16 **Abstract.** Isotopic labeling techniques have the potential to minimize the uncertainty of plant root water uptake (RWU)  
17 profiles estimated through multi-source (statistical) modeling, by artificially enhancing soil water isotopic gradient.  
18 On the other end of the modelling continuum, physical models can account for hydrodynamic constraints to RWU if  
19 simultaneous soil and plant water status data is available.

20 In this study, a population of tall fescue (*Festuca arundinacae* cv Soni) was grown in a macro-rhizotron and monitored  
21 for a 34-hours long period following the oxygen stable isotopic (<sup>18</sup>O) labeling of deep soil water. Aboveground  
22 variables included tiller and leaf water oxygen isotopic compositions ( $\delta_{\text{tiller}}$  and  $\delta_{\text{leaf}}$ ) as well as leaf water potential  
23 ( $\psi_{\text{leaf}}$ ), relative humidity, and transpiration rate. Belowground profiles of root length density (RLD), soil water content  
24 and isotopic composition were also sampled. While there were strong correlations between hydraulic variables as well  
25 as between isotopic variables, the experimental results underlined the partial disconnection between temporal dynamics  
26 of hydraulic and isotopic variables.

27 In order to dissect the problem, we reproduced both types of observations with a one-dimensional physical model of  
28 water flow in the soil-plant domain, for 60 different realistic RLD profiles. While simulated  $\psi_{\text{leaf}}$  followed clear  
29 temporal variations with little differences across plants as if they were “on board of the same rollercoaster”, simulated

30  $\delta_{\text{tiller}}$  values within the plant population were rather heterogeneous (“swarm-like”) with relatively little temporal  
 31 variation and a strong sensitivity to rooting depth. The physical model thus explained the discrepancy between isotopic  
 32 and hydraulic observations: the variability captured by  $\delta_{\text{tiller}}$  was spatial and may not correlate with the temporal  
 33 dynamics of  $\psi_{\text{leaf}}$ .  
 34 For comparison purposes, a Bayesian statistical model was also used to simulate RWU. While they predicted relatively  
 35 similar cumulative RWU profiles, the physical model could differentiate spatial from temporal dynamics of the isotopic  
 36 signature. It further supported that concomitant increases of soil water content and isotopic composition observed  
 37 overnight above the soil region influenced by the labeling were due to hydraulic lift.

### 38 **List of variables with symbols and units**

39 Name	Symbol	Units
40 Leaf water potential/head:	$\psi_{\text{leaf}}$	MPa
41 Soil water potential/head:	$\psi_{\text{soil}}$	MPa
42 Water volumetric mass:	$\rho_w$	kg m <sup>-3</sup>
43 Soil apparent density:	$\rho_b$	kg m <sup>-3</sup>
44 Soil gravimetric water content:	$\theta_{\text{grav}}$	kg kg <sup>-1</sup>
45 Soil volumetric water content:	$\theta$	m <sup>3</sup> m <sup>-3</sup>
46 Intensity of water uptake (sink term):	$S$	d <sup>-1</sup>
47 Transpiration rate per unit soil area:	$T$	m d <sup>-1</sup>
48 Air relative humidity	RH	%
49 Soil horizontal area:	$A_{\text{soil}}$	m <sup>2</sup>
50 Soil layer depth (for each layer):	$z$	m
51 Soil layer thickness (for each layer):	$\Delta Z$	m
52 Root length (for each soil layer):	$l_{\text{root}}$	m
53 Relative Root Water Uptake	rRWU	dimensionless
54 Best run	$br$	dimensionless
55 Root Length Density:	RLD	m m <sup>-3</sup>
56 Soil water oxygen isotopic composition:	$\delta_{\text{soil}}$	‰
57 Tiller water oxygen isotopic composition:	$\delta_{\text{tiller}}$	‰
58 Leaf water oxygen isotopic composition:	$\delta_{\text{leaf}}$	‰
59 Soil-root system conductance:	$K_{\text{soil-root}}$	m <sup>3</sup> MPa <sup>-1</sup> s <sup>-1</sup>
60 Soil-root radial conductance:	$K_{\text{radial}}$	m <sup>3</sup> MPa <sup>-1</sup> s <sup>-1</sup>
61 Root radial conductivity:	$L_{\text{pr}}$	m MPa <sup>-1</sup> s <sup>-1</sup>
62 Root axial conductance:	$K_{\text{axial}}$	m <sup>3</sup> MPa <sup>-1</sup> s <sup>-1</sup>
63 Equivalent root axial conductivity:	$k_{\text{axial}}$	m <sup>4</sup> MPa <sup>-1</sup> s <sup>-1</sup>
64 Soil hydraulic conductivity:	$k_{\text{soil}}$	m <sup>2</sup> MPa <sup>-1</sup> s <sup>-1</sup>
65 Saturated soil hydraulic conductivity:	$k_{\text{sat}}$	m <sup>2</sup> MPa <sup>-1</sup> s <sup>-1</sup>
66 Soil hydraulic conductivity parameter	$\lambda$	dimensionless
67 Soil relative water content	$Se_j$	dimensionless
68		

## 69 **1 Introduction**

70 Since the seminal work of Washburn and Smith [1934] where it was first reported that willow trees did not fractionate  
71 hydrogen stable isotopes in a hydroponic water solution during root water uptake (RWU), water stable isotopologues  
72 ( $^1\text{H}^2\text{H}^{16}\text{O}$  and  $^1\text{H}_2^{18}\text{O}$ ) have been used as indicators for plant water sources in soils. In their review, Rothfuss and  
73 Javaux [2017] reported in the period 2015-2016 about no less than 40 publications in which RWU was retrieved from  
74 stable isotopic measurements. Novel measuring techniques (e.g., cavity ring-down spectroscopy – CRDS and off-axis  
75 integrated cavity output spectroscopy – ICOS) providing ways for fast and cost-effective water stable isotopic analyses  
76 certainly enable and emulate current research in that field. Water stable isotopologues are no longer powerful tracers  
77 waiting for technological developments [Yakir and Sternberg, 2000] but are on the verge to be used to their full  
78 potential for addressing eco-hydrological research questions and identify processes in the soil-plant-atmosphere  
79 continuum [Werner et al., 2012; Dubbert and Werner, 2019; Sprenger et al., 2016].

80 The isotopic determination of RWU profiles is based on the principle that the isotopic composition of xylem water at  
81 the outlet of the root system (i.e., in the first aerial and non-transpiring node of the plant) equals the sum of the product  
82 between the soil water isotopic composition and relative contribution to RWU across plant water sources. Results come  
83 only with reasonable precision when (i) the soil water isotopic composition depth gradient is strong and monotonic  
84 (thus avoiding issues of identifiability) and (ii) the temporal dynamics of RWU and soil water isotopic composition is  
85 relatively low. Condition (i) is fulfilled mostly at the surface of the soil, while soil water isotopic composition gradients  
86 become usually lower or null with increasing depth (due to the isotopic influence of the groundwater table and  
87 increasing dispersion with depth). As illustrated by Oerter and Bowen [2019], the lateral variability of the soil water  
88 isotopic composition profiles can become significant in the field and could have great implications on the  
89 representability and meaningfulness of isotopic-derived estimate of RWU profiles. Condition (ii) is often neglected  
90 but is required due to the instantaneous nature of the sap flow samples.

91 To overcome these limitations, labeling pulses have been increasingly used in recent works to artificially alter the  
92 natural isotopic gradients [e.g., Beyer et al., 2016; Beyer et al., 2018; Grossiord et al., 2014; Jesch et al., 2018;  
93 Volkmann et al., 2016b]. However, a precise characterization of the artificial spatial (i.e., lateral and vertical) and  
94 temporal distributions of the soil water isotopic composition (driven by e.g., soil isotopic water flow) is crucial. The  
95 punctual assessments of the isotopic composition profiles following destructive sampling in the field and subsequent  
96 extraction of water in the laboratory might neither be spatially nor temporally representative and can lead to erroneous  
97 estimates of RWU profiles [Orlowski et al., 2018; Orlowski et al., 2016a].

98 The vast majority of isotopic studies use statistical (e.g., Bayesian) modeling to retrieve RWU profile solely from the  
99 isotopic composition of water extracted in the soil and the shoot [Rothfuss and Javaux, 2017]. However, when data on  
100 soil and plant water status is available, hydraulic modeling tools can also be used to connect different data types in a  
101 process-based manner and estimate root water uptake profiles [Passot et al., 2019]. Some of the most simplistic models

102 use 1-D relative root distribution and plant-scale hydraulic parameters [Sulis et al., 2019], while the most complex rely  
103 on root architectures and root segment permeabilities [Meunier et al., 2017c]. Only a handful of studies coupled  
104 isotopic measurements in plant tissues and soil material with models describing RWU in a mechanistic manner. For  
105 instance, Meunier et al. [2017a] could both locate and quantify the volume of redistributed water by *Lolium multiflorum*  
106 by labeling of the soil with  $^{18}\text{O}$  enriched water under controlled conditions.

107 Building on the work of Meunier et al. [2017a], the objective of the present study is to (i) model in a physically-based  
108 manner (i.e., by accounting for soil and plant and environmental factors) the temporal dynamics of the isotopic  
109 composition of RWU of a population of *Festuca arundinacae* cv Soni. (tall fescue) during a semi-controlled  
110 experiment following an isotopic labeling of deep soil water, (ii) investigate the implication of the model-to-data fit  
111 quality in terms of meaningfulness of the isotopic information to reconstruct RWU profiles, and finally (iii) confront  
112 the simulated root water uptake profiles with estimations obtained on basis of isotopic information alone (i.e., provided  
113 by a Bayesian mixing model).

## 114 **2 Material and methods**

115 Our experiment consisted in supplying labeled water from the bottom to a macro-rhizotron in which tall fescue was  
116 grown. Data on soil and plant oxygen stable isotopic signature and hydraulic status were monitored for 34 hours. In  
117 the following, the oxygen isotopic composition of water will be expressed in per mil (‰) on the “delta” ( $\delta^{18}\text{O}$ ) scale  
118 with respect to the international water standard V-SMOW [Gonfiantini, 1978].

### 119 **2.1 Rhizotron experimental setup**

120 The macro-rhizotron (dimensions: 1.6 m x 1.0 m x 0.2 m, see picture in Appendix A) was placed inside a glasshouse  
121 (INRA Lusignan, France), where it was continuously weighed (KE1500, Mettler-Toledo, resolution: 20 g) to monitor  
122 water effluxes (i.e., bare soil evaporation or evapotranspiration). Underneath the soil compartment and in contact with  
123 it, a water reservoir (height: 0.1 m) filled with gravel acted as water table and allowed the supply of water to the  
124 rhizotron. The rhizotron was equipped with two sets of CS616 time domain reflectometer (TDR) profiles (Campbell  
125 Scientific, USA) with 30 cm long probe rods positioned at six depths (−0.05, −0.10, −0.30, −0.60, −1.05 and −1.30 m)  
126 and one profile of tensiometers (SMS 2000, SDEC-France) located at four depths (−0.05, −0.10, −0.30, and −0.60 m)  
127 in order to monitor the evolution of soil water volumetric content ( $\theta$ , in  $\text{m}^3 \text{m}^{-3}$ ) and matric potential ( $\psi_{\text{soil}}$ , in MPa).  
128 Finally, relative humidity (RH, %) was recorded above the vegetation with one humidity and temperature probe  
129 (HMP45D, Vaisala, Finland). The transparent polycarbonate sides (front and back) allowed the daily observations of  
130 root maximal depth. The experimental setup allowed precisely controlling the amount and  $\delta^{18}\text{O}$  of soil input water.

131 Another important feature was the soil depth (i.e., 1.60 m) which minimized the influence of the water table on  
132 superficial layers water content and  $\delta^{18}\text{O}$ .

## 133 **2.2 Soil properties and installation**

134 The soil substrate originates from the Lp horizon of an agricultural field part of the Observatory of Environment  
135 Research (ORE), INRA Lusignan, France (0°60W, 46°250N) which is classified as District Cambisol (particle size  
136 distribution: sand 15%, silt 65%, clay 20%). Prior installation in the rhizotron, the substrate was sieved at 2 mm and  
137 dried out in an air oven at 110 °C during 48 h to remove most of the residual water. 450 kg of soil was filled in the  
138 rhizotron by 0.10 m increment and compacted in order to reach a dry bulk density value of  $\rho_b = 1420 \text{ kg m}^{-3}$ . The  
139 closed-form soil water retention curve of van Genuchten [1980] was derived in a previous study by Meunier et al.  
140 [2017a] from synchronous measurements of soil water content and matric potential from saturated to residual water  
141 content (see Appendix B for its hydraulic parameters). It was used to compute the soil water matric potential ( $\psi_{\text{soil}}$ , in  
142 MPa) on basis of volumetric water content data during the present experiment.

## 143 **2.3 Experimental protocol**

144 After installation, the soil was gradually flooded with local water ( $\delta^{18}\text{O} = -6.8 \text{ ‰}$ ) from the bottom reservoir up to the  
145 top of the profile for a period of three days in order to reduce as much as possible the initial lateral and vertical  
146 heterogeneities in water content and  $\delta^{18}\text{O}$ . The tall fescue (*Festuca arundinaceae* cv Soni) was sown at a seeding  
147 density of  $3.6 \text{ g m}^{-2}$  (which corresponds for the rhizotron surface area of  $0.2 \text{ m}^2$  to roughly 300 plants) when soil water  
148 content reached  $0.25 \text{ m}^3 \text{ m}^{-3}$  (corresponding to pF 2.3) at  $-0.05 \text{ m}$ , as measured by the soil water sensors, and emerged  
149 12 days later. During a period of 165 day following seeding, the tall fescue cover was exclusively watered from the  
150 reservoir with local water in order to (i) keep the soil bottom layer ( $< -1.3 \text{ m}$ ) close to water saturation, and to (ii) not  
151 to disrupt the natural soil water  $\delta^{18}\text{O}$  profile.

152 166 days after seeding (DaS 166) the following conditions were fulfilled: (i) there was a strong soil water content  
153 gradient between the soil deep [ $-1.5 \text{ m}$ ,  $-1.0 \text{ m}$ ] and superficial [ $-0.3 \text{ m}$ ,  $0 \text{ m}$ ] layers, (ii) the tall fescue roots had  
154 reached a depth of  $-1.5 \text{ m}$  (observed through polycarbonate transparent sides). That same day at 17:00, the reservoir's  
155 water was labelled and its  $\delta^{18}\text{O}$  measured at  $+470 \text{ ‰}$ . Soil was sampled before (DaS 166 - 15:45) and after labeling on  
156 DaS 167 - 07:00, DaS 167 - 17:00 and DaS 168 - 05:00 using a 2 cm diameter auger through the transparent  
157 polycarbonate side of the rhizotron on four occasions from the surface down to  $-1.3 \text{ m}$  for the determination of soil  
158 gravimetric water content ( $\theta_{\text{grav}}$ , in  $\text{kg kg}^{-1}$ ) and oxygen stable isotopic composition ( $\delta_{\text{soil}}$ , in ‰). Gravimetric water  
159 content was then converted to volumetric water content ( $\theta = \theta_{\text{grav}} * \rho_b / \rho_w$ , in  $\text{m}^3 \text{ m}^{-3}$ , where  $\rho_b$  is the bulk soil density  
160 and  $\rho_w$  is the water density). The hypothesis of a constant value for  $\rho_b$  across the reconstructed soil profile was further

161 validated from the quality of the linear fit (coefficient of determination  $R^2 = 1.0$ ) between the  $\theta$  values measured by the  
162 sensors at the six available depths and ( $-0.05$ ,  $-0.10$ ,  $-0.30$ ,  $-0.60$ ,  $-1.05$  and  $-1.30$  m) and those computed from  $\theta_{\text{grav}}$ .  
163 On 40 occasions during a 34-hour long period three whole plants were sampled from the vegetation (i.e., 120 plants  
164 were sampled in total from the cover). Each plant's tiller and leaves were pooled into two separate vials. Dead material  
165 as well as the oldest living leaf around each tiller were removed in order not to contaminate tiller samples with  
166 transpiring material [Durand et al., 2007]. In addition, air water vapor was collected from the ambient atmosphere  
167 surrounding the rhizotron. The air was run at a flow rate of  $1.5 \text{ l min}^{-1}$  through two glass cold traps in series immersed  
168 in a mixture of dry ice and pure ethanol at  $-80^\circ\text{C}$ . Water from plant (i.e., tillers and leaves) and soil samples was  
169 extracted by vacuum distillation for 14 to 16 hours depending on the sample mass (e.g., ranging between 18 to 28 g  
170 for soil) at temperatures of 60 and  $90^\circ\text{C}$ , respectively. The residual water vapor pressure at the end of each successful  
171 extraction procedure invariably reached  $10^{-1}$  mbar. The oxygen isotopic compositions of tiller, leaf, and soil water  
172 (i.e.,  $\delta_{\text{tiller}}$ ,  $\delta_{\text{leaf}}$ , and  $\delta_{\text{soil}}$ ) together with that of atmospheric water vapor ( $\delta_{\text{atm}}$ ) were measured with an IRMS (Isoprep  
173 18 - Optima, Fison, Great-Britain, precision accuracy of 0.15 ‰). Finally, leaf water potential ( $\psi_{\text{leaf}}$ , in MPa) was  
174 monitored with a pressure chamber on two leaves per sampled plant, and evapotranspiration rate (in  $\text{m d}^{-1}$ ) was derived  
175 from the changes in mass of the rhizotron at the same temporal scale as plant sampling.

176 Root biomass was determined from the horizontal sampling of soil between the polycarbonate sides using a 2 cm  
177 diameter auger at  $-0.02$ ,  $-0.08$ ,  $-0.10$ ,  $-0.40$ ,  $-0.55$ ,  $-0.70$ ,  $-0.90$ ,  $-1.10$ , and  $-1.30$  m soil depth. Each depth was  
178 sampled once to thrice. Each soil core was washed of soil particles and roots were collected over a 0.2 mm mesh filter,  
179 and dried at  $60^\circ\text{C}$  for 48 hours. Finally, Root Length Density (RLD, in  $\text{m root (m soil)}^{-3}$ ) distribution was determined  
180 from the root dry mass using the specific root length determined by Gonzalez-Dugo et al. [2005] specifically for tall  
181 fescue ( $95 \text{ m g}^{-1}$ ). The reader is referred to Appendix C for an overview of the type and timing of the different  
182 destructive measurements during the intensive sampling period.

#### 183 **2.4 Modeling of RWU and $\delta_{\text{tiller}}$**

184 The experimental setup included about 300 tall fescue plants. In order to limit the computational requirement in the  
185 inverse modelling loop, we only generated 60 virtual root systems whose rooting depths ranged from  $-1.30$  to  $-1.60$   
186 m depth [based on our own observations and those of the literature, e.g., Schulze et al., 1996; Fan et al., 2016] with  
187 the root architecture simulator CRootBox [Schnepf et al., 2018], so that the simulated RLD matched observations (Fig.  
188 1a). In order to reach the right amount of plants, each root system was replicated 5 times, forming a “group”. Each  
189 group was assumed to occupy one sixtieth of the total horizontal area, and considered as a “big root” hydraulic network  
190 (5 identical plants per “big root”) with equivalent radial and axial hydraulic conductances (thus neglecting architectural  
191 aspects but accounting for each group's respective root length density profile).

192 The radial soil-root conductance between the bulk soil and each group's ( $i$ ) root surfaces in soil layer  $j$  ( $K_{radial,j}$ ,  $m^3$   
 193  $MPa^{-1} d^{-1}$ ), as derived by Meunier et al. [2017a], was assumed as variable in time ( $t$ ):

$$194 \quad K_{radial,i,j}(t) = \frac{2\pi r_{root} \cdot l_{root,i,j} \cdot B_j \cdot L_{pr} \cdot k_{soil,j}(t)}{B_j \cdot k_{soil,j}(t) + r_{root} \cdot L_{pr}} \quad (1)$$

195 with  $r_{root}$  (m) the root radius,  $l_{root,i,j}$  (m) the root length of plants of group  $i$  in soil layer  $j$ ,  $L_{pr}$  ( $m MPa^{-1} d^{-1}$ ) the root  
 196 radial hydraulic conductivity,  $k_{soil,j}$  ( $m^2 MPa^{-1} d^{-1}$ ) the soil hydraulic conductivity in layer  $j$ , and  $B_j$  (dimensionless) a  
 197 geometrical factor simplifying the horizontal dimensions into radial domains between the bulk soil and root surfaces,  
 198 as given by Schroeder et al. [2009]:

$$199 \quad B_j = \frac{2(1-\rho_j)(1+\rho_j)}{2\rho_j^2 \ln \rho_j - \rho_j^2 + 1} \quad (2)$$

200 where  $\rho$  (dimensionless) represents the ratio of the distance between roots and the root averaged diameter. It can be  
 201 deduced from the observed root length density ( $RLD_j$ ,  $m m^{-3}$ ):

$$202 \quad \rho_j = \sqrt{\frac{1}{\pi RLD_j}} \quad (3)$$

203 The soil hydraulic conductivity function of Mualem [1976] and van Genuchten [1980] was used:

$$204 \quad k_{soil,j}(t) = k_{sat} \cdot Se_j^\lambda(t) \left(1 - \left(1 - Se_j^{\frac{1}{m}}\right)^m\right)^2 \quad (4)$$

205 where  $k_{sat}$  ( $m^2 MPa^{-1} d^{-1}$ ),  $m$  (dimensionless) and  $\lambda$  (dimensionless) are soil hydraulic parameters (with  $m = 1 - 2/n$ )  
 206 and  $Se_j$ , the relative water content (dimensionless), is computed from the saturated ( $\theta_{sat}$ ,  $m^3 m^{-3}$ ) and residual ( $\theta_{res}$ ,  $m^3$   
 207  $m^{-3}$ ) water contents as:

$$208 \quad Se_j = \frac{\theta_j - \theta_{res}}{\theta_{sat} - \theta_{res}} \quad (5)$$

209 Unlike the geometrical parameter  $B$ , which defines a domain geometry between the bulk soil and roots of the overall  
 210 population, the  $l_{root}$  term is group specific ( $i$ ) and uses the simulated root length density profiles over an area  
 211 corresponding to one sixtieth of the total setup horizontal area:

$$212 \quad l_{root,i,j} = \frac{\Delta Z_j \cdot A_{soil} \cdot RLD_{i,j}}{60} \quad (6)$$

213 with  $\Delta Z$  (m) and  $A_{soil}$  ( $m^2$ ) the soil layer thickness and horizontal surface area, respectively.

214 To finalize the connection between root xylem and shoot, axial conductances per root system group ( $K_{axial}$ ,  $m^3 MPa^{-1}$   
 215  $d^{-1}$ ) were calculated as equivalent "big root" specific axial conductance per root system group ( $k_{axial}$ ,  $m^4 MPa^{-1} d^{-1}$ , to  
 216 be optimized by inverse modelling) as:

$$217 \quad K_{axial,j} = \frac{k_{axial}}{\Delta Z_j} \quad (7)$$

218 At each time step, both the total soil-root system conductance ( $K_{\text{soil-root}}$ ,  $\text{m}^3 \text{MPa}^{-1} \text{d}^{-1}$ ) and the standard sink distribution  
 219 ( $SSF$ , dimensionless, summing up to 1), were calculated from  $K_{\text{radial}}$  and  $K_{\text{axial}}$ , using the algorithm of Meunier et al.  
 220 [2017b]. The variable  $SSF$  is the relative distribution of water uptake in each soil layer under vertically homogeneous  
 221 soil water potential conditions [Couvreur et al., 2012], and  $K_{\text{soil-root}}$  represents the water flow per unit water potential  
 222 difference between the  $SSF$ -averaged bulk soil water potential and the leaf (assuming a negligible stem hydraulic  
 223 resistance [Steudle and Peterson, 1998]).

224 Adding soil hydraulic conductance to the one-dimensional hydraulic model of Couvreur et al. [2014] yields the  
 225 following solutions of leaf water potential ( $\psi_{\text{leaf}}$ , MPa) and water sink terms ( $S$ ,  $\text{d}^{-1}$ ) whose formulation approaches that  
 226 of Nimah and Hanks [1973]:

$$227 \quad \psi_{\text{leaf}}(t) = -\frac{T(t)}{K_{\text{soil-root}}(t)} + \sum SSF_j(t) \cdot \psi_{\text{soil},j}(t) \quad (8)$$

228 Where one sixtieth of the overall transpiration rate ( $T$ ,  $\text{m} \text{d}^{-1}$ ) is allocated to each group, and  $\psi_{\text{soil},j}$  (MPa) is the soil  
 229 water potential in soil layer  $j$ .

$$230 \quad S_{i,j}(t) = \frac{K_{\text{soil-root},i}(t) \cdot SSF_{i,j}(t) \cdot (\psi_{\text{soil},j}(t) - \psi_{\text{leaf},i}(t))}{A_{\text{soil}} \cdot \Delta Z_j} \quad (9)$$

231 where  $K_{\text{soil-root}}$  was assumed to control the compensatory RWU which arise from a heterogeneously distributed soil  
 232 water potential, due to large axial conductances [Couvreur et al., 2012].

233 Finally, the tiller water oxygen isotopic composition ( $\delta_{\text{tiller}}$ ) was calculated as the average of local soil water oxygen  
 234 isotopic compositions ( $\delta_{\text{soil}}$ ) weighted by the relative distribution of positive water uptakes (i.e., not accounting for  $\delta_{\text{soil}}$   
 235 at locations where water is exuded by the root), assuming a perfect mixture of water inside the root system [Meunier  
 236 et al., 2017a]:

$$237 \quad \delta_{\text{tiller}} = \frac{\sum_{S_j > 0} S_j \cdot A_{\text{soil}} \cdot \Delta Z_j \cdot \delta_{\text{soil}}(t)}{\sum_{S_j > 0} S_j(t) \cdot A_{\text{soil}} \cdot \Delta Z_j} \quad (10)$$

238 Like in the experiment,  $\delta_{\text{tiller}}$  from three plants were randomly pooled at each observation time. A hundred pools of 3  
 239 plants (possibly including several plants of the same group) were randomly selected in order to obtain the pooled  
 240 simulated  $\delta_{\text{tiller}}$  by arithmetic averaging.

241 The unknown parameters of the soil-root hydraulic model, i.e., the root radial conductivity ( $L_{\text{pr}}$ ), the root axial  
 242 conductance ( $k_{\text{axial}}$ ), the soil saturated hydraulic conductivity ( $k_{\text{sat}}$ ), and the soil tortuosity factor ( $\lambda$ ) were finally  
 243 determined by inverse modeling. For details on the procedure, the reader is referred to Appendix D.

244 In order to evaluate the robustness of the hydraulic model predictions (parametrized solely based on the reproduction  
 245 of shoot observations in the inverse modeling scheme) from independent perspectives, we also compared predictions  
 246 and measurements over 4 quantitative “soil-root domain” criteria: (i) the depth at which the transition between  
 247 nighttime water uptake and exudation ( $S_{i,j} < 0$ , i.e. release of water from root to soil) takes place, (ii) quantities of exuded

248 water and overnight increase of soil water content, (iii) the enrichment of labelled water at the depth where water  
249 content increase is observed overnight, and (iv) the order of magnitude of the optimal root radial conductivity value as  
250 compared to literature data in tall fescue.

251 Finally, and as a comparison point, the Bayesian inference statistical model SIAR [Parnell et al., 2013] was used to  
252 determine the profiles of water sink terms of ten identified potential water sources. These water sources were defined  
253 to originate from 10 distinct soil layers (0.00-0.03, 0.03-0.07, 0.07-0.15, 0.15-0.30, 0.30-0.60, 0.60-0.90, 0.90-1.20,  
254 1.20-1.32, 1.32-1.37, and 1.37-1.44 m) for which corresponding  $\delta_{\text{soil}}$  values were computed [Rothfuss and Javaux,  
255 2017]. SIAR solely bases its estimates from the comparison of  $\delta_{\text{tiller}}$  observations to the isotopic compositions of the  
256 soil water sources ( $\delta_{\text{soil}}$ ). For this,  $\delta_{\text{tiller}}$  measurements were pooled in twelve groups corresponding to different time  
257 periods, selected to best reflect the observed temporal dynamics of  $\delta_{\text{tiller}}$ . The reader is here referred to Appendix E for  
258 details on the model parametrization and running procedure.

## 259 **3 Results and discussion**

### 260 **3.1 Experimental data**

#### 261 **3.1.1 Soil profiles**

262 Figure 2a and b show a very stable soil water content profile and a more variable  $\delta_{\text{soil}}$  profile from DaS 166 - 15:45 to  
263 DaS 168 - 05:00. Soil was dry at the surface ( $0.058 \text{ m}^3 \text{ m}^{-3} < \theta < 0.092 \text{ m}^3 \text{ m}^{-3}$  for layer 0.015 - 0.040 m) whereas  
264 closer to saturation at depth  $-1.30 \text{ m}$  ( $\theta = 0.34 \text{ m}^3 \text{ m}^{-3} \pm 0.012 \text{ m}^3 \text{ m}^{-3}$ , estimated  $\theta_{\text{sat}} = 0.40 \text{ m}^3 \text{ m}^{-3}$ , see Appendix A).  
265 According to the measured soil matric potentials (Fig. 2c), soil water was virtually unavailable ( $\leq -1.5 \text{ MPa}$ ) above  $-$   
266  $0.5 \text{ m}$  depth. Soil moisture remained unchanged in the top 25 cm during the sampling period ( $\theta = 0.08 \pm 0.00 \text{ m}^3 \text{ m}^{-3}$ )  
267 as well as at  $-1.30 \text{ m}$  from DaS 166 - 15:45 to DaS 168 - 05:00 ( $\theta = 0.33 \pm 0.01 \text{ m}^3 \text{ m}^{-3}$ ), showing that roots were  
268 predominantly extracting water from deep soil layers.

269 Water in the top soil layers ( $-0.040 \text{ m} < z < -0.015 \text{ m}$ ) was isotopically enriched ( $-3.2 \text{ ‰} < \delta_{\text{soil}} < 0.3 \text{ ‰}$ ) as opposed  
270 to the deepest layer ( $\delta_{\text{soil}} = -7.34 \text{ ‰} \pm 0.30 \text{ ‰}$  at  $-1.30 \text{ m}$ ). Following labeling of the reservoir water on DaS 166 -  
271 17:00,  $\delta_{\text{soil}}$  reached a value of  $36.9 \text{ ‰}$  at  $-1.50 \text{ m}$  on DaS 167 - 17:00. The development of the vegetation on DaS 166-  
272 168 (LAI = 5.6) and the observed surface  $\theta$  values lead us to assume that the rhizotron water losses were due to  
273 transpiration flux solely (i.e., evapotranspiration = transpiration). The soil water oxygen isotopic exponential-shaped  
274 profiles were the product of fractionating evaporation flux, and to a great extent when the soil was bare or when the  
275 tall fescue cover was not fully developed. The differences in soil water oxygen isotopic profile observed at the four  
276 different sampling dates were therefore either due to lateral heterogeneity (e.g., upper soil layers), to the soil capillary  
277 rise of labelled water from the reservoir (deep soil layers), or to the hydraulic redistribution of water through roots (to  
278 the condition that the isotopic composition of the redistributed water differs from that of the soil water at the release

279 location). We noted an isotopic enrichment of 1.0 ‰ of soil water observed on DaS 168 - 05:00 at -0.9 m with respect  
280 to the mean  $\delta_{\text{soil}}$  value across previous sampling dates. This could partly be due to, e.g., upward preferential flow of  
281 labelled water from the bottom soil layers and therefore be the sign of the lateral heterogeneity of the soil. Another  
282 reason for this would be hydraulic redistribution of labelled water by the roots. It was however not possible to evaluate  
283 the relative importance of these three processes (lateral heterogeneity, capillary rise/preferential flow, and hydraulic  
284 redistribution) in the setting of the soil water isotopic profile since the physically-based soil-root model presented in  
285 section 2.4 does not account for soil liquid and vapor flow. This was also not the primary intent of the present study.  
286 The observed RLD profile (Fig. 1a) showed a typical exponential shape, i.e., maximum at the surface ( $5.42 \pm 0.34 \text{ cm}$   
287  $\text{cm}^{-3}$ ) down to a minimum at -1.10 m ( $0.540 \pm 0.35 \text{ cm cm}^{-3}$ ), while it increased again from the latter depth up to a  
288 value of  $1.660 \text{ cm cm}^{-3}$  at -1.30 m. This significant trend was most probably a direct consequence of the high soil  
289 water content value in this deeper layer.

### 290 **3.1.2 Plant water and isotopic temporal dynamics**

291 The temporal variation of  $\delta_{\text{tiller}}$  (Fig. 3a) was found to be either (i) moderate during day and night, i.e., from DaS 167 -  
292 06:00 to 11:00 ( $\delta_{\text{tiller}} = -2.6 \pm 1.4 \text{ ‰}$ ) and from DaS 167 - 21:30 to DaS 168 - 00:00 ( $\delta_{\text{tiller}} = -2.7 \pm 0.4 \text{ ‰}$ ), or (ii) strong  
293 during the day, i.e., from DaS 167 - 11:00 to 18:00 (maximum value of 20.9 ‰ at DaS 167 - 12:40), or else (iii) strong  
294 during the night, i.e., from DaS 167 - 04:00 to 06:00 (max = 36.4 ‰ at DaS 167 - 05:15) and from DaS 168 - 00:00 to  
295 06:00 (max = 14.6 ‰ at 28:00, DaS 168). Note that transpiration (Fig. 3b) occurred also at night during the sampling  
296 period, due to relatively high temperature in the glasshouse leading to a value of atmospheric relative humidity smaller  
297 than 85%, Fig. 3b). From 12:00 to 14:00 and from 16:00 to 17:00 on DaS 167 (case (ii)) high values of leaf transpiration  
298 corresponded to high values of  $\delta_{\text{tiller}}$ .

### 299 **3.1.3 Partial decorrelation between water and isotopic state variables**

300 Figure 4 shows that variables describing plant water status, i.e.,  $T$  and RH (Fig. 4a) and  $T$  and  $\psi_{\text{leaf}}$  (Fig. 4b) were well  
301 correlated: coefficient of determination  $R^2$  was equal to 0.78 and 0.70 for the entire experimental duration, respectively.  
302 However, linear relationships between water status and isotopic variables were either nonexistent, e.g., between  $T$  and  
303  $\delta_{\text{tiller}}$  ( $R^2=0.01$ , Fig. 4c) and between  $\psi_{\text{leaf}}$  and  $\delta_{\text{tiller}}$  ( $R^2=0.00$ , Fig. 4h) or characterized by a low  $R^2$  and high p-value  
304 (e.g., between  $T$  and  $\delta_{\text{leaf}}$ ,  $R^2=0.43$ ,  $p>0.05$ , Fig. 4d). The partial temporal disconnection between  $\delta_{\text{leaf}}$  and  $T$  could not  
305 be attributed to problems of the isotopic methodology, during e.g., the vacuum distillation of the water from the plant  
306 tillers and leaves: water recovery rate was always greater than 99 % and Rayleigh distillation corrections [Dansgaard,  
307 1964; Galewsky et al., 2016] were applied to standardize the observed oxygen isotopic composition values to a 100 %  
308 water recovery (based on the comparison of sample weight loss during distillation and mass of collected distilled  
309 water). The evolution of  $\delta_{\text{leaf}}$  was strongly correlated with that of  $\delta_{\text{tiller}}$  during the day ( $R^2 = 0.90$ ) whereas non-correlated

310 during the night ( $R^2 = 0.00$ , Fig. 4j). These observed correlations are in agreement with the Craig and Gordon [1965]  
311 model revisited by Dongmann [1974] and extensively used in the current literature [e.g., Dubbert et al., 2017]: at  
312 isotopic steady-state,  $\delta_{\text{leaf}}$  is a function of the input water oxygen isotopic composition ( $\delta_{\text{tiller}}$ ) among other variables,  
313 i.e., leaf temperature (not measured during the experiment), stomatal and boundary layer conductances, oxygen  
314 isotopic composition of atmospheric water vapor, and relative humidity.

315 It is generally difficult to observe a statistically significant  $\delta_{\text{leaf}}-\delta_{\text{tiller}}$  (Fig. 4j) relationship at this temporal scale under  
316 natural abundance conditions in the field since the soil water isotopic weak gradient translates into weaker  $\delta_{\text{tiller}}$   
317 temporal dynamics. The quality of linear fit between  $\delta_{\text{leaf}}$  and  $\delta_{\text{tiller}}$  data collected during the day ( $R^2=0.90$ ) was made  
318 possible in this specific experiment by the artificial isotopic labeling pulse that enhanced the soil water isotopic  
319 gradient, which in turn increased the range of variation of  $\delta_{\text{tiller}}$ , ultimately highlighting the  $\delta_{\text{leaf}}-\delta_{\text{tiller}}$  temporal  
320 correlation. Air relative humidity is a driving variable of  $\delta_{\text{leaf}}$  in the model of Dongmann [1974] via the competing  
321 terms  $(1-RH)\cdot\delta_{\text{tiller}}$  and  $RH\cdot\delta_{\text{atm}}$ , where  $\delta_{\text{atm}}$  is the atmospheric water vapor isotopic composition inside the glasshouse.  
322 An overall significant linear correlation was observed between RH and  $\delta_{\text{leaf}}$  during the experiment ( $R^2=0.57$ , Fig. 4g).  
323 During the two night periods (i.e., from 04:00-06:00 and from 20:30-07:00), as relative humidity increased in the  
324 glasshouse ( $51\% < RH < 85\%$ , Fig. 3b), the influence of the isotopic labeling of the tiller water (due to the labeling  
325 of deep soil water) through term  $(1-RH)\cdot\delta_{\text{tiller}}$  decreased to the benefit of term  $RH\cdot\delta_{\text{atm}}$  (with  $\delta_{\text{atm}}$  values ranging from  
326  $-15.9$  to  $-10.7\%$ , mean =  $-13.1\pm 1.6\%$ , data not shown). This was especially visible between 04:50 and 06:00 on DaS  
327 167 and between 01:00 to 06:00 on DaS 168, when  $\delta_{\text{tiller}}$  reached greater values than  $\delta_{\text{leaf}}$ .  
328 From a different perspective, as three plant water samples were pooled to reach a workable volume for the isotopic  
329 analysis at each observation time without replicates, the isotopic signal fluctuations may reflect both its temporal  
330 dynamics and its variability within the plant population.

## 331 **3.2 Simulations**

### 332 **3.2.1 Rooting depth and transpiration rate control $\delta_{\text{tiller}}$ and $\psi_{\text{leaf}}$ fluctuations, respectively**

333 Despite the use of a global optimizer and 4 degrees of freedom ( $L_{\text{pr}}$ ,  $k_{\text{axial}}$ ,  $k_{\text{sat}}$ ,  $\lambda$ , see optimal values in Table 1)  
334 specifically aiming at matching the simulated and observed temporal dynamics of  $\delta_{\text{tiller}}$ , none of the 60 root system  
335 groups or average population could reproduce the measured fluctuations in time ( $R^2=0.00$ , Fig. 5a), regardless of the  
336 weight attributed to this criterion in the objective function. The predicted versus observed  $\delta_{\text{tiller}}$  distributions including  
337 all plant groups and observation times differed noticeably but not significantly ( $6.6 \pm 8.4\%$  and  $3.7 \pm 8.4\%$ ,  
338 respectively) when pooling 3 simulated  $\delta_{\text{tiller}}$  randomly at each observation time ( $P>0.01$  in 92 cases out of 100 repeated  
339 drawings), as in measurements. Besides, the simulated  $\psi_{\text{leaf}}$  fitted well the observations ( $R^2=0.67$ , overall distributions:  
340  $-0.175 \pm 0.053$  MPa and  $-0.177 \pm 0.053$  MPa, respectively, Fig. 5c). When analyzing the distributions of  $\psi_{\text{leaf}}$  and  $\delta_{\text{tiller}}$

341 per maximum root system depth (Fig. 5b and d), it appears that the  $\psi_{\text{leaf}}$  signal is not sensitive to the rooting depth (Fig.  
342 5d), while  $\delta_{\text{tiller}}$  is more sensitive to rooting depth than to the temporal evolution of the plant environment (Fig. 5b).  
343 This leaves us with two hypotheses. The “rollercoaster hypothesis”:  $\delta_{\text{tiller}}$  rapidly goes up and down with all  
344 individuals on board of the same car (i.e. little variability within the population, unlike predictions in Fig. 5a, but like  
345 the simulated  $\psi_{\text{leaf}}$  in Fig. 5c). If that is correct, the physical model lacks a process that would capture the observed  
346 temporal fluctuations of  $\delta_{\text{tiller}}$ . The “swarm pattern hypothesis”:  $\delta_{\text{tiller}}$  is rather stable in time but its values within the  
347 plant population are dispersed like in a flying swarm, so that  $\delta_{\text{tiller}}$  values sampled at different times fluctuate, not due  
348 to temporal dynamics but to the fact that different individuals are sampled (Fig. 5a).  
349 The model suggests that the tall fescue population  $\psi_{\text{leaf}}$  follows a “rollercoaster” dynamics driven by transpiration rate,  
350 while the population  $\delta_{\text{tiller}}$  follows a “swarm” pattern driven by the maximum rooting depth of the sampled plants. As  
351 no correlation could be expected between the drivers (the maximum rooting depth of the sample plants and canopy  
352 transpiration rate), our analysis explains the absence of correlation between  $\delta_{\text{tiller}}$  and  $\psi_{\text{leaf}}$  or transpiration rate.  
353 In future experiments and in the specific context of labeling pulses, sampling more plants at each observation time  
354 would help disentangle the spatial from temporal sources of variability of  $\psi_{\text{leaf}}$  and  $\delta_{\text{tiller}}$ . It would however be at the  
355 cost of the temporal resolution of observations, or would necessitate a larger setup with more plants in the case of  
356 controlled conditions experiments.

### 357 **3.2.2 Independent observations support the validity of the hydraulic model predictions**

358 In the last 12 hours of the experiment (DaS 167 – 17:00 to DaS 168 – 05:00), the measured soil water content increased  
359 by  $0.029 \text{ m}^3 \text{ m}^{-3}$  at  $-0.9 \text{ m}$  depth, which could be a sign of nighttime hydraulic redistribution. During the same period,  
360 the physical model predicted a cumulative water exudation sufficient to increase soil water content by  $0.003 \text{ m}^3 \text{ m}^{-3}$ ,  
361 as soil water potential was sufficiently low to generate reverse flow, but high enough not to disrupt the hydraulic  
362 continuity between soil and roots [Carminati and Vetterlein, 2013; Meunier et al., 2017a]. While this increase is smaller  
363 than the observed water content change, it is only a component in the soil water mass balance. Given the soil water  
364 potential vertical gradient, upward soil capillary water flow may have accounted for another part of the observed  
365 moisture change. Experimental observations also show that  $\delta_{\text{soil}}$  increased by  $1.0 \text{ ‰}$  at  $0.9 \text{ m}$  depth during that time ( $-$   
366  $6.2 \text{ ‰}$ , a value significantly higher than  $-7.1 \text{ ‰} \pm 0.1 \text{ ‰}$  at earlier times based on ANOVA analysis,  $P < 0.01$ ), while  
367 our simulations of hydraulic redistribution generated an increase of  $\delta_{\text{soil}}$  by  $0.34 \text{ ‰}$ . As soil capillary flow may not  
368 generate local maxima of  $\delta_{\text{soil}}$  (no enrichment observed at surrounding depths, see Fig. 2b), and soil evaporation is  
369 assumed negligible at that depth, it is likely that the observed local enrichment was entirely due to hydraulic  
370 redistribution, which would then be underestimated by a factor of about 3 in our simulations. Increasing water  
371 exudation by a factor 3 would imply a simulated water content change due to exudation of  $0.0090 \text{ m}^3 \text{ m}^{-3}$  absolute  
372 water content, which remains compatible with the experimental observation. Between  $-1.1 \text{ m}$  and  $-0.9 \text{ m}$  depths, the

373 nighttime water flow pattern transitioned from exudation to uptake in both measurements and predictions. At  $-1.1$  m,  
374 the model predicted a cumulative water uptake sufficient to decrease soil water content by  $0.0101 \text{ m}^3 \text{ m}^{-3}$ , as compared  
375 to the observed  $0.0141 \text{ m}^3 \text{ m}^{-3}$  total soil water content decrease. The remaining  $0.004 \text{ m}^3 \text{ m}^{-3}$  water content decrease  
376 may have contributed to the recharge to the soil layers above through capillary flow, which was not simulated.  
377 Therefore, all relevant measurements (local increase of soil water content, local enrichment of water isotopic signature)  
378 and simulation results ( $S < 0$ , i.e. local water release from roots) clearly converge to the conclusion that hydraulic lift  
379 occurred in the vicinity of  $-0.9$  m depth in the early morning of DaS 168.

380 As far as fitted parameter values are concerned,  $L_{pr}$  ( $2.3 \cdot 10^{-7} \text{ m MPa}^{-1} \text{ s}^{-1}$ ) was in the range found by Martre et al.  
381 [2001] in tall fescue ( $2.2 \cdot 10^{-7} \pm 0.1 \text{ m MPa}^{-1} \text{ s}^{-1}$ ) and falls in the range obtained by Meunier et al. [2017a] for another  
382 grass (*Lolium multiflorum* Lam.,  $6.8 \cdot 10^{-8}$  to  $6.8 \cdot 10^{-7} \text{ m MPa}^{-1} \text{ s}^{-1}$ ). Our  $k_{axial}$  value cannot be compared to values of  
383 axial root conductance from the literature as it transfers the water absorbed by roots in a single “big root” per group  
384 of 5 identical plants. The optimal value of  $k_{sat}$  was quite high (Table 1) but reportedly very correlated to  $\lambda$  (i.e. soil  
385 unsaturated hydraulic conductivity is proportional to  $k_{sat}$ , but also to  $Se^2$  [van Genuchten, 1980]), so that the low value  
386 of the latter compensated the high value of the former, thus they should be considered as effective rather than physical  
387 parameters.

### 388 3.2.3 Other sources of variability and observational error

389 Our treatment of the soil medium in this experiment (sieving, irrigation from the bottom) makes it laterally more  
390 homogeneous than natural soils. This method allowed us to study specifically the impact of the vertical gradients of  
391  $\delta_{soil}$  on  $\delta_{tiller}$ . It also justified the use of a simplistic 1-D model adapted to the vertically resolved measurements. If  
392 lateral heterogeneity of soil water content remained and was accounted for, our predictions of root water uptake  
393 distribution,  $\delta_{tiller}$  and  $\psi_{leaf}$  would be altered. Observational errors in the gravimetric soil water content measurement  
394 (turned into soil water potential using the soil water retention curve) would as well alter these predictions. In order to  
395 quantify the sensitivity of our simulated results to such heterogeneity or observational error, we varied the soil water  
396 content input by  $\pm 0.02 \text{ m}^3 \text{ m}^{-3}$  at three critical depths ( $-0.9$ ,  $-1.1$  and  $-1.3$  m, before interpolation), at the last  
397 observation time, during which measurements and simulations suggested that hydraulic lift occurred. Our results were  
398 mostly sensitive to soil water content alterations at  $-0.9$  m, and barely differed in response to alterations at  $-1.1$  and  
399  $-1.3$  m, though the conclusions were not affected qualitatively. No statistically significant difference between predicted  
400 and observed  $\delta_{tiller}$  distributions for the overall dataset could be found when pooling 3 simulated  $\delta_{tiller}$  randomly at each  
401 observation time (predicted and observed  $\delta_{tiller}$  distributions were closest to differ when soil water content was reduced  
402 by  $0.02 \text{ m}^3 \text{ m}^{-3}$  at  $0.9$  m depth;  $P > 0.01$  in 76 cases out of 100 repeated drawings). Measured and simulated  $\psi_{leaf}$  remained  
403 very correlated in all cases (from  $R^2 = 0.69$  to  $0.74$  when adding or removing  $0.02 \text{ m}^3 \text{ m}^{-3}$  at  $0.9$  m depth, respectively).  
404 Furthermore, when adding or removing  $0.02 \text{ m}^3 \text{ m}^{-3}$  at  $0.9$  m depth, cumulative water exudation at  $-0.9$  m varied

405 between 0.0019 and 0.0035 m<sup>3</sup> m<sup>-3</sup>, uptake at -1.1 m varied between 0.0080 and 0.0108 m<sup>3</sup> m<sup>-3</sup>, and the simulated  
406 change of  $\delta_{\text{soil}}$  ranged between 0.28 and 0.40 ‰, respectively.

407 Lateral heterogeneity of soil water isotopic composition may as well occur at the microscopic scale. As water in  
408 micropores is less mobile than water in meso- and macropores [Alletto et al., 2006], it is likely that, in the lower half  
409 of the profile, the capillary rise of labelled water affected the signature of water in meso- and macropores more than  
410 in micropores. If roots have more access to meso- and macropore water, then the water absorbed by roots would be  
411 isotopically enriched, as compared to the “bulk soil water” characterized experimentally. The importance of this  
412 possible bias depends on soil texture and heterogeneity (e.g. existence of more isolated “pockets” of soil or compact  
413 clusters), as well as on the speed of water mixing between mobile and immobile water fractions [Gazis and Feng,  
414 2004]. Including this process in the modelling would necessitate sufficient observations to estimate the aforementioned  
415 properties, and ideally some quantification of the lateral heterogeneity of soil water isotopic composition at the micro-  
416 scale.

417 The lateral heterogeneity of soil hydraulic properties and root distribution may also have participated to the generation  
418 of lateral soil water potential heterogeneities, particularly in undisturbed soils. If one had access to data on lateral  
419 heterogeneity of soil properties and rooting density, it would be possible to simulate 3D soil-root water flow with a  
420 tool such as R-SWMS [Javaux et al., 2008], using a randomization technique for soil properties distribution as in  
421 Kuhlmann et al. [2012], in order to obtain estimations of the relative importance of this type of heterogeneity on  $\delta_{\text{tiller}}$   
422 and  $\psi_{\text{leaf}}$  variability.

423 Unlike the tiller water isotopic signature, leaf water potential turned out to be very sensitive to transpiration rate in our  
424 simulations (see temporal fluctuations of grey lines in Figure 5 panel c) and not very sensitive to root distribution (see  
425 small variations of leaf water potential across individuals in Figure 5 panel d). This suggests that in this setup the  
426 hydraulic conductance of the soil-root system limited shoot water supply more than the distribution of roots, as in Sulis  
427 et al. [2019]. Simulated baseline (i.e. for uniform transpiration rates) leaf water potentials are shown as grey lines in  
428 Figure 5 panel c, and measured leaf water potentials as a green line in the same panel. The fact that they match well,  
429 despite the high sensitivity of leaf water potential to transpiration rate, reinforces the idea that transpiration rate was  
430 likely not spatially heterogeneous among the plant population. Therefore, the tiller water isotopic signature, whose  
431 sensitivity to transpiration rate is already very low, was likely not affected by transpiration rate heterogeneity.

### 432 **3.2.4 Do root water uptake profiles predicted by hydraulic and Bayesian models differ?**

433 The root water uptake dynamics predicted by the mechanistic model are shown in Fig. 6a. The overall pattern of  
434 peaking water uptake in the lower part of the profile during daytime matched that of the statistical model, and the  
435 correlation coefficient of both model predictions was relatively high ( $R^2=0.53$ ) in average over the simulation period,  
436 see Figure 7). The main differences were the following: (i) in the upper soil layers where the soil water potential was

437 lower  $-1.5$  MPa, the statistical model predicted water uptake, which is theoretically impossible given the leaf water  
438 potential above  $-0.4$  MPa [van Den Honert, 1948]; (ii) In the upper half of the profile, the physical model predicted  
439 exudation at a rate limited by the low hydraulic conductivity between root surface and bulk soil, with a peak at night,  
440 at  $-0.9$  m depth (quantitative analysis in previous section); (iii) Below  $-1.0$  m depth, the water uptake rate predicted  
441 by the statistical model steadily increased with depth while that of the physical model was more uniform, likely due to  
442 axial hydraulic limitation [e.g., Bouda et al., 2018] counteracting the increasing soil water potential with depth. Note  
443 that the outcome of the statistical model may significantly depend on the definition of the a priori relative RWU  
444 (rRWU) profile. In the present study, we set it to follow a “flat” uniform distribution (i.e.,  $rRWU_j = 1/10$ , see Appendix  
445 E), in other words, each layer was initially defined to contribute equally to RWU. To the contrary of other studies [e.g.,  
446 Mahindawansa et al., 2018], where the a priori rRWU profile was empirically constructed on basis of soil water  
447 content and root length density profiles, we decided not to further arbitrarily constrain the Bayesian model for the sake  
448 of comparison with the physically-based soil-root model.

### 449 **3.3 Progresses and Challenges in soil water isotopic labeling for RWU determination**

450 Often in the field, the vertical dynamics of both soil water oxygen and hydrogen isotopic compositions are not strong  
451 enough (or show convolutions leading to issues of identifiability) for partitioning RWU among different contributing  
452 soil water sources. As a consequence, we unfortunately cannot make use of the natural variability in isotopic  
453 abundances for deciphering soil-root transfer processes [Beyer et al., 2018; Burgess et al., 2000]. To address this  
454 limitation of the isotopic methodology, labeling pulses have been applied locally at different depths in the soil profile  
455 [e.g., Beyer et al., 2016] or at the soil upper/lower boundaries under both lab and field conditions by mimicking rain  
456 events [e.g., Piayda et al., 2017] and/or rise of the groundwater table [Meunier et al., 2017a; Kühnhammer et al., 2019].  
457 After labeling, we are faced with two problems: (i) the labeling pulse might enhance RWU at the labeling location if  
458 the volume of added water significantly changes the value of soil water content. It therefore poses the question of the  
459 meaningfulness of the derived RWU profiles, and this independently from the model used (i.e., physically-based soil-  
460 root model or statistical multi-source mixing model). In other words: are we observing a natural RWU behavior of the  
461 plant individual or population or are we seeing the influence of the labeling pulse? Certainly a way to move forward  
462 is environmental observatories such as ecotron and field lysimeters [e.g., Groh et al., 2018; Benettin et al., 2018] that  
463 provide means to better constrain hydraulic boundary conditions and reduced their isotopic heterogeneity. They allow  
464 for a mechanistic and holistic understanding of soil-root processes from stable isotopic analysis.

465 Another topic of concern is (ii) the difficulty to properly observe in situ (1) the propagation of the labeling pulse in the  
466 soil after application and (2) the temporal dynamics of the plant RWU isotopic composition. Beyer and Dubbert [2019]  
467 presented a comprehensive review on recent isotopic techniques for non-destructive, online, and continuous  
468 determination of soil and plant water isotopic compositions [e.g., Rothfuss et al., 2013; Quade et al., 2019; Volkmann

469 et al., 2016a] as alternatives of the widely used combination of destructive sampling and offline isotopic analysis  
470 following cryogenic vacuum extraction [Orlowski et al., 2016b] or liquid-vapor direct equilibration [Wassenaar et al.,  
471 2008]. These techniques have the potential for a paradigm change in isotopic studies on RWU processes to the  
472 condition that, e.g., isotopic effects during sample collection are fully understood.

473 The present study highlights the need not to “trust” our isotope data alone and always complement them by information  
474 on environmental factors as well as on soil and plant water status to go beyond the simple application of statistical  
475 models. This is especially the case in the framework of labeling studies where strong soil water isotopic gradients may  
476 induce strong dynamics of the RWU isotopic composition from a low variability of rooting depths.

#### 477 **4 Conclusion**

478 In the present study, light could be shed on RWU of *Festuca arundinacae* by specifically manipulating the lower  
479 boundary conditions for water content and oxygen isotopic composition. The new version of the one-dimensional  
480 model of Couvreur et al. (2014) implemented here accounted for both root and soil hydraulics in a population of “big”  
481 root systems of known root length density profile. This approach underlined the high sensitivity of  $\delta_{\text{tiller}}$  to rooting  
482 depth and suggested that if  $\delta_{\text{tiller}}$  is measured on a limited number of individuals, its variations in time may reflect the  
483 heterogeneity of rooting depth within the population, rather than temporal dynamics which was minor in our  
484 simulations. The model avoided the prediction of water uptake at locations where it was physically unavailable (e.g.,  
485 in the top half of the soil profile), by accounting for water potential differences observed between the leaves and the  
486 soil, and explained quantitatively the local isotopic enrichment of soil water as the occurrence of nighttime Hydraulic  
487 Lift at  $-0.9$  m depth. On the other hand, the Bayesian statistical approach tested for comparison, which was driven by  
488 isotopic information solely, naturally translated the observed changes of  $\delta_{\text{tiller}}$  into profound temporal dynamics of  
489 RWU, at the expense of eco-physiological consideration (e. g., temporal dynamics of leaf water potential and  
490 transpiration rate).

491 This case study highlights (i) the potential limitations of water isotopic labeling techniques for studying RWU: the soil  
492 water isotopic artificial gradients induced from water addition result in an improvement in RWU profiles determination  
493 to the condition that they are properly characterized spatially and temporally. As already pointed out in the review of  
494 Rothfuss and Javaux (2017), the study also (ii) underlines the interest of complementing in-situ isotopic observations  
495 in soil and plant water with information on soil water status and plant ecophysiology; it finally (iii) calls for the use of  
496 simple soil-root models (though requiring additional water status measurements and making more explicit assumptions  
497 on the description of the soil-plant system, as compared to the traditional Bayesian approach) for inverting isotopic  
498 data and gain insights into the RWU process.

499 **Acknowledgements**

500 The experiment was part of the ASCHYD (“Biogeochemical characterization of Hydraulic Lift”) project and supported  
501 by the French EC2CO/BIOHEFFECT program (CNRS – INSU, ANDRA, BRGM, CNES, IFREMER, IRSTEA, IRD,  
502 INRA and Météo France). During the preparation of this manuscript, V.C. was supported by the Belgian National Fund  
503 for Scientific Research (FNRS, FC 84104) the Interuniversity Attraction Poles Programme-Belgian Science Policy  
504 (grant IAP7/29), and the “Communauté française de Belgique-Actions de Recherches Concertées” (grant ARC16/21-  
505 075); FM was first funded by the BAEF and the WBI, then by the FWO as a junior postdoc and is thankful to these  
506 organizations for their support.

507 **Data sets**

508 Upon acceptance, all research data needed for creating plots will be available in reliable FAIR-aligned data repositories  
509 with assigned DOIs.

510 **Author contribution**

511 TB, JLD, and PB designed the experiments and TB, JLD, PB, and YR carried them out. VC, FM, and MJ developed  
512 the physically-based root water uptake model code and VC and FM performed the simulations. YR performed the  
513 statistical simulations. VC, YR, FM, and MJ prepared the manuscript with contributions from all co-authors.

514 **Competing interests**

515 The authors declare that they have no conflict of interest.

721 **Appendix D. Inverse modeling scheme**

722 The parametrization method was inverse modeling, with four targets: (i) minimizing the differences between observed  
 723 and predicted  $\delta_{tiller}$  in each pool  $p$ , (ii) minimizing the difference between the standard deviations of observed and  
 724 predicted  $\delta_{tiller}$  (temporal and population deviations altogether), (iii) minimizing the differences between observed and  
 725 predicted  $\psi_{leaf}$  in each root system group  $i$ , (iv) minimizing the difference between the standard deviations of observed  
 726 and predicted  $\delta_{tiller}$  (temporal and population deviations altogether). These targets translated as an objective function  
 727 ( $OF$ ) to be minimized, where differences were normalized by the standard deviation ( $SD$ ) of observations in order to  
 728 make the error function dimensionless:

729  $OF$

$$\begin{aligned}
 730 \quad = & \sqrt{\frac{1}{2} \left( \frac{1}{N_p N_t} \sum_i \sum_t \left( \frac{\delta_{tiller,obs}(t) - \delta_{tiller,p,sim}(t)}{SD(\delta_{tiller,obs}(t))} \right)^2 + \frac{1}{N_i N_t} \sum_i \sum_t \left( \frac{\psi_{leaf,obs}(t) - \psi_{leaf,i,sim}(t)}{SD(\psi_{leaf,obs}(t))} \right)^2 \right)} \\
 731 \quad & + \left| \frac{SD(\delta_{tiller,obs}(t)) - SD(\delta_{tiller,p,sim}(t))}{SD(\delta_{tiller,obs}(t))} \right| + \left| \frac{SD(\psi_{leaf,obs}(t)) - SD(\psi_{leaf,i,sim}(t))}{SD(\psi_{leaf,obs}(t))} \right| \quad (D1)
 \end{aligned}$$

732 where  $N_p$  is the number of  $\delta_{tiller}$  pools simulated (100) at each observation time,  $N_i$  is the number of plant groups  
 733 simulated (60), and  $N_t$  the total number of observation times (40).

734 The global optimizer Multistart heuristic algorithm OQNLP (Optimal Methods Inc.) of the MATLAB (The  
 735 MathWorks, Inc., USA) optimization toolbox was used to minimize the error function within the lower and upper  
 736 limits of the parametric space reported in Table 1.

737 **Appendix E. Statistical determination of relative RWU profiles with SIAR**

738 The Bayesian inference statistical model SIAR [Parnell et al., 2013] was used to determine the profiles of relative  
739 contributions to RWU (rRWU, dimensionless) of ten identified potential water sources. These water sources were  
740 defined to originate from the soil layers 0.00-0.03, 0.03-0.07, 0.07-0.15, 0.15-0.30, 0.30-0.60, 0.60-0.90, 0.90-1.20,  
741 1.20-1.32, 1.32-1.37, and 1.37-1.44 m. Their corresponding isotopic compositions were obtained from the measured  
742 soil water isotopic compositions ( $\delta_{soil}$ ) and volumetric content ( $\theta$ ) values following Eq. (E1) [Rothfuss and Javaux,  
743 2017]:

$$744 \delta_{soil,J} = \frac{\sum_{j \in J} \delta_{soil,j} \cdot \theta_j \cdot \Delta Z_j}{\sum_{j \in J} \theta_j \cdot \Delta Z_j} \quad (E1)$$

745 where J is the soil layer index, j is the soil sub-layer index, and  $\Delta Z_j$  is the thickness of the soil sub-layer j. Therefore,  
746 equation (E1) translates the soil water isotopic composition measured across sub-layers j into representative isotopic  
747 compositions of the different sources (i.e., across layers J). The computed  $\delta_{soil,J}$  were compared to  $\delta_{tiller}$  values. For this,  
748  $\delta_{tiller}$  measurements were pooled in twelve groups corresponding to different time periods. These groups were defined  
749 to best reflect the apparent temporal dynamics of  $\delta_{tiller}$ .

750 For each of the twelve time periods:

- 751 (i) the function *siarmcmcdirichletv4* of the SIAR R package ([https://cran.r-](https://cran.r-project.org/web/packages/siar/index.html)  
752 [project.org/web/packages/siar/index.html](https://cran.r-project.org/web/packages/siar/index.html)) was run 500,000 times with prescribed burnin and thinby  
753 equal to 50000 and 15, respectively. The output of the model (i.e., the *a posteriori* rRWU distribution  
754 across the ten soil water sources J) was obtained from a flat Dirichlet *a priori* rRWU distribution (i.e.,  
755  $rRWU_j=1/10$ );
- 756 (ii) the ‘best run’ (*br*, dimensionless) was selected from SIAR’s output. It was defined as the closest solution  
757 of relative contributions across sources from the set of most frequent values (*mfv*, dimensionless), i.e.,  
758 the relative contribution with the greatest probability of occurrence. The best run was identified as  
759 minimizing the objective function below, i.e., the RMSE (root mean square error) with respect to the set  
760 of *mfv<sub>j</sub>*:

$$OF = \sqrt{\frac{\sum_{j=1}^{10} (mf v_j - br_j)^2}{10}} \quad (E2)$$

(iii)  $br$  was then multiplied by transpiration rate (in  $\text{m d}^{-1}$ ) and divided by soil layer thicknesses ( $\Delta Z_l$ , in m) to obtain sink terms ( $S_j$ , i.e. root water uptake rate per unit soil volume, expressed in  $\text{d}^{-1}$ ). The interest of sink terms in a comparison is that they do not vary with soil vertical discretization.

Steps (i)-(iii) were repeated a 1,000 times to estimate the variance of the best run for each time period and soil water source J.
