors are
539 zero. The spatial resolutions of 1.5 and 4.5 km have generally little impact on the water table
540 depth in the Central Valley alluvial aquifers. Larger errors in water table depths are mostly
541 observed for the results obtained with the 13.5 and 40.5 km forcing. These errors are not uniform
542 and are most significant along the Cosumnes River, its tributaries, and outside urban areas. The
543 connection between the upper and lower point of the watershed, as well as the integrated nature
544 of the system, is apparent in the maps of AE_{WTD} . As already discussed, because the spatial
545 resolution of forcing impacts snowpack dynamics, evapotranspiration and infiltration rates and
546 patterns, streamflow distributions, it, therefore, impacts groundwater dynamics and the exchange

547 of groundwater and surface water. We highlight here that these differences accumulate over time
 548 as indicated by the errors that increase as the simulation progresses.

553 Figure 12: Spatial distributions of (a) the absolute error of Water Table Depth (WTD) (AE_{WTD})
 554 with respect to the highest spatial resolution of meteorological forcing (0.5 km) at WY day 333,
 555 and (b) the $max(AE_{WTD})$, with respect to the highest spatial resolution of meteorological forcing
 556 (0.5 km).

557

558 Figure 12b depicts the maximum differences (for all time steps) of the water table depth
559 in absolute value between the results obtained with the highest spatial resolution and the other
560 four spatial resolutions. As previously stated, due to the almost zero permeability of the
561 intrusion, the latter is insensitive to the spatial resolution of the meteorological data. The water
562 table depth differences are as high as 5 m in several places, particularly in the Sierra Nevada
563 Mountains, following mostly trends in topography. In the Central Valley, noticeable differences
564 are mainly observed in the areas near the rivers and close to the pumping wells.

565 Figure 13 shows the temporal variations of the difference in the water table depth
566 between the highest resolution and the four other resolutions at 6 selected points. We selected
567 points located in the Central Valley as this zone hosts an alluvium aquifer (see their location in
568 Figure 1). For all these points, we note that the differences are almost zero for the spatial
569 resolution of 1.5 km indicating that this spatial resolution is sufficient to represent the
570 groundwater dynamics of this region. The spatial resolution of 4.5 km also shows relatively low
571 differences, the latter is indeed zero at three points and only points 2, 4 and 5 have non-zero
572 differences, but these remain less than 50 cm. The strongest differences are observed for results
573 obtained with forcing spatial resolutions of 13.5 and 40.5 km; note that the coarsest resolution
574 does not necessarily give the highest differences. In fact, at points 4 and 5, the highest
575 differences are obtained with the resolution of 13.5 km, indicative of the complex over- and
576 under- estimation patterns of bias observed at these coarser resolutions of forcing. In general, the
577 use of these large-scale spatial resolutions of forcing can lead to an over- or under -estimation of
578 the pressure-head between 50 cm and 10 m. Thus, while our results indicate that the spatial
579 resolution of meteorological forcing has little impact on the total groundwater storage, at discrete
580 points within the watershed the spatial resolution of forcing is very important, especially for

581 resolutions greater than 4.5 km. Again, this is particularly an issue for model calibration
 582 purposes given that hydrologic numerical models are typically validated/calibrated by comparing
 583 the groundwater measurements with the model outputs. In this case, our results indicate that
 584 careful attention must be given to the spatial resolutions of forcing, as some errors are only due
 585 to the latter not to any model parameterization.
 586

587
 588 Figure 13: Absolute Error of the Water Table Depth (AE_{WTD}) with respect to the highest spatial
 589 resolution of meteorological forcing (0.5 km) at six selected points.

590
 591

592 **5. Conclusions**

593 Numerical methods that solve integrated hydrologic models are becoming increasingly
 594 precise and spatially resolved. They thus require high-resolution and accurate input data such as
 595 meteorological forcing. However, while integrated hydrologic models increase in precision, the

596 meteorological data used are most often of coarse resolution whereas these data are strongly
597 heterogeneous in space. It is, therefore, important to better understand not only how the
598 uncertainties associated with the spatial distribution of meteorological data affect hydrologic
599 model outputs, but also the meteorological forcing spatial resolution required to minimize these
600 uncertainties. Moreover, thanks to the advancement of atmospheric models, it is now possible to
601 obtain meteorological data closer to that of the resolution of hydrologic models.

602 In this study, we utilized the integrated hydrological model ParFlow-CLM to simulate the
603 hydrodynamics of a representative Californian watershed spanning the Sierra Nevada Mountains
604 and the Central Valley interface. The Cosumnes offers a unique opportunity to study semi-
605 natural flow conditions given its rare un-dammed river, one of the last in the state. Five different
606 spatial resolutions of meteorological data were obtained via the dynamical downscaling approach
607 of the Weather Research Forecasting (WRF) model. Both models were simulated in a high-
608 performance computing environment to accommodate the high spatio-temporal resolution of the
609 study. The Cosumnes watershed is characterized by strong variations of topography, geology,
610 land use and land cover leading to highly heterogeneous and complex atmospheric and
611 hydrologic dynamics, and is, therefore, an excellent candidate to better understand how the
612 different spatial resolutions of forcing affect the results of an integrated hydrologic model of a
613 watershed which include snow water equivalent, evapotranspiration, infiltration, surface and
614 groundwater levels.

615 Our results show that the impact of the spatial resolution of meteorological data depends
616 on the hydrologic component of interest, as well as the temporal and spatial scale.

- 617 • Snow accumulation and snowmelt are considerably impacted by forcing
618 resolution, even at the watershed scale. The results obtained with the different

619 spatial distributions suggest that meteorological data with a resolution close to the
620 one of the hydrologic model is needed to accurately reproduce the Snow Water
621 Equivalent (*SWE*) distribution as well as the total volume of *SWE*. Our results
622 show that the errors of *SWE* depend on both the spatial resolution of forcing and
623 topography and can be greater than 100 mm for a single point in time.

624 • At the watershed scale, global estimates of total evapotranspiration fluxes are
625 more or less insensitive to the spatial resolution of forcing. However, to obtain an
626 accurate spatial distribution of evapotranspiration which shows impacts of land
627 use, geology, and topography, higher resolutions of forcing are needed.

628 • The results obtained with infiltration are quite similar to those of
629 evapotranspiration. Note that for these two processes, the percent errors induce by
630 a coarser resolution are most often significant after a precipitation event, and that
631 these errors quickly subside once the precipitation ends.

632 • Forcing spatial resolution does not impact total surface water storage at the
633 watershed scale. Even for the coarsest resolution of forcing (40.5 km), the error,
634 increasing with time, is approximately 5%. However, we emphasize that for the
635 surface water levels at one point and at a given time, the differences between the
636 highest spatial resolution of the forcing data and the four other resolutions can
637 exceed 3 m. Regions within the Sierra Nevada Mountains are the most sensitive to
638 the spatial resolution of forcing data.

639 • Similar to surface water storage, the five different spatial resolutions of forcing
640 considered in this study led to similar groundwater storages. Therefore, the spatial
641 resolution of forcing has very small impacts on the hydrology simulated at a

642 watershed scale or hydrologic unit, hence non-grid based hydrologic models are
643 likely to be less sensitive to the spatial resolution of forcing than numerical
644 models. However, at a local scale, the variations of pressure head in the
645 subsurface obtained with the different resolutions can differ considerably, with
646 error as high as 9 m, especially in the Central Valley alluvium aquifers.
647 Groundwater level variations are the result of the aggregated impacts of land
648 surface processes. As such, the spatial resolutions of forcing affecting land
649 surface processes also impact groundwater levels. Our results show that these
650 impacts on groundwater are delayed in time due to the timing of the transfer of
651 water from the land surface to the subsurface.

652 Although the total water balance of the five spatial-resolutions of the meteorological
653 forcing is the same, the different spatial resolutions lead to different hydrological processes that
654 change both in time and space. For a good representation of the land surface processes
655 (infiltration, evapotranspiration and snow dynamics), a spatial resolution of the meteorological
656 data which is close to that of the hydrologic model is required due to the instantaneity and
657 complexities of these phenomena. For the surface and subsurface processes, we demonstrated
658 that for this watershed and those with similar characteristics, a spatial resolution of 4.5 km is
659 sufficient to reproduce the general physical trends of the hydrology. As a result, satellite-based
660 products such as NLDAS (with a resolution of around 14 km) may induce errors that may limit
661 the use of their products if spatially accurate studies are needed. Because coarse spatial
662 resolutions of forcing may lead to very different groundwater and streamflow variations,
663 particular attention must be paid to the spatial resolution of meteorological data, especially in the
664 calibration and/or validation processes of numerical models. Indeed, the differences between the

665 measured and simulated hydrologic variables are not only due to the hydrodynamic parameters
666 of the model but may also be related to the parameterization of the meteorological data.

667 While in this study our focus is on the spatial distribution of meteorological data, future
668 studies will assess the propagation of uncertainties related to the temporal resolution of
669 meteorological forcing. Climate models are also used to predict the future weather conditions, it
670 would also be important to determine the ideal spatial-resolution of forcing in the context of a
671 warming climate. **Because, Hydrologic Response Unit (HRU) based hydrologic models are also**
672 **commonly used, future work could further assess the sensitivity of these models to the spatial**
673 **distribution of meteorological data.**

679

680

681

682

683 **Appendix A**

684 *A.1 Mass Balance Validation*

685 The physics represented for the four WRF domains are identical, except for cumulus
686 parameterization which is used for domains d01 (resolution of 13.5 km) and d02 (resolution of
687 13.5 km) and not for domains d03 (resolution of 1.5 km) and d04 (resolution of 0.5 km). This is
688 due to the fact that WRF can resolve convection explicitly at resolutions higher than around 4 km
689 (Gilliland and Rowe, 2007). To assess the sensitivity of the WRF simulated forcings to this
690 inevitable inconsistency between the domains, we compare watershed-wide daily precipitation
691 and air temperature in Figure A1. Our results show that there are minimal differences (RMSE of
692 less than 0.002 m and 0.01°C for precipitation and temperature, respectively) between the four
693 WRF domains, when averaged over the watershed. This shows that the only difference between
694 the forcings from WRF domains are due to different resolutions and the effects of described
695 difference in physics representations are limited.

696

697 Figure A1: Daily variations of WRF simulated precipitation (a) and air temperature (b), averaged

698 over the entire watershed for spatial resolutions of 0.5, 1.5, 4.5, 13.5, and 40.5 km.

699

700 *A.2 Spatial distributions of precipitation and temperature over the domain d04*

701 Figure A2: Spatial distributions of precipitation associated with the five spatial resolutions of
702 meteorological at three selected times corresponding to periods where the storm has high (day 1)
703 and low (day 83) intensity and a time a very located and low intensity (day 125).
704

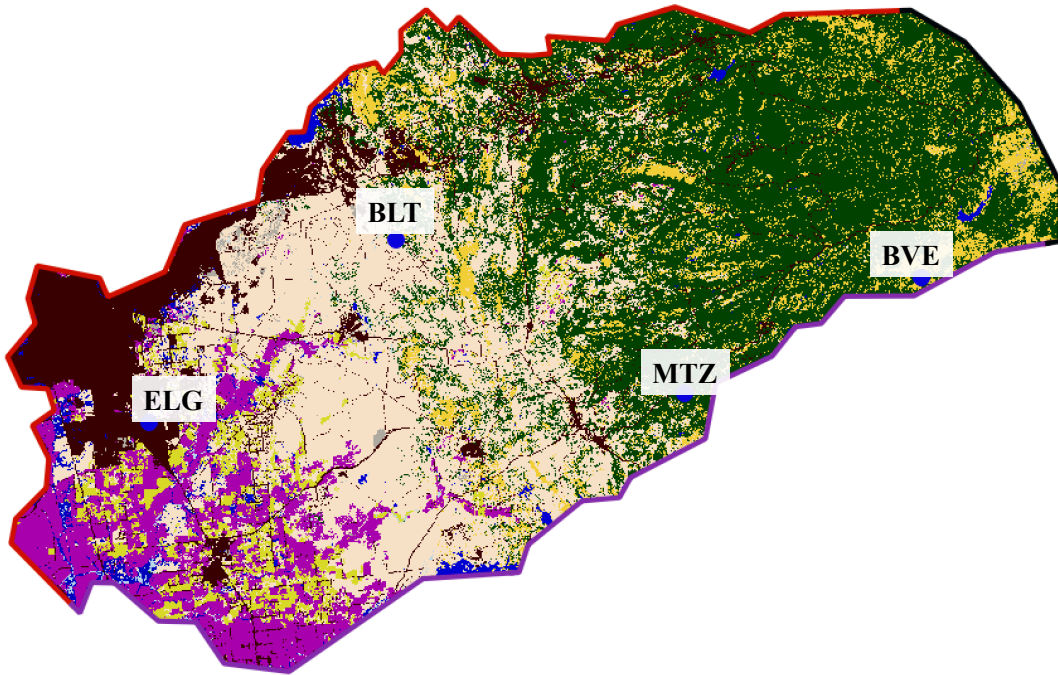

706 Figure A3: Spatial distributions of temperature associated with the five spatial resolutions of
707 meteorological at three selected times corresponding to periods where the storm has high (day 1)
708 and low (day 83) intensity and a time a very located and low intensity (day 125).

709

710

711 *A.3 Comparisons with ground measurements*

712 We compared simulated precipitation and temperature with ground measurements. We
713 selected four stations, which continuously measure precipitation and temperature. The Figure
714 below shows the location of these stations as well as the comparisons. We only show
715 comparisons with the results obtained with the highest resolution (i.e. d04) for graphical
716 purposes.

717
718 Figure A4a: location of the four selected stations. These stations allow comparing the simulated
719 precipitation and temperature with measurements in the Sierra Nevada mountains (BVE and
720 MTZ), the volcanic intrusion (BLT), and the Central Valley (ELG).

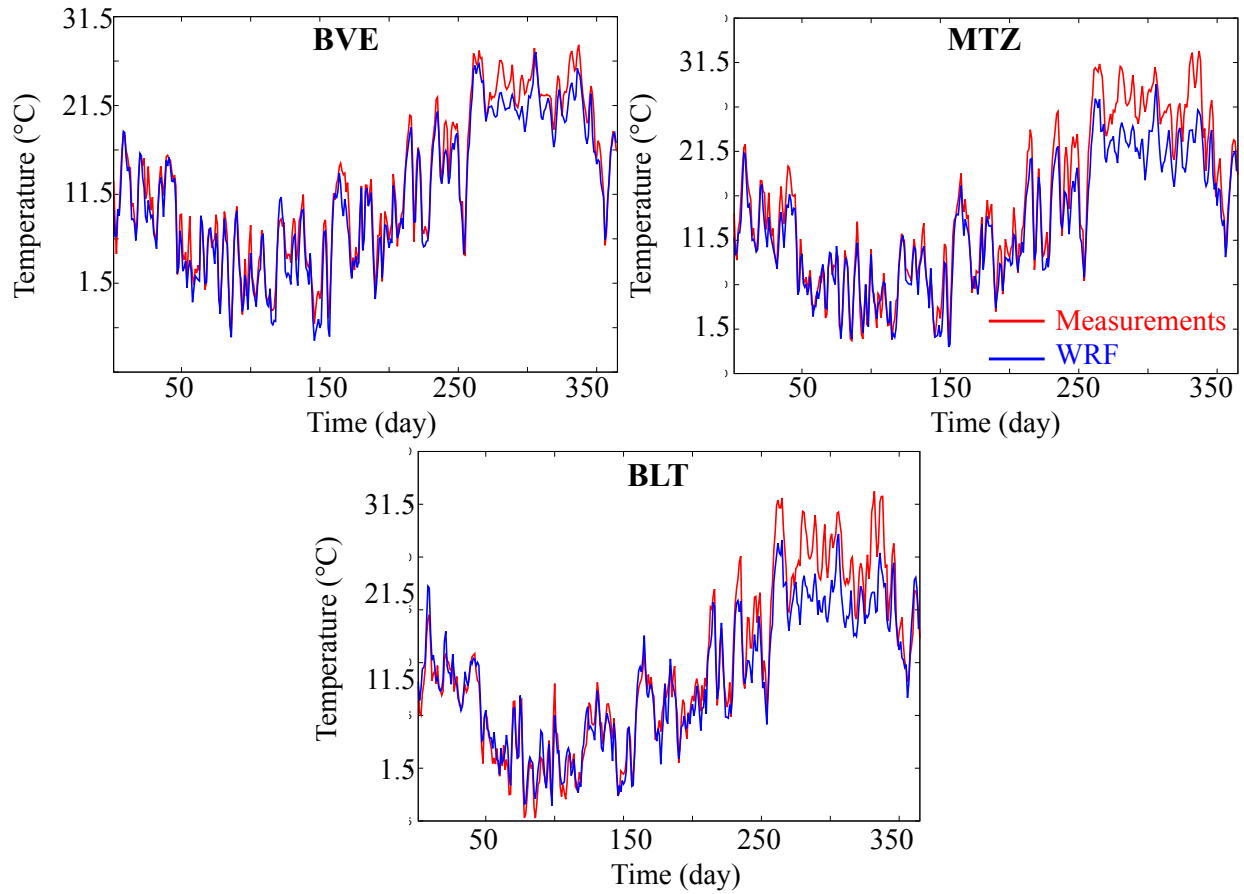

721

722

723

724 Figure A4b: Comparisons between simulated and measured precipitation at the four selected
 725 stations. The reasonable match between measurements and simulations at different locations
 726 allows gaining confidence in the WRF simulations to reproduce the atmospheric dynamics at
 727 different elevations

728

729 Figure A4c: Comparisons between the simulated and measured temperature at three selected
 730 stations. The station ELG does not have measurements of temperature. Like the precipitations
 731 results, our comparisons indicate a reasonable match between measurements and simulations.

732

733

734 **Author contribution**

735 The authors contribute equally to this work.

736

737 **Competing interests**

738 The authors declare that they have no conflict of interest.

739

740 **Acknowledgements**

741 This work was supported by <http://dx.doi.org/10.13039/100007000> (LDRD) funding from
742 Berkeley Lab, provided by the Director, Office of Science, of the U.S. Department of Energy
743 under Contract No. DE-AC02-05CH11231. This research used computing resources from the
744 National Energy Research Scientific Computing Center, a DOE Office of Science User Facility
745 supported by the [http:// dx.doi.org/10.13039/100006132](http://dx.doi.org/10.13039/100006132) of the U.S. Department of Energy under
746 Contract No. DE-AC02-05CH11231.

747 The authors are thankful to Peter-James Dennedy-Frank for his careful reading and constructive
748 suggestions and comments.
