Abstract. Surface waters are under pressure of diffuse pollution from agricultural activities and groundwater is known to be a
15 connection between the agricultural fields and streams. This paper is one of the first to calculate long-term in-stream
concentrations of tritium, chloride and nitrate using dynamic groundwater travel time distributions (TTDs) derived from a
distributed, transient 3D groundwater flow model using forward particle tracking. We tested our approach in the Springendalse
Beek catchment, a lowland stream in the east of the Netherlands, for which we collected long time series of chloride and nitrate
concentrations (1969-2018). The Netherlands experienced a sharp decrease in concentrations of solutes leaching to
20 groundwater in the 1980s due to legislations on that reduces the application of nitrogen to agricultural fields in the 1980s
leading to a trend reversal in the solutes input to groundwater. The Our sStream-se measurements of chloride and nitrate showed
that the corresponding trend reversal in solute concentrations following legislations in the 1980s in the groundwater-fed stream
occurred after a limited time lag of 5-10 years. By combining calculated TTDs with the known solute input history of nitrogen
and chloride input series, we found that the variable contribution of different groundwater flow paths to stream water quality
25 reasonably explained the majority of long-term and seasonal variation in the measured stream nitrate concentrations. However,
this initial model run underestimated the time lag between the peak in nitrogen input and the following trend reversal of nitrate
in the stream. This feature was further investigated through A an exploration of the model behaviour under different scenarios
was done to study the time lag between the peak in nitrogen input and the in the breakthrough of agricultural nitrate in the
stream. nitrogen and it was found that this A time lag of several years and up to decades can occur due to mainly depends on
30 1) a thick unsaturated zone with long hydrological travel times, 2) persistent organic matter with a slow release of N in the
unsaturated zone 1) the travel time in the unsaturated zone, including slow release of organic N, 2) the combination of a long
Mean Travel Time (MTT) and compared to the rate of the solute input nit reduction in nitrogen application, and 3) the spatial

(bio)chemical processes close to the stream or and the drainage network. In absence of these processes, the effect of input

35 ~~reduction measures can generally be expected instantly, which is an important conclusion for water managers.~~ By making the connection between dynamic groundwater travel time distributions and in-stream concentration measurements, we provide a method for validating the travel time approach and make the step towards application in water quality modelling and management.

1 Introduction

40 Diffuse pollution with nutrients is one of the main pressures on Europe's surface- and groundwaters (EEA, 2018). Intensive agricultural land-use and the accompanying use of manure and fertilizers have significantly increased the amount of nitrate in the hydrological system in the period after 1950 (Aquilina et al., 2012; Broers and van der Grift, 2004; Hansen et al., 2011; Worrall et al., 2015). Nitrate leaches to the groundwater (Boumans et al., 2008; Wang et al., 2012) from where it is transported towards surface waters through fast and slow flow paths, creating a stress on surface water quality (Howden et al., 2011b; 45 Kaandorp et al., 2018b; van der Velde et al., 2010). From 1985 concentrations leaching towards the groundwater decreased as a result of national and European legislations (Dutch Manure Law, 1986; EU Nitrates Directive, 1991), that contain rules for the reduction of N applications in farming. The following trend reversal in the concentrations of surface waters has been reported in few countries, amongst which The Netherlands (e.g. van den Brink et al., 2008; Visser et al., 2007; Zhang et al., 2013; Rozemeijer et al., 2014) and Denmark (Hansen et al., 2011).

50

Flow paths are the routes that water particles travel through the subsoil, crossing different geological formations and reaching certain depths, which takes a certain travel time from infiltration to exfiltration (Broers and van Geer, 2005; van der Velde et al., 2010). The mean and variance of nitrate concentrations in groundwater and streams both in time and space depends on these groundwater flow paths and travel times, as well as on land-use (for instance use of manure and fertilizer). Both the flow 55 route and travel time influence hydrochemical processes, as they determine which mediiums are passed and the time that is allowed for (biogeo)chemical reactions. Nitrate concentrations may for instance decrease by denitrification when passing organic or pyrite-rich layers (e.g. Zhang et al., 2013).

Land-use determines the timing and quantity of nitrate input as well as its spatial distribution (Boumans et al., 2008). Thus, all 60 water particles may carry different nitrate concentrations depending on their place and time of infiltration, their flow paths and their travel times along their flow paths. For example, the input of nutrients is higher on fertilized agricultural fields than in forested areas. In catchments, groundwater flow paths provide the hydrologic connection between infiltration areas and seepage zones in streams (e.g. Ali et al., 2014; Birkel et al., 2015; McGuire and McDonnell, 2010). Because groundwater flow paths are dynamic throughout the year, with activation/deactivation and changes in outflow locations~~variable in time~~, the 65 delivery of nitrate from groundwater to surface waters also varies in time (Rozemeijer and Broers, 2007).

In a recent paper, Kaandorp et al. (2018a) presented dynamic travel time distributions (TTDs) for lowland catchments in the Netherlands. They showed how groundwater flow paths in these catchments vary in time and discussed differences in mixing processes between young and old groundwater in the streams with time. Connecting this ~~hydrologic~~ approach with solute transport would enable validation of calculated travel times using stream concentration data and would highlight the potential of using TTDs for non-point source transport modelling. Therefore, we combine in this follow-up paper these dynamic travel time distributions with application rates of input curves for tritium, chloride and nitrate to reconstruct the concentrations in ~~the~~ Dutch Springendalse Beek stream from 1969 until present, while including the dynamic nature of catchments both in time and space. ~~Our aims are twofold: first to validate the results of the TTD method by comparing them to measurements of solutes, and second to explore the effect of different processes and parameters on the breakthrough patterns and time lags of groundwater derived solutes as a way forward in a) model calibration and b) management of (ground)watersheds.~~ This work extends on recent advances in research ~~on~~ the groundwater contribution to streams (e.g. Engdahl et al., 2016; McDonnell et al., 2010; Morgenstern et al., 2010; Solomon et al., 2015; van der Velde et al., 2012), and is one of the first to couple measurement data of water quality and isotopes to dynamic TTDs calculated using a forward particle tracking model. Even though many recent papers suggest that this method holds a lot of potential (e.g. Hrachowitz et al., 2016), the papers which have attempted to do so are still scarce due to a lack of long-term solute input in the range of 5-50 years and discharge concentration data. In addition, the amount of subsurface nitrogen storage and denitrification capacities are generally unknown. The data availability within our study catchment provides a unique opportunity to explore the application of dynamic TTD's for solute transport calculation.

In our study, tritium and chloride were included as water tracers. Tritium because it is part of the actual water molecule, ~~while~~ chloride ~~was~~ because it was considered to be a conservative tracer of manure and fertilizers when it passes through the aquifer; ~~and nitrate reactive~~. Convolutions of the solute input curves-time series with the modelled TTDs were compared with observed stream concentrations of tritium, chloride and nitrate, which ~~opens-provides a first the possibility of~~ validation of the model-derived TTDs.

Interestingly, measurements show a short time lag of 5-10 years between a decrease in the nitrogen application and the peak of nitrogen in the Springendalse Beek stream. This time lag, defined as the time between the peak in solute application and the observed peak in the stream, was further studied using the model. Our aim was not to further calibrate the model by adding local details; instead we aimed at understanding the catchment mechanisms relevant for time lags. We used the strong physical basis of particle based dynamic TTDs to explore the controls on time lags, e.g. biogeochemical legacy effects in the soil, TT in the unsaturated zone, TT in groundwater, denitrification in soils and groundwater. We used the model to assess whether the fluctuation in flow paths and contributing areas explain the variability of stream water quality, as has been found in other studies (Musolff et al., 2016; Rozemeijer and Broers, 2007), and ran an exploration of the model behaviour under different scenarios to analyse the parameters that determine lag times between recharge of the solutes and discharge in the stream, such

~~as unsaturated zone delay, the distance between fields and the stream and the mean travel time of the system.~~ Lastly, we explored the effects of ~~input scenarios~~ a more delayed and an instantaneous input reduction and of different the spatial input patterns on the breakthrough of agricultural nitrate. Our aims are thus twofold: firstly to get a first validation of the results of the TTD method by comparing them to measurements of solutes, and secondly to explore the effect of different processes and parameters on the breakthrough patterns and time lags of groundwater derived solutes as a way forward in a) model calibration and b) management of (ground)watersheds.

2. Methods

2.1. Study area

110 A lowland stream in the east of the Netherlands, the Springendalse Beek (Figure 1), was selected for this study because of its high nitrate concentrations and differences in land-use and discharge characteristics between upstream and downstream parts of the catchment (Kaandorp et al., 2018b). The catchment has a temperate marine climate with a mean temperature of 9.6 °C and mean annual precipitation and evaporation of around 850 and 560 mm respectively. The size of the catchment is 4 km² and the average discharge downstream is 0.043 m³/s with a baseflow index of 0.8 (Gustard et al., 1992).

115

The catchment is located on the flank of an ice-pushed ridge that was formed during the Saalian glaciation and has a maximum elevation of 75 m above sea level. Recent hydrogeological inventories suggest a complex ice-pushed structure, composed of a series of tilted slabs of Tertiary clays (Formation of Breda and older) intercalated with Pleistocene moderately coarse, organic poor sands and some gravel that ~~were~~ was deposited by a braided river (Formation of Appelscha). These slabs roughly have a N-S strike direction, perpendicular to the receiving Springendalse Beek stream (pers. comm. Harting and Bakker, TNO Geological Survey of the Netherlands) and can hardly be passed by groundwater flow, leading to relatively high groundwater tables compared to more sandy ice-pushed ridges in the Netherlands. In general, the average depth of the water table is around 0.5 m below the surface in the downstream part of the catchment and up to about 3.0 meter below the surface in the highest parts of the upstream catchment, presumably concentrated at outcrops of the Pleistocene sands. The streambed of the stream is sandy with some occasional gravel, which represents material from the tilted Appelscha Formation.

125

The upstream part (2 km²) of the Springendalse Beek catchment has several spring areas and is mostly forested with some agricultural fields, while farmland is more abundant in the downstream part (2 km²) of the catchment. Many of these farmlands are artificially drained by a system of tile drains and ditches, especially in the downstream part of the catchment due to the flatter topography and more shallow groundwater tables compared to the upstream part of the catchment. Available data indicates that the drainage density is around 20-30% lower in the upstream part of the catchment than in the downstream part.

130

Due to its constant flow and permanent springs, the stream is known to have a high ecological value (e.g. Nijboer et al., 2003; Verdonschot et al., 2002).

135 2.2. Collecting water quality measurements of surface water

Surface water quality measurements were collected from various sources (Table 1), with a focus on the availability of data on chloride and nitrate. First, historical data from 1969 onwards of chloride and nitrate concentrations was obtained from earlier studies (Dam et al., 1993; Higler et al., 1981; Hoek, 1992; van der Aa et al., 1999; Verdonschot and Loeb, 2008). This dataset was complemented with a 1985-present time series of chloride and nitrate that was collected by the monitoring program of the local Waterboard Vechtstromen. In addition, we started sampling for 3H in 2016 because we anticipated that tritium could give an independent validation of our transient TTD model. In total 10 samples were taken over the period 2016 to 2018. These were stored in 1L plastic containers and measured at the Bremen mass spectrometric facility by degassing followed by analysis of ^3He with a Sectorfield mass-spectrometer (MAP 215-50) (Silttenfuß et al., 2009).

145 2.3. Groundwater Model and TTDs

Backward Travel Time Distributions describe the distribution of ages of the water that contributes to discharge in a catchment. Dynamic TTDs do this in a time-variable way and include for instance seasonality in the contribution of older and younger water. Dynamic TTDs for the Springendalse Beek catchment were calculated using forward particle tracking on a high-resolution spatially distributed groundwater flow model following the method described by Kaandorp et al. (2018a). Groundwater flow was calculated using an existing finite-difference groundwater flow model (MODFLOW, Harbaugh, 2005) created and calibrated on groundwater heads and validated with both groundwater heads and river discharge in earlier studies (Hendriks et al., 2014; Kuijper et al., 2012). Groundwater flow was simulated with a monthly time step on a regional scale (total modelled area 58 by 45 km) with cells of 25*25 m. The top of the model followed the surface elevation and the model consisted of seven layers of variable thickness, based on the Dutch Geohydrological Information System (REGIS II, 2005). Figure 1 gives a 2D cross-section through the model's hydrogeological schematization of the subsurface, which is a gross simplification typical in regional groundwater flow models. Mean aquifer thickness in the model was approximately 18 m, but varied between 0.5 and 30 m. Transmissivity in the aquifers was approximately 40 m²/day, porosity was assumed to be 0.3 m³/m³ and some anisotropy was added in the ice pushed ridges (Kuijper et al., 2012). The entire drainage system in the catchment was modelled using the DRN and RIV MODFLOW packages (Harbaugh, 2005). Flow through the unsaturated zone was modelled using the MetaSWAP model for a seasonal representation of the groundwater recharge based on land-use (De Lange et al., 2014; van Walsum and Groenendijk, 2008; van Walsum and Veldhuizen, 2011). To allow for the calculation of long groundwater flow paths the model was run for the period of 1700-2017, repeating climate data from the period 1965-2017 (see Kaandorp et al., 2018a).

165 Backward groundwater travel times (TTs), that represent the age of the water that contributes to streamflow (Benettin et al.,
2015; Harman, 2015; van der Velde et al., 2012), were calculated using a combination of forward particle tracking and volume
“book keeping” (Kaandorp et al., 2018a). Using the flow velocities calculated by the groundwater flow model, particle tracking
software MODPATH version 3 (Pollock, 1994) was used to calculate transient flow paths and TTs. Particles were released
170 of that month. Particles were released for the total model period spanning 317 years yielding a total of 3,804 particle tracking
runs, with around 14 thousand particles each. Particles were stopped [at sinks, such as wells, rivers or drains \(Visser et al. 2009\).](#)
[at strong sinks or at weak sinks if/when](#) the fraction of discharge to the sink was larger than 50% of the total inflow to the cell
([see also](#) Kaandorp et al., 2018a). To construct monthly TTDs, particles were collected on a monthly time scale at their end
points in an area of interest (whole catchment or part of catchment).

175 Using this model approach, Kaandorp et al. (2018) showed a travel time distribution with an exponential- like shape. About
20% of discharge in the Springendalse Beek is water with a travel time less than 1 year, while about 15% of discharge has a
travel time of more than 25 years (Figure 3a and b). The discharge in the Springendalse Beek thus consists mainly of medium
aged water (1 – 25 years) and the mean travel time is approximately 11 years and median travel time around 4 years. Based on
180 the land-use map (Figure 1) and the particle tracking, between 15 and 25% of discharge infiltrated under agricultural fields in
the upstream part of the catchment (Figure 3c). For the total catchment this is slightly higher at about 25 to 35% (Figure 3d),
because a slightly larger part of the stream’s capture zone in the downstream part of the catchment is used for agriculture. In
the modelling results, the discharge contribution from agricultural fields shows a seasonal pattern especially for the total
catchment (Figure 3d), with a higher contribution to discharge of water that was infiltrated under agricultural fields during the
185 wet winter.

The modelling assumptions and simplifications that were made have some drawbacks. As we started the particles at the water
table, we effectively neglected the travel time through the unsaturated zone (e.g. Green et al., 2018; Sprenger et al., 2016;
Wang et al., 2012), but this layer was generally thin in the study area (mostly <1 m) and is partly bypassed by preferential
190 flow. Because particles were released monthly at the centre of each model cell, short travel times (<1 month) were not included
at all and particles had to travel at least 12.5 m before reaching a next cell, causing further uncertainty to short travel times.
Several processes were not included in the modelling approach such as overland flow and re-infiltration of seeped water.
Because of these limitations, this manuscript focusses on longer ~~As we started the particles at the water table, we effectively
neglected the travel time through the unsaturated zone (e.g. Green et al., 2018; Sprenger et al., 2016; Wang et al., 2012), but
195 this layer was generally thin in the study area (mostly <1 m) and is partly bypassed by preferential flow. Also, our focus was
on the~~ groundwater TTs and time scales. Chemical processes in the unsaturated zone concerning nitrate were included in

constructing the solute input curve-time series. ~~By adding input curves of tritium, chloride and nitrate to the calculated flow paths it is possible to calculate the water quality of the catchment's streams.~~

200 **2.4. Tritium input curve-time series**

In pPrincipally, a series of tritium measurements in streams can be used to derive (ground)water age distributions (Broers and van Vliet, 2018a; Cartwright and Morgenstern, 2015; Duvert et al., 2016; Gusyev et al., 2014; Morgenstern et al., 2010; Solomon et al., 2015; Stewart et al., 2016). Here, we intend to use ^3H in an opposite approach; validating our dynamic groundwater model TTDs using a short series of ^3H measurements in the gaining stream (as e.g. Rodriguez et al., 2020). For
205 the ^3H input into our model, we combined the monthly measurements of tritium in precipitation of the closest measurement stations Groningen (1970-2010) and Emmerich (1978-2016) (distance from the catchment to these stations is 80 to 90 km), taken from the GNIP Database of tritium activity in precipitation (IAEA/WMO, 2018). For months that both stations had measurements, we used the average concentration, as our study area is located approximately halfway between these two measurement stations. For months that measurements from both stations were not available, we adjusted the available data
210 using a factor based on the average difference between the stations, following an approach similar to Meinardi (1994). Because the relation between the values measured at the two stations seemed to differ before and after 1997, we use two factors: before 1997, we used $\text{Emmerich} = \text{Groningen} * 1.49$. From 1997 onwards, we used $\text{Emmerich} = \text{Groningen} * 1.03$. For the period before 1970 we used adjusted measurements from Vienna and Ottawa, roughly following Meinardi (1994).

215 **2.5. Land-use and chemical input curve-input time series for N and Cl**

Two types of land-use were distinguished: farmlands and natural vegetation, which includes forests and heather (Figure 1). Concentrations of solutes reaching the water table below natural areas were assumed to be constant in time: 15 mg/L for chloride and 5 mg/L for nitrate, which are conservative estimates based on Kros et al. (2004) and Van Beek et al. (1994). Although these concentrations of solutes have not been constant during the last decades (e.g. Boumans et al., 2013), we feel
220 this assumption is acceptable as the concentration changes due to atmospheric deposition are much smaller than those due to agricultural inputs. For agricultural fields, a solute input curve-time series was constructed on an annual basis. For the period 2000 to 2017, we used the data from the Dutch sandy areas of the Dutch Minerals Policy Monitoring Programme (LMM), which includes monitored concentrations in the uppermost first meter below the water table at agricultural fields since 1991 (see e.g. Boumans et al., 2005; Fraters et al., 2015). For the period 1950 to 2000, we used the nitrogen (N) and chloride surplus
225 that was derived from historical bookkeeping records of minerals applied to farmlands and corrected for crop uptake (Broers and van der Grift, 2004; van den Brink et al., 2008; Visser et al., 2007). We combined this data with the 2000-2017 LMM data by fitting the overlap between 1991-2000 by adjusting the older data to correspond to a groundwater recharge of 0.35 m/year and to represent (part of) the nitrate transformation processes in the unsaturated zone we used a nitrate transformation factor

of 0.85. ~~This factor represents an average nitrate denitrification in the unsaturated zone and in the unsaturated zone, which the~~
230 ~~value used here~~ corresponds with Dutch data for soils with average water tables around 1 m depth (Steenvoorden et al., 1997;
van den Brink et al., 2008). Land use change was considered for two agricultural fields: a large field in the upstream part of
the catchment which has been in use only since approximately 1985, and an agricultural field of approximately 7.5 ha that was
converted to natural vegetation in 1998. What was not considered is that small parts of the catchment changed from nature in
agriculture and vice versa. This does not have a large effect on the downstream surface water concentrations.

235

2.6. Water quality modeling

~~By combining the input time series of tritium, chloride and nitrate with the calculated dynamic TTD it is possible to calculate~~
~~the water quality of the catchment's streams. The dynamic TTD was combined with the solute input curves~~~~For this, by~~
~~assigning~~ tritium, chloride and nitrate ~~inputs were assigned~~ to the particles based on their starting time and location
240 (natural/agricultural). Figure 1 shows the areas where the constructed agricultural input ~~curve-time series~~ was used as input for
the model, the other parts of the catchments were given the constant concentration of natural vegetation. For each month the
particles that contributed to stream discharge were combined, and their concentrations weighted based on their volumes to
simulate the concentrations in the stream. The input concentrations of chloride and nitrate were assumed constant over a
specific year, whereas monthly ³H measurements were directly assigned to the particles in the start month. The model keeps
245 trace of particles that are lost through evapotranspiration within the months after their initial start, thus effectively removing
water and ³H in periods of a precipitation deficit. For chloride and nitrate the solute input is constant over the year and based
on concentrations in the uppermost groundwater, thus there is no need to further account for evaporation for these solutes.

~~In the initial water quality model run, no chemical processes such as denitrification were implemented. With this approach,~~
250 ~~we isolate the input time series and groundwater travel time effects on the stream concentrations. We did not intend to add~~
~~further local details to improve the model performance; instead we aimed at understanding the catchment mechanisms relevant~~
~~for time lags between application of solutes and discharge in the stream, which is also useful outside our study catchment. For~~
~~this, we explored the model behaviour under different scenarios of chemical and hydrological processes.~~

255 2.7. Exploration of the model behaviour under different scenarios

The initial run of the water quality model was only based on the calibrated groundwater flow model and the constructed solute
input curvestime series; and is not further calibrated for solute transport. We ~~did not intend to add further local details to~~
~~improve the model performance; instead we aimed at understanding the catchment mechanisms relevant for solute transport~~
~~which is also useful outside our study catchment. Therefore, we~~ explored the model behaviour under different scenarios by
260 applying scenarios of. ~~In this model exercise, we explored the effect of~~ the following processes on the breakthrough of solutes

in the upstream part of the catchment: 1a) unsaturated zone hydrological delay, 1b) unsaturated zone N species delay, 2) increased saturated zone travel times, 3) different temporal input of solutes, 4) spatial differences in solute input, and 5) denitrification in the saturated zone (Table 2). The initial run of the model used the land-use maps of the catchment of the year 2007 (Figure 1) where the agricultural fields received chloride and nitrate following the constructed solute input curves-time series and the calculated backward TTDs remain unchanged. Nitrate transformation processes in the unsaturated zone are (partly) captured in the solute input curves, by using a nitrate transformation factor of 0.85 (Steenvoorden et al., 1997; van den Brink et al., 2008).

Set 1a, unsaturated zone hydrological delay

The initial model neglected hydrological transport time in the unsaturated zone, while-although it takes time for water to flow from the surface to the groundwater table. This creates a time delay in the order of months to multiple years (Green et al., 2018; Sprenger et al., 2016) and even decades (Wang et al., 2012), depending on the depth of the water table and soil characteristics. In our model exploration we applied a time delay of 5 years for all particles in our model, assuming that piston flow occurs through an unsaturated zone with an equal thickness everywhere in the catchment area. In reality, flow through the unsaturated zone is much more complicated due to e.g. macropores, but this was outside of the scope of the current study. Note that the value of 5 years is not chosen to represent unsaturated zone travel times in this catchment as realistically as possible, but this rather high value only serves to clearly show the effect of such process on the lag time between input and stream concentration.

Set 1b, unsaturated zone N species delay

N added to agricultural fields as organic manure consist of directly available N and persistent N. Whereas-While the directly available N is quickly taken up by crops or leached towards the groundwater, the mineralization of organic N takes more time (e.g. Ehrhardt et al., 2019). We explore the effect of this distinction by creating a time delay of 10 years in 50% of the nitrate that is added to the TTD model.

Set 2, increased saturated zone travel times

Next, we explored the effect of saturated zone travel time uncertainty by applying a multiplication factor of 5 on all the calculated travel times of all flow paths. For this, the calculated travel times at the moment of discharge to the stream of all individual particles was multiplied by this factor during postprocessing. Increasing the ages of groundwater implies an increase in mean travel time (MTT), which could result from a different aquifer thickness, porosity, groundwater recharge or a change in drainage density (Broers, 2004; Duffy and Lee, 1992; Raats, 1978; van Ommen, 1986).

Set 3, different temporal input of solutes

295 The solute input curve-time series for chloride and nitrate was created on a regional scale and has been successfully used at a local scale in earlier studies (van den Brink et al., 2008; Visser et al., 2007). We explored the effect of a more delayed decrease in the solute input curve-time series after 1985 (scenario 3a), which could for instance be caused by slightly different local farming practices compared to the regional input curvestime series. For this, we added a linear decrease in time from the peak in 1985 (Figure 6a). In addition, we explored the effect of a sharp decrease in the input by removing all agricultural application of N after the year 1985 (scenario 3b). In both scenarios the peak of the agricultural input curve-time series for chloride and nitrate was kept at 1985, as this timing of the peak has been found all over the Netherlands (e.g. van den Brink et al., 2008; 300 Visser et al., 2007; Zhang et al., 2013). This input trend reversal results from the EU milk quota legislations in 1984 and EU and Dutch manure laws (Dutch Manure Law, 1986; EU Nitrates Directive, 1991).

Set 4, spatial differences in solute input

305 We explored the effect of different land-use configurations by moving the agricultural fields either towards the stream (shorter travel times; scenario 4a) or away from the stream (towards longer travel times; scenario 4b) ~~or towards the stream (shorter travel times)~~. A buffer zone of 200 m around the stream was used and two scenarios were tested. First the buffer zone was turned into an agricultural area, while all fields outside the buffer zone were turned into natural areas. Second, the reverse was done: the buffer zone was turned into natural areas with agricultural fields outside of the buffer zone. A ratio of 50% agriculture and 50% natural vegetation was used for the agricultural areas in these scenarios to prevent excessive nitrate concentrations and to keep the total input in the system approximately equal as based on the present land-use maps. 310

Set 5, denitrification in the saturated zone

Denitrification is known to remove nitrate from the groundwater, partly by oxidation of organic C (Equation 1) or pyrite 315 (Equation 2):

320

When applied as zero or first order, denitrification does not change the timing of the peak as the denitrification takes place equally along all flow paths. When this is not the case denitrification does affect the shape and timing of the breakthrough of nitrate, for instance when denitrification takes place only at certain depths. Zhang et al. (2013) and more recently Kolbe et al. (2019) showed that varying denitrification with depth has a major influence on nitrate delivered to streams via groundwater. 325

To see the possible effects of different conceptualizations, denitrification was modelled in two ways. First, it was simulated as a kinetic zero order reaction following $NO_3[output] = NO_3[input] - rate * travel time$ (scenario 5a). We used 10 mg NO₃/L/year as the rate of denitrification, which is in the range of values reported by Van Beek et al. (1994) for the Netherlands.

330 Second, denitrification was based on the occurrence of a pyrite layer at a certain depth (scenario 5b), similar to the model of Zhang et al. (2013). Oxidation of pyrite has been found to be the main nitrate reducing process in several studies in the Netherlands (e.g. Broers and van der Grift, 2004; Postma et al., 1991; Prommer and Stuyfzand, 2005; Tesoriero et al., 2000; Visser et al., 2007; Zhang et al., 2009) and in some other regions as reported by Tesoriero et al. (2000). In this model scenario, all nitrate passing through the denitrifying pyrite layers was instantaneously removed.

335

3. Results

3.1 Input curves-time series of Chloride, nitrate and tritium

~~Figure 2 shows the constructed solute input curve that indicates the historic input of tritium, nitrate and chloride towards the groundwater.~~ Tritium in precipitation increased in the 1950s and 1960s following hydrogen bomb testing and has been returning to natural values since the 1980s (Figure 2). The monthly ^3H concentration in precipitation was fed directly into the modelled groundwater recharge, as tritium is part of the actual water molecule. The application of cChloride and nitrate increased from the 1950s until around 1985 due to intensification of agriculture (Figure 2). From 1985 concentrations leaching from agricultural fields decreased as a result of national and European legislations (Dutch Manure Law, 1986; EU Nitrates Directive, 1991), that contain rules for the reduction of N applications in farming.

345

3.2. Water quality measurements of surface water

Tritium concentrations measured in the upstream catchment in 2016 and 2017 were between 4.8 and 6.0 TU with no clear seasonality (Figure 4a). For chloride and nitrate the measurements show some seasonality, with higher concentrations in winter than in summer. This variability seems larger for the total catchment than for the upstream part of the catchment (Figure 4).

350 The long-term chloride concentrations varied between 20 and 40 mg/L with slightly lower values in the upstream than in the downstream catchment. Nitrate concentrations varied between approximately 30 and 50 mg/L during the last few decades. Both the chloride and nitrate measurements show a clear trend reversal in the 1990s (Figure 4c-f) that resembles the trend reversal in the solute input curves-time series (Figure 2) due to legislations. Chloride concentrations in the upstream part of the catchment increase from about 20 mg/L in the 1970s to up to 30 mg/L between 1990 and 1994 (Figure 4c), which is about 5
355 to 10 years after the peak in the input (Figure 2). In the same period, the chloride concentrations measured at the outlet of the total catchment peak at a concentration up to about 42 mg/L (Figure 4d). After 1994, the chloride concentrations decrease both up- and downstream and have been approximately stable between 20 and 25 mg/L since the year 2000, similar to the trend in the chloride concentrations in the uppermost groundwater. The measured timing of nitrate at the outlet of the catchment (Figure 4f) is similar to chloride (figure 4d) with an increase up to 1994 when the maximum of 50 mg/L is reached. After that, nitrate

360 concentrations have decreased but at a slower rate than chloride. What is especially noticeable is that for the upstream part of the catchment, the timing of the chloride and nitrate peaks in the measurements do not coincide. While chloride peaks around 1990 and quickly drops after that, nitrate concentrations only start decreasing after approximately 2000.

3.3. Groundwater TTDs

365 ~~The model indicated that about 20% of discharge in the Springendalse Beek is water with a travel time less than 1 year, while about 15% of discharge has a travel time of more than 25 years (Figure 3a and b). The discharge in the Springendalse Beek thus consists mainly of medium aged water (1—25 years) and the mean travel time is approximately 11 years and median travel time around 4 years. Based on the land use map (Figure 1) and the particle tracking, we found that in the upstream part of the catchment between 15 and 25% of discharge infiltrated under agricultural fields (Figure 3c). For the total catchment this is slightly higher at about 25 to 35% (Figure 3d), because a slightly larger part of the streams capture zone in the downstream part of the catchment is used for agriculture. In the modelling results, the discharge contribution from agricultural fields shows a seasonal pattern especially for the total catchment (Figure 3d), with a higher contribution to discharge of water that was infiltrated under agricultural fields during the wet winter.~~

370

3.3.4. Water quality modelling

375 The initial combination of the TTD results and solute input ~~curves-time series~~ was based on the land-use and ~~solute-input curvestime series-~~ described in paragraph 2.5 and included no further processes or changes to the original flow model. The initial model run showed higher chloride and nitrate concentrations in winter than in summer, and this seasonal variation was larger for the total catchment than the upstream catchment. This agrees with the ~~findings measurements and conclusion-~~ of

380 Kaandorp et al. (2018a) that the contribution of different flow paths differ between the two parts of the catchment.

The modelled chloride concentrations confirmed the observed long-term trends (Figure 4c and d), although the modelled concentrations were too low for the period between 1990 and 1995 (underestimation of 5-15 mg/L) and the chloride peak was simulated around 1985 instead of 1990. For tritium, the model overestimates the measured concentrations by approximately

385 0.5 TU (Figure 4a), which could indicate either an underestimation of the mean age of water in the catchment (allowing for more decay) or an underestimation of the amount of younger water (contributing water with low tritium concentrations). While the measurements showed the nitrate peak around 1994 and 1997 for the total catchment and upstream respectively, the initial model run showed the nitrate peak around 1987 for both the total and upstream catchment. This may suggest that travel times were underestimated in the model, which is supported by the tritium measurements. The modelled trend reversal for nitrate

390 thus occurs approximately 3 years after the trend reversal in the input, which is the same for the modelled chloride concentrations.

3.45. Exploration of model behaviour: Effects on the breakthrough of tritium, chloride and nitrate

Overall, the simulated tritium, chloride and nitrate concentrations in the stream did not completely match the measurements, both in concentration and in the arrival in time of the agricultural peak (Figure 4). Instead of attempting to further adapt and calibrate the groundwater flow model, we explored the model behavior under different scenarios, exploring the parameters that might determine the apparent mismatch with the measured concentrations; thereby increasing our understanding of the flow and transport system in catchments in general.

400 *Set 1a, unsaturated zone hydrological delay*

An unsaturated zone was added to the upstream catchment model with a travel time of 5 years, as a separate piston flow component superimposed on the groundwater system that was modelled. This delay shifted the tritium peak in time and led to a decrease in the tritium concentrations because decay takes place while travelling through the unsaturated zone (Figure 5a). This scenario lowered the modelled stream tritium concentrations closer to the observed tritium concentrations. Because chloride and nitrate were not reactive, this unsaturated zone scenario merely added a certain amount of time to the whole travel time distribution, simply shifting the chloride and nitrate output by 5 years-curves in time (Table 3 Figure 5b and e).

Set 1b, unsaturated zone N species delay

The lag-time lag created in the unsaturated zone by the slower release of persistent N was simulated by putting a delay of 10 years on 50% of the nitrate input. Because the input of nitrate is spread out over a longer period, this resulted in a lower peak value that was 11 mg/L lower but extended the duration of period with high nitrate levels (Table 3; Figure 5c).

Set 2, increased saturated zone travel times

The multiplication of application of a factor 5 on the calculated mean travel times by a factor 5 decreased the overall tritium concentrations due to the extra time for decay (Figure 5a). The input of solutes towards the stream was distributed more in time which lowered the chloride and nitrate peak and increased the length and size of the tail of the peak (Figure 5b and c). This scenario thus has a similar effect on the shape of the breakthrough curve of nitrate as scenario 1b (Figure 5c). When all travel times were increased a-5-fold the chloride and nitrate peaks shifted by approximately 10 years (Table 3).

420 *Set 3, different temporal input of solutes*

We modelled two alternative solute input curves-time series of agricultural fields. In the second scenario First, we removed all agricultural input after the 1985 nitrate peak (Figure 6a, green line). This instantly lowered the stream nitrate concentrations from 1986 onwards, as the stream consists of a large amount of young water and after removal of agriculture is only affected by nitrate from older flow paths that started before 1986 (Figure 6b, green line). First In scenario 3b, we used a solute input

425 ~~curve time series~~ in which the rate of the decrease of nitrate after the 1985 peak is lowered (Figure 6a, red line). This slower
decrease in the agricultural input resulted in an increase of nitrate during a longer period, remarkably ~~also~~-extending also into
the period when the input is already decreasing and creating a time lag of 10 years to the trend reversal (Table 3), followed by
a slower decrease after that (Figure 6b, red line). ~~In the second scenario, we removed all agricultural input after the 1985 nitrate
peak (Figure 6a, green line). This instantly lowered the stream nitrate concentrations from 1986 onwards, as the stream consists
of a large amount of young water and after removal of agriculture is only affected by nitrate from older flow paths that started
before 1986 (Figure 6b, green line).~~

Set 4, spatial differences in solute input

The effect of spatial changes of the input was modelled in two scenarios: one scenario where only the zone of 200 m around
435 the stream was used for agriculture (4a), and one scenario where agricultural input only took place outside of the same 200 m
zone (4b). With the agricultural fields directly around the stream (~~Buffer-scenario 4a+~~) the nitrate peak shifted to 1985 (Figure
6c), which is the year of maximum input (Figure 2). With the agricultural fields in the more upstream parts of the catchment
(~~Buffer-scenario 4b2~~), representing e.g. a natural buffer strip, the nitrate peak ~~shifted-was delayed towards-by 4 years later in
time~~ and became flatter with a much slower decrease over time (Figure 6d). This results from the fact that the fields further
440 away are connected with the stream by longer flow paths with longer travel times. When fields are further away, the agricultural
input to the stream is distributed more over time resulting in a lower peak but a longer tail with higher concentrations.

Set 5, denitrification in the saturated zone

Two denitrification scenarios were modelled, using different conceptualizations. Zero order denitrification with a rate of 10
445 mg/L per year resulted in continuously lower nitrate concentrations without a shift in time (Figure 7). In ~~the other~~-scenario 5b,
denitrification was modelled based on the depth that the particles flowed through, for which nitrate was removed from all
particles travelling through deeper layers (> model layer 2, >0.5-15 m below surface). This also resulted in decreased nitrate
concentrations, but with higher values in the concentration tail than in the zero order scenario (Figure 7).

450 **4. Discussion**

Aim of this study ~~is-was~~ to test whether the use of ~~dynamic~~-TTDs as derived from a groundwater flow model helps us to
understand the observed breakthrough pattern of solutes in a lowland stream. We collected long time series of chloride and
nitrate which showed a clear trend reversal in the 1990 following national and European legislations restricting the use of
manure and fertilizers. By combining the TTDs with input curves-time series for solutes, we were able to calculate stream
455 concentrations which we could compare with the long time series of chloride and nitrate. This base model, which did not
include time delays due to the unsaturated zone or chemical processes (~~except a simple correction for nitrate in the unsaturated~~

~~zone), was able to reasonably capture the long-term trends of chloride and nitrate. However, this initial model run underestimated the time lag between the peak in nitrogen input and the following trend reversal of nitrate in the stream. In addition to the trend reversal in the 1990s, both the measurements and model indicated seasonality in the in-stream concentrations, with higher concentrations in winter and lower concentrations in summer (Paragraph 3.2).~~

~~Interestingly, a time lag seems to exist between the reduction of the solute input and the following trend reversal observed in the long-time series. This time lag, defined as the time between the peak in solute application and the observed peak in the stream, was further studied using the model. For this, we did an exploration of the model behaviour under different scenarios, to get more understanding of the effect of different processes on the long-term breakthrough of the solutes.~~

In the discussion we will first focus on the effect of different processes on the breakthrough of solutes, based on the exploration of the model behaviour under different scenarios. We will evaluate how unsaturated zone processes, advective saturated flow, the spatial source zones and temporal patterns of solute inputs and transformation processes such as denitrification will influence time lags in the receiving water body. Using our dynamic TTD model, we will then introduce ‘contributing areas’ to discuss the spatial and temporal effects of land-use and groundwater flow paths. We will subsequently discuss the measurements and model results of the study area and take another look at the observed breakthroughs and time lags of the different solutes. Lastly, we will discuss the implications of our findings for catchment management.

4.1. The effect of processes on modelled breakthroughs

~~The unsaturated zone was considered in a simplified way in the model by 1) coupling the groundwater model with an unsaturated zone model (MetaSWAP, see also Kaandorp et al., 2018a) to provide a realistic groundwater recharge and by 2) including part of the unsaturated zone processes in the solute input time series by using a nitrate transformation factor of 0.85 on the data before 2000 and using the concentrations of shallow groundwater from 2000 onwards. Although in this way many unsaturated zone processes were accounted for, it did not include a potential delaying effect on the breakthrough of solutes. The model exploration showed that unsaturated zones lead to a shift in time of the solute breakthrough as it takes time for water to percolate from the surface towards the groundwater (Figure 5; Table 3). This is purely a hydrological effect (scenario 1a). In catchments with thick unsaturated zones, the time lag due to unsaturated zones has been calculated to be up to decades such as for aquifers in the U.K. (Wang et al., 2012). Biochemical processes in the unsaturated zone can also create time lags in the breakthrough of nitrate (scenario 1b). N applied on agricultural fields comes partly in the form of directly available N and partly in the form of persistent organic N. While the directly available N is rapidly leached towards the groundwater, persistent N is only slowly transformed into nitrate and leaches towards the groundwater over a time scale of decades (e.g. Ehrhardt et al., 2019). This not only lowers the height of the nitrate peak, but also leads to a time lag and elevated nitrate levels over a longer period of time.~~

490

The scenario in which the TTD of all flow paths was multiplied by ~~Multiplication of the TTD a factor 5~~ lowered the ~~nitrate~~ peak of nitrate observed in the stream. Reason is that the mean ~~because the larger~~ age of the discharging groundwater ~~was increased~~ resulted in a larger contribution of pre-1950 water, which has been less influenced by agricultural activities. ~~In addition, Because the ages of the younger flow paths were increased, the the solutes agricultural peak from applied by~~ ~~agriculture in~~ the 80s ~~is are~~ distributed over a larger amount of time. ~~In addition to lowering the peak, this, result in result ed~~ in a shift in ~~the~~ arrival of the ~~peak trend reversal~~ and a slower decrease of concentrations after ~~wards the maximum stream concentration has been reached~~ (Figure 5; Table 3). The ~~multiplication of factor 5 we multiplied~~ the MTT ~~with in our results clearly shows has a clear the~~ effect on the breakthrough, but ~~the factor 5~~ is a very extreme case. It would represent a system with an aquifer that is ~~also~~ 5 times as thick (or with an unrealistic porosity 5 times higher) given the same groundwater recharge rate (van Ommen, 1986; Vogel, 1967).

500

~~Obviously, the solute input time series and its uncertainty have a large effect on the stream concentrations (Howden et al., 2011a). Changing the shape of the solute input curve time series led to a change in stream concentrations similar to that applied to the input. In the case we presented, this was a slower decrease in concentrations after the concentration peak (Figure 6a). We did not shift the time of the peak in the input because we have strong indications that the peak in Dutch agriculture occurred during the same year in all of the Netherlands, due to the strict measures taken around 1985 (van den Brink et al., 2008; Visser et al., 2007). It seems obvious that the solute input curve and its uncertainty have a large effect on the stream concentrations (Howden et al., 2011a). In the scenario 3a where in which all agriculture was removed from the year 1986 onwards, nitrate concentrations in the stream instantly decreased following the removal of input. This follows from the relatively large amount of young water discharges by our catchment and is in line with the quick response observed for other catchments in the Netherlands (e.g. Rozemeijer et al., 2014). Van Ommen (1986) used a conceptual case to illustrate the same fast reaction: in catchments with an exponential TTD (or in our case close to exponential TTD; Kaandorp et al., 2018a), a change in the input directly affects stream concentrations for all MTTs. This is caused by the fact that the maximum of an exponential distribution is always at the beginning. In scenario 3b, the decrease of input concentrations after the trend reversal in the 80s was more gradual. In this scenario, we did not shift the moment of the peak in the input because we have strong indications that the peak in Dutch agriculture occurred during the same year in all of the Netherlands, due to the strict measures taken around 1985 (van den Brink et al., 2008; Visser et al., 2007). Surprisingly, a time lag occurred before the trend reversal, suggesting that a direct response to changes in the input (This is however not always the case when the reduction in inputs is more gradual: the scenario where the solute input curve was changed to have a slower decrease of NO₃ resulted in a time lag of the peak observed in the surface water. Thus, the time for a change in input to show in stream concentrations seems to depend also on the reduction rates of the input.~~

520

To further study this observation, we did a conceptual exercise in which we combined exponential TTDs with varying MTTs with different conceptual input scenarios and no other processes. Results show that a time lag in the arrival of the peak is possible when the MTT is rather long or the input decreases slowly or a combination of those (Table 4). Figure 8 illustrates three input scenarios for a conceptual catchment with an exponential Travel Time distribution TTD with a Mean Travel Time (MTT) of 5 or 10. The three input scenarios are a direct stop, a slow decrease of the input (decrease 1% of maximum per timestep) and a fast decrease of the input (decrease 5% of maximum per timestep), all following a block input of '100' between time=0 and time=10. The A direct stop leads to a direct decrease in output concentrations, showing an 'inverse' exponential distribution which represents the new unpolluted front travelling through the groundwater system. The other two-three scenarios on the contrary do not show a direct decrease: the scenario with the fast decrease of the input and a MTT of 5 shows a concentration increase for one extra time step (1 month) before decreasing, and this decrease is much slower than the scenario with the direct input stop as a result from the extra input after t=10. When the same input scenario is used with an MTT of 10, the time lag before the trend reversal is increased. The scenario with a slowly decreasing input shows the same behaviour but more extreme: an increase in output concentration until t=16, even with awhile the input decreasesing input in that period.

The time lag until peak output concentration following a decrease in the input is thus controlled by both the MTT of the exponential travel time distribution and the speed of the input change (Table 4). Figure 9 shows the time to peak for different MTTs and input decreases. The time lag thus increases with increasing MTTs and with slower decreasing input decreases. This behaviour is only the result of the hydrology of the groundwater system and is related to the net result of mass loading through groundwater recharge and mass removal at the outflow point. Concentrations at the outflow only start decreasing once the net input is smaller than the net output (Broers and van Geer, 2005). In other words, the output will only decrease when the nitrate input by recharge reaches a lower concentration than the convoluted output into the stream, as shown by the intersect of the input and output lines in Figure 8. The time lag thus depends on the difference between the input and output concentrations. A higher MTT typically results in lower convoluted output concentrations (see also scenario 2 earlier) and input concentrations will exceed those output concentrations for a longer time given the same reduction rage; it effectively takes longer for the input to decrease to the level of the output for a system with a higher MTT. This analysis shows that in the general case of a catchment with an exponential groundwater TTD the effect of measures on the solute input towards groundwater can only be expected to show directly, but that a lag time can be introduced by certain combinations of MTTs, and solute input reduction rates when the decreased solute input is lower than the current concentration of the discharging water.

The unsaturated zone was considered in a simplified way in the model by 1) coupling the groundwater model with an unsaturated zone model (MetaSWAP, see also Kaandorp et al., 2018a) to provide a realistic groundwater recharge based on e.g. recharge and by 2) including part of the unsaturated zone processes in the solute input curves by using a nitrate transformation factor of 0.85 on the data before 2000 and using the concentrations of shallow groundwater from 2000 onwards.

Although in this way many unsaturated zone processes were accounted for, it did not include potential delays caused on the breakthrough of solutes. The model exploration showed that unsaturated zones lead to a shift in time of the breakthrough of the nitrate curve due to the time it takes for water to percolate from the surface towards the groundwater (Figure 5; Table 3). This is purely a hydrological effect (Set 1a). In catchments with thick unsaturated zones, the lag time due to unsaturated zones has been calculated to be up to decades such as for aquifers in the U.K. (Wang et al., 2012). The time lag introduced by the unsaturated zone is often averaged on a catchment scale, due to spatial variation in its thickness, although it can lead to long tails in the nitrate concentrations. On the other hand, longer residence times in the unsaturated zone will promote the uptake efficiency by crops and potential denitrification in saturated parts of the unsaturated zone. Other biochemical processes in the unsaturated zone can also create time lags in the breakthrough of nitrate (Set 1b). N applied on agricultural fields comes partly in the form of directly available N and partly in the form of persistent organic N. While the directly available N is rapidly leached towards the groundwater, persistent N is only slowly transformed into nitrate and leaches towards the groundwater over a time scale of decades (e.g. Ehrhardt et al., 2019). This not only lowers the height of the nitrate peak, but also leads to a time lag in the output with elevated nitrate levels over a longer period of time.

~~We saw that zero-order denitrification removes (part of) the nitrate and thus lowers concentrations and does not change the timing of the peak (Table 3), which was expected as the denitrification takes place equally along all flow paths. Moreover, denitrification at larger depths (scenario 5b) did not shift the peak in the receiving stream either. When this is not the case denitrification does affect the shape and timing of the breakthrough of nitrate, for instance when denitrification takes place only at certain depths (Figure 7, Table 3). Zhang et al. (2013) and more recently Kolbe et al. (2019) showed that varying denitrification with depth has a major influence on nitrate delivered to streams via groundwater.~~ Our scenarios were relatively simple with equal denitrification rates and depths throughout the catchment. It is however known that there is a large variability in the reactivity of for instance organic matters (e.g. Hartog et al., 2004; Middelburg, 1989; Postma et al., 1991), which could lead to spatial or temporal differences in denitrification and therefore a change in the nitrate breakthrough. If denitrification for instance occurs predominantly in the stream valley close to the stream, where conditions are wet and organic matter is abundant, denitrification removes nitrate mostly from younger flow paths, thus shifting the nitrate peak due to the delivery of nitrate mostly by older flow paths, which generally originate from a larger distance from the stream (e.g. Modica et al., 1998). ~~This~~ Such a spatial effect was also shown by the model scenario in which a buffer without agriculture was introduced around surface waters (Figure 6c and d) and is a result of the difference in travel time of the flow paths from the fields close to the stream and the fields more upstream (e.g. Musolff et al., 2017).

The location of agricultural fields in relation to the catchments' drainage network, and more precisely the location of high loading is thus another important factor that largely governs the travel times of the agricultural solutes. Both seasonal and long-term concentration-discharge relationships strongly depend on spatial source patterns (e.g. Musolff et al., 2017) and spatial differences in reactivity (e.g. Kolbe et al., 2019) can further cause spatial variability between solute concentrations of water in

595 different flow paths. It can therefore be argued that in modelling not only the location of fields must be known but also more information about leaching towards the groundwater at every field, as there can be a significant difference in the use of manure and fertilizers due to for instance differences in crops. However, for our catchment, national and EU regulations put strong constraints on the application of nitrogen, thus levelling differences in inputs to farmlands (e.g. Oenema et al., 1998; Schroder et al., 2007). Effectively, soil properties and groundwater levels determine the areas with strongest leaching towards the groundwater as those factors determine the potential for unsaturated zone denitrification.

600 ~~Summarizing the observations from the model exploration, a time lag of the breakthrough of a trend reversal can be caused by: 1) travel time of the unsaturated zone, including slow release of (part of the) N, 2) the combination of MTT and solutes input reduction, 3) spatial setting between solute input, (bio)chemical processes and the drainage network (e.g. locations of agricultural fields and denitrification).~~

4.2. Contributing area of streams

605 In the previous paragraph, we have seen that the spatial distribution of inputs and processes is an important factor in the breakthrough of agricultural solutes. Recently Barlow et al. (2018) restated the definition of the ‘contributing area’ as “the two-dimensional areal extent of that portion of a capture zone that intersects the water table and surface-water features where water entering the groundwater-flow system is discharged”. They did this for groundwater wells, but streams also have a contributing area, which is variable in time and not the same as the catchment. The catchment of a stream is the area in which all discharging water finally ends up in the stream. ~~Within this catchment, The contributing area of streams is also not to be~~
610 ~~confused by the ‘contributing area’ or ‘upslope area’ used in many distributed hydrologic models by catchment scientists, which is the runoff generating area, i.e. the parts of the catchment where seepage and discharge towards the surface water occur (e.g. Ambroise, 2004; Beven and Wood, 1983; Beven and Kirkby, 1979; Meglynn and Seibert, 2003; Yang et al., 2018). To avoid further confusion,~~ we introduce the terms ‘groundwater contributing area’ and ‘runoff contributing area’, which in our model method are respectively the starting point and ending point of particles (Figure 9). The groundwater contributing area (GCA) is defined as the area where the water that is actively contributing to streamflow at a certain moment of time through active flow paths entered the coupled groundwater-surface water system as precipitation (~~recharge area~~). The runoff contributing area (RCA) is defined as the area where at a certain moment in time water is leaving the subsurface domain (catchment storage) to become discharge area where at a certain moment in time water is discharged from the catchment storage as seepage or overland flow, and thus is the area where runoff is generated (Figure 10). Areas that are neither groundwater- nor runoff contributing
620 areas do not actively contribute to streamflow at that specific moment in time. ~~In our particle tracking method, the GCA is the starting point and the RCA is the ending point of a particle (Figure 11).~~

Because flow paths change based on wetness conditions (e.g. Kaandorp et al., 2018a; Rozemeijer and Broers, 2007; Yang et al., 2018) the groundwater contributing area also shifts through the seasons. This includes the inactivation of flow through shallow flow paths towards e.g. drainage pipes and ditches in dry periods, which leads to a non-linear reaction of the dynamic TTD to discharge. When wetness conditions decrease, groundwater levels decrease, and drainage units fall dry. Consequently, the water that was flowing towards these drainage units suddenly stays in the aquifer and/or flows towards another drainage unit. When wetness conditions increase again, groundwater levels first have to rise to the point that they can activate these flow paths again. This also (at least partly) explains why concentration-discharge relationships vary with the wetness of catchments. In our results, the discharge originating from agricultural fields changes in time as a result of this variation in the GCA (Figure 3 and 9), and this seasonal variation in flow paths lead to fluctuations in the concentrations of nitrate in the stream (e.g. Figure 4). Figure 10 illustrates how the groundwater contributing area may shift based on wetness conditions: in the wet period all flow paths are active while during the dry period only the older flow paths are active, and flow through shallow short flow paths has ceased. Therefore, in this example the groundwater contribution of the field close to the stream stops in the dry period and removing this field thus only affects stream nitrate concentrations during the wet period. This concept extends on the ideas presented by Rozemeijer and Broers (2007), by adding the spatial dimension and groundwater contributing area to their concept of variation in the contribution of flow paths with depth. Information about the GCA is important for solute transport, as time lags occur if there is a difference between the forward TTD of the nitrate-contributing areas and the forward TTD of the entire catchment.

640

4.3. Understanding nitrate in the Springendalse Beek catchment

The previous paragraphs discussed more generally the important processes that affect the breakthrough of agricultural solutes, which we will use in this paragraph to discuss the observations from both the measurements and TTD model in the study area. Overall the model was able to describe the trend reversal that was observed in the measurements of the Springendalse Beek catchment. but –the time lag between the peak in nitrogen input and the following trend reversal of nitrate in the stream was underestimated. The time series of discharge and solutes showed that the upstream area has less seasonal variation in the amount of discharge than the downstream catchment, as well as less variation in the contribution from agricultural fields and in the stream concentrations of chloride and nitrate (Figures 3 and 4). Our groundwater-based model was able to simulate this difference between up- and downstream which indicates that this variation can largely be explained by variations in the contribution of different groundwater flow paths originating from different locations in the catchment, as was also concluded by e.g. Martin et al. (2004); Musolff et al. (2016); Rozemeijer and Broers (2007) and van der Velde et al. (2010a). High chloride and nitrate concentrations from agricultural activities are mostly present in the shallower layers (0-5m below surface) (e.g. Bohlke and Denver, 1995; Broers and van der Grift, 2004; Rozemeijer and Broers, 2007; van der Velde et al., 2009; Zhang et al., 2013) and especially in the downstream part of the catchment. The downstream catchment has a, with its larger dense drainage density from the many (shallow) network with agricultural tile drains and ditches which promotes a larger

655

~~contribution of young water in, these~~ shallow flow paths ~~contribute more water of a young age~~ in the wet period with high groundwater tables ~~relative to than in~~ the dry period (Kaandorp et al., 2018a). This increase in relative old water contribution during dry periods has been found in several studies and is called the ‘inverse storage effect’ (e.g. Benettin et al., 2017; Harman, 2015). Similar to our model, van der Velde et al. (2010) and Wriedt et al. (2007) were able to model seasonality of in-stream nitrate concentrations using only groundwater dynamics and concluded it to be an important process that is further superposed by denitrification and variability in loading. We conclude that the upstream part of the Springendalse Beek catchment with its stable year-round discharge ~~compared to the downstream part of the catchment~~, provides a base level to the lower limit of the nitrate concentrations, ~~while whereas~~ the drained downstream part of the catchment ~~mainly~~ causes the greater part of the seasonal variation in the stream concentrations.

The fact that most of the discharge has travel times larger than one year might explain that no seasonality was observed in the tritium measurements. The model overestimated all observed tritium concentrations in the initial model run, by approximately 0.5 TU on average (Figure 4a). This could indicate the uncertainty in the measured concentrations but based on experience in other catchments (Broers and van Vliet, 2018a; Morgenstern et al., 2010; Stolp et al., 2010) this might be caused by the model underestimating the mean age of water in our catchment, for instance due to an underestimation of the aquifer volume caused by the complex geology in the area ~~overestimation of the recharge~~. On the other hand, an overestimation of the mean water age by the model could also cause higher modelled tritium concentrations, as more recently infiltrated water has lower tritium concentrations (Figure 2). Unfortunately, no earlier measurements of tritium are available for the Springendalse Beek to draw further conclusions using tritium.

Denitrification does not seem to occur substantially in the upstream part of the study area as the modelled nitrate concentrations are generally already lower than the measurements. This is confirmed by the oxic nature of the sandy sediments that the groundwater discharges from (Kaandorp et al., 2019), the presence of oxygen and lack of iron in the discharge water (data not shown). Although the upstream part of the catchment contains less agriculture than the downstream part (Figure 3), the nitrate concentrations in the stream are comparable. This may be an indication of denitrification in the downstream part of the catchment where water levels are close to the root zone, promoting shallow denitrification, which could be a reason for the overestimation of nitrate as well as the fact that the model overestimates the seasonal variation in the downstream catchment (Figure 4f). Another important aspect is uptake of nitrate and denitrification within the surface water system. This is currently not accounted for and probably limited in winter (high flow velocities and low temperatures), but may be causing lower nitrate concentrations in summer.

Measurements of chloride and nitrate showed a time lag between the trend reversal in the solute input and in the discharge. In the lowland groundwater-driven study catchment, unsaturated zones are relatively thin in the downstream part of the catchment (maximum a few meters, but mostly <1 m) and slightly thicker in the upstream part (up to 3 meters), and thus only a maximum

690 time lag of a few years would be realistic. Due to the complex hydrogeology of the ice pushed ridge, especially in the upstream
part of the catchment, there is quite some uncertainty in the exact depths and volumes of the aquifers that are present within
the ice-pushed ridge. In the regional groundwater flow model, this complex geology was highly simplified based on the version
of the hydrogeological schematization of REGIS (REGIS II, 2005) that was available when building the flow model. The
695 complex geological structure of the ice-pushed ridge makes it difficult to exactly pinpoint the position of the tilted Pleistocene
sand layers that probably form the main pathways to the stream, as the tilted slabs of Tertiary clays form hydraulic barriers for
groundwater flow (pers. comm. Harting, TNO Geological Survey of the Netherlands). Given the approximate N-S strike
direction of the sandy intercalations, this may have influence on the distinct farmlands that contribute to the nitrate
concentrations in the stream, that may be positioned further away than the modelled schematization might allow in the regional
groundwater flow model. It might also affect the mean travel times in the groundwater system as a larger aquifer volume would
700 result in overall longer travel times (Vogel, 1967; van Ommen, 1986). The observation that the time lag is larger for nitrate
than for chloride, especially in the downstream catchment, can be explained by processes that only affect nitrate and not the
more conservative chloride, such as a difference in residence time of different N species or spatial differences in denitrification.
The difference could also indicate that the ratio between chloride and nitrate has changed in the fertilizers used.

705 Although a time lag was observed, the measurements showed that legislations in the 1980s and thereafter were effective in
lowering the concentrations of agricultural solutes in the stream. The model was reasonably able to simulate the long-term
trends, but could be improved by adding more detail based on the lessons learned from the model exploration. However, these
lessons on the breakthrough of solutes are already applicable in other catchments and will be further discussed in the next
paragraph.

710

4.4. Management implications

~~The exploration of the model behaviour indicated that removing the source of diffuse pollution leads to an immediate decrease
of in-stream concentrations (Figure 6b), due to the large fraction of younger water in the TTD. Therefore, contrary to what is
often thought, the response of measures through the groundwater system is instant in the general case that the TTD is (close
715 to) exponential and thus managing the input of agricultural pollutants is a good management option with direct benefits. We
showed however that this direct impact does not occur when decreases are very slow or the MTT is very large. After the
immediate decrease, the legacy from older groundwater flow paths leads to a slow further decrease in time.~~

According to scenarios modelled by Tufford et al. (1998) the management of stream water quality is most effectively done at
720 riparian and adjacent lands. Our results show that the location of agricultural fields indeed has a large effect on stream
concentrations. Not only does the location of the fields affect the time lag and shape of the breakthrough ~~curve~~ of stream
concentrations, longer flow paths from the fields further away from the stream also have more time for processes such as

denitrification. ~~The s~~Scenario 4b with the 200 m agricultural-free zone around the stream can be compared with a (natural) riparian zone, on which much research has been done (e.g. Anderson et al., 2014; Feld et al., 2018; Hefting and Klein, 1998; Hill, 1996; Ranalli and Macalady, 2010). These studies show that riparian zones positively affect stream water quality because of their high rate of denitrification. Johnes and Heathwaite (1997) even suggested to move agricultural fields to the locations with the highest potential for nutrient retention. The importance of the spatial setting of land-use in the landscape means that a map of forward TTDs combined with the locations of high solute input can be used for a vulnerability assessment of a catchment.

Our results further show that in addition to the denitrification potential of a riparian buffer zone, the longer length of the groundwater flow paths lags the arrival of and dampens the nitrate peak. In fact, as denitrification rates are highly variable (e.g. Tesoriero and Puckett, 2011; Van Beek et al., 1994) and riparian zones can be by-passed by deeper groundwater flows (Bohlke and Denver, 1995; Flewelling et al., 2012; Hill, 1996; O'Toole et al., 2018; Ranalli and Macalady, 2010), the longer distance and thus distribution of solutes in time ~~is at some locations and/or moments arguable~~ may be the more important effect of riparian buffer zones. Therefore, creating a (significant) riparian buffer zone lags and dampens the effect of agricultural pollution on surface water quality and riparian buffers have a positive effect even when it is bypassed or when denitrification is low. Although overall positively affecting water quality of the stream by decreasing concentrations, the longer travel times of agricultural solutes will also lead to a longer tail and thus invoke a longer lasting effect of agricultural solutes on streams ~~on but at lower concentration levels~~ stream concentrations.

The modelling approach using Travel Time Distributions is a valuable approach for water quality management. While often (ground)water models focus on representing groundwater heads and discharges, a better representation of travel times and flow paths is essential to correctly simulate non-point source solute transport. Using TTDs therefore delivers more realistic scenario's predicting future concentration trends and/or the effects of mitigation options.

5. Conclusions

This paper study is among the first ~~to attempt~~ to couple decades long time series of water quality to dynamic travel time distributions based on a high-resolution spatially distributed groundwater flow model. We collected a unique dataset of solute measurements for the period 1969-2018 for the Springendalse Beek, a Dutch lowland stream. We then combined calculated groundwater TTDs with input ~~curves~~ time series for tritium, chloride and nitrate spanning the period 1950 to 2018. This way, we calculated d solute concentrations in the Springendalse Beek between 1969 and 2018. By making this connection between dynamic groundwater travel time distributions and long-term in-stream concentration measurements, we were able to show

755 that the seasonal and long-term fluctuations of in-stream solute concentrations were mainly caused by the dynamic contribution
of different groundwater flow paths.

760 Both the measurements and model showed a trend reversal in concentrations which followed legislations to reduce the leaching
of nitrate to groundwater on the solute input in the 1980s. Because we observed a time lag of 5-10 years between the time of
the peak solute in nitrate inputs to groundwater and the peak in nitrate concentrations in the stream, we ran an exploration of
765 the model behaviour under different scenarios to explore the effect of different processes and parameters on the breakthrough
patterns and time lags of groundwater derived solutes. understand the important transport factors. We found that a time lag
towards in the arrival of the trend reversal of nitrate in the stream can be caused by: 1) longer travel times in the unsaturated
zone, ~~both~~ due to slow percolation and retardation due to (bio)chemical processes such as the slow mineralisation of organic
N; 2) the combination ~~of MTT and input reduction, caused by combination~~ of a slow decrease of the nitrate input with a
770 relatively long MTT causing a prolonged period in which nitrate input concentrations still exceed the convoluted nitrate output
discharging in the stream; and 3) ~~the~~ spatial setting configurations of solutes between input, locations of (bio)chemical
processes and ~~the~~ drainage that promote older groundwater with higher nitrate loadings to dominate the outflow to the stream.
network This spatial effect may result from a higher input on older flow paths further from the drainage network (e.g.
agricultural fields upstream) in combination with near-stream (bio)chemical attenuating processes in shorter flowpaths (e.g.
775 shallow locations of agricultural fields and denitrification in the riparian zone). To better describe the spatial effect of processes
and land-use on the breakthrough of solutes, we introduced the term 'groundwater contributing area' ~~of a stream~~, which is the
catchment area where the discharging water infiltrated. This groundwater contributing area, increases and shrinks based on
wetness conditions, which leads to varying solute concentrations in the stream with wetness.

780 ~~The results of this study are interesting for water managers of catchments with diffuse pollution from agriculture, as it provides
an insight into the possible parameters to steer on. We show that for most catchments, which have a (close to) exponential
TTD, a direct reaction of stream nitrate concentrations can be expected to reductions in the nitrogen inputs, even if mean travel
times are high, which is contrary to what is often expected. However, we also showed the different processes that can cause a
time lag.~~ Furthermore, we show that creating riparian buffer zones is a good management option, due to the importance of the
785 spatial distribution and (distance) of agricultural fields and the reactivity of the subsurface on the breakthrough patterns of
diffuse pollutants.

A limited amount of stream tritium measurements proved to be a valuable indication of the performance of the model. The
method presented in this paper can be used to validate calculated TTDs and provides an opportunity to validate groundwater
785 models not only on celerities, but also on water velocities. Further research could be aimed on application of the same method
in other catchments and focus on gathering further knowledge on time lags and dynamic contributing areas in other
hydrogeochemical and topographical settings.

Competing interests

1055

Figure 1: Location of the study area (a, b), model conceptualization (c), and the location of agricultural fields in the year 2019 (d). *Background maps and DEM from PDOK (PDOK.nl/datasets).*

1060

Figure 2. Input curve-time series for tritium (left axis) and the estimated concentrations of nitrate and chloride under farmland (right axis). The tritium input curve-time series is based on precipitation measurements at stations Vienna and Ottawa (before 1970) and Groningen and Emmerich (from 1970). The 1985 peak in chloride and nitrate coincides with the start of the legislations from the Dutch Manure Law that placed restrictions on the applications of N in agriculture.

Figure 3. Three age classes of the travel time distributions of the discharge in the Springendalse Beek for the upstream part of the catchment (a) and the total catchment (b). The lower panels show the percentage of discharge originating from agricultural fields for the upstream part of the catchment (c) and the total catchment (d). **Panel e shows the time-weighted averaged CDF of the travel time distributions of the total catchment in summer (red) and winter (blue).**

1065

1070
 Figure 4. Measurements, agricultural input curves-time series and initial model results based on the TTDs from Kaandorp, et al. (2018) and the solute input-input time series curves in Figure 2. No further processes were added. Note that tritium samples were only available for the upstream part of the catchment (panel a).

1075

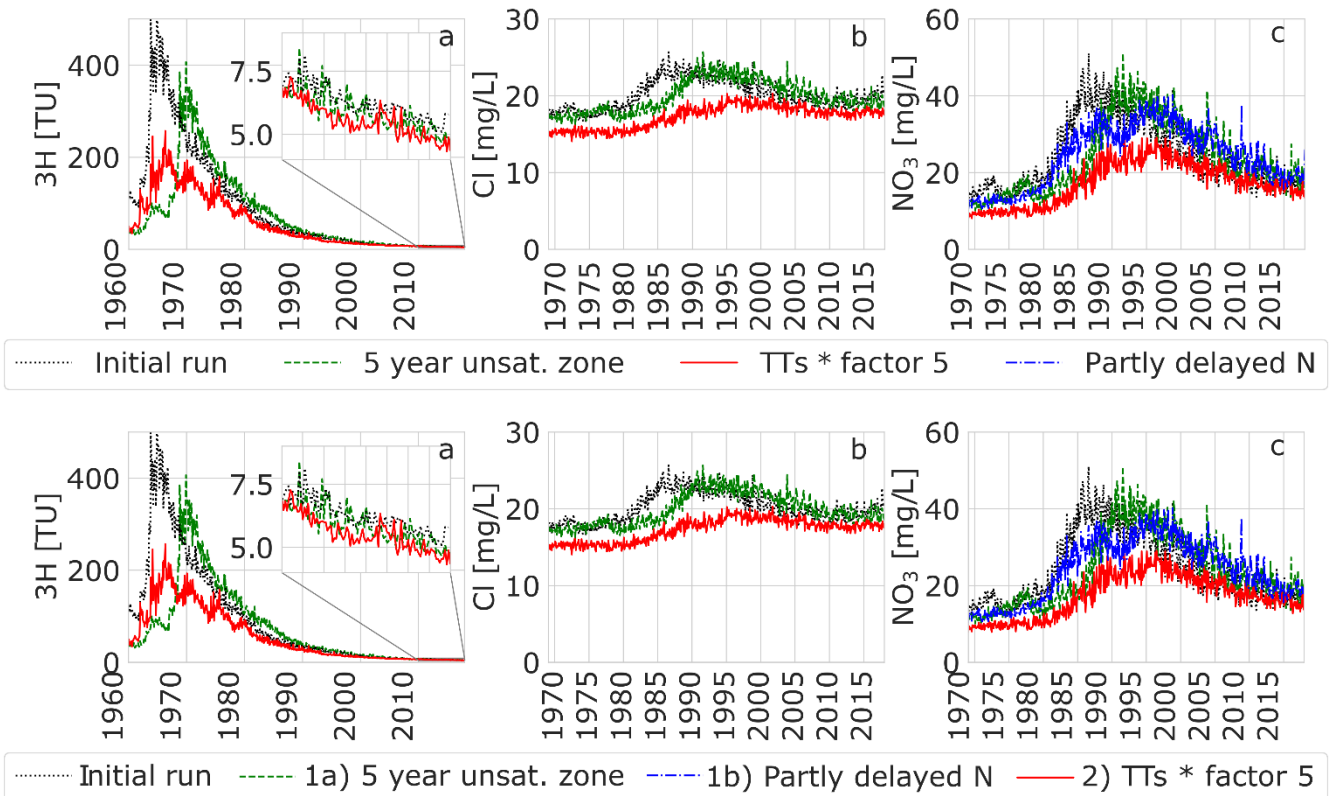

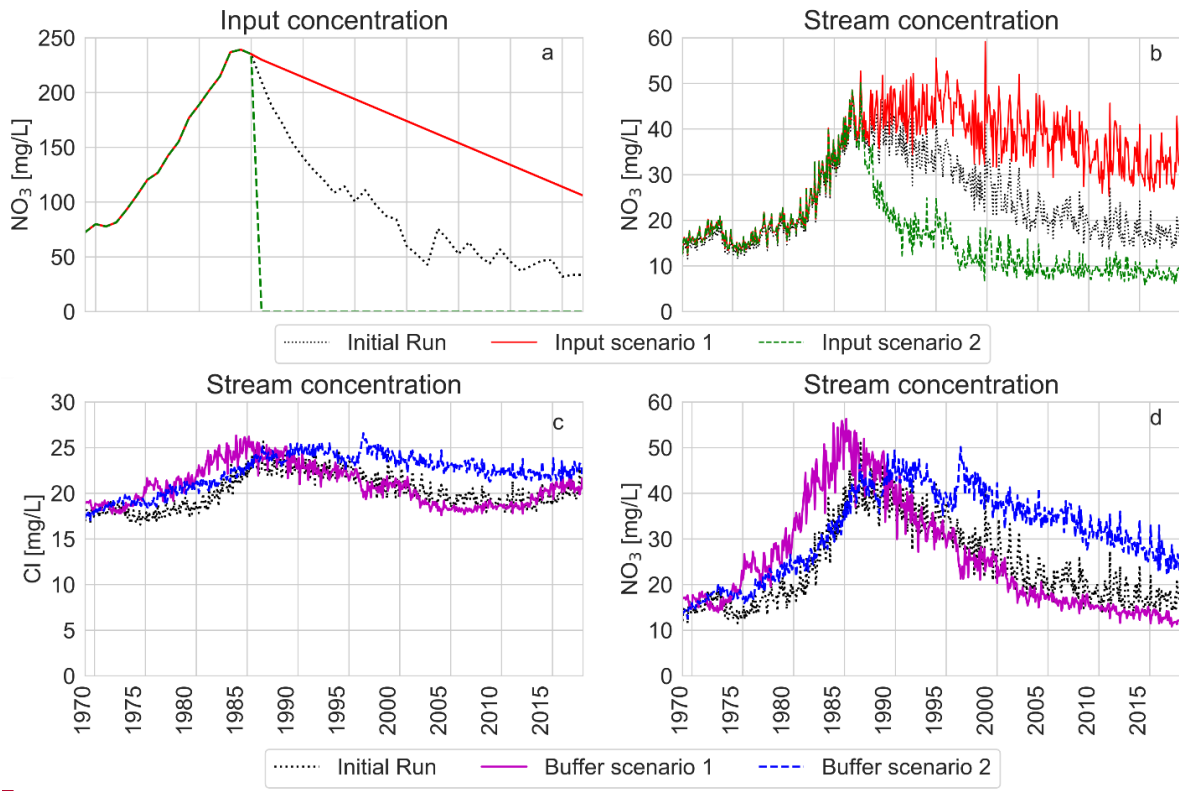

Figure 5. The effect on tritium (a), chloride (b) and nitrate (c) in the upstream part of the catchment of a scenario with a 5-year delay due to an unsaturated zone, a scenario where part of the input of N was delayed and a scenario where all travel times were increased by a factor 5.

1080

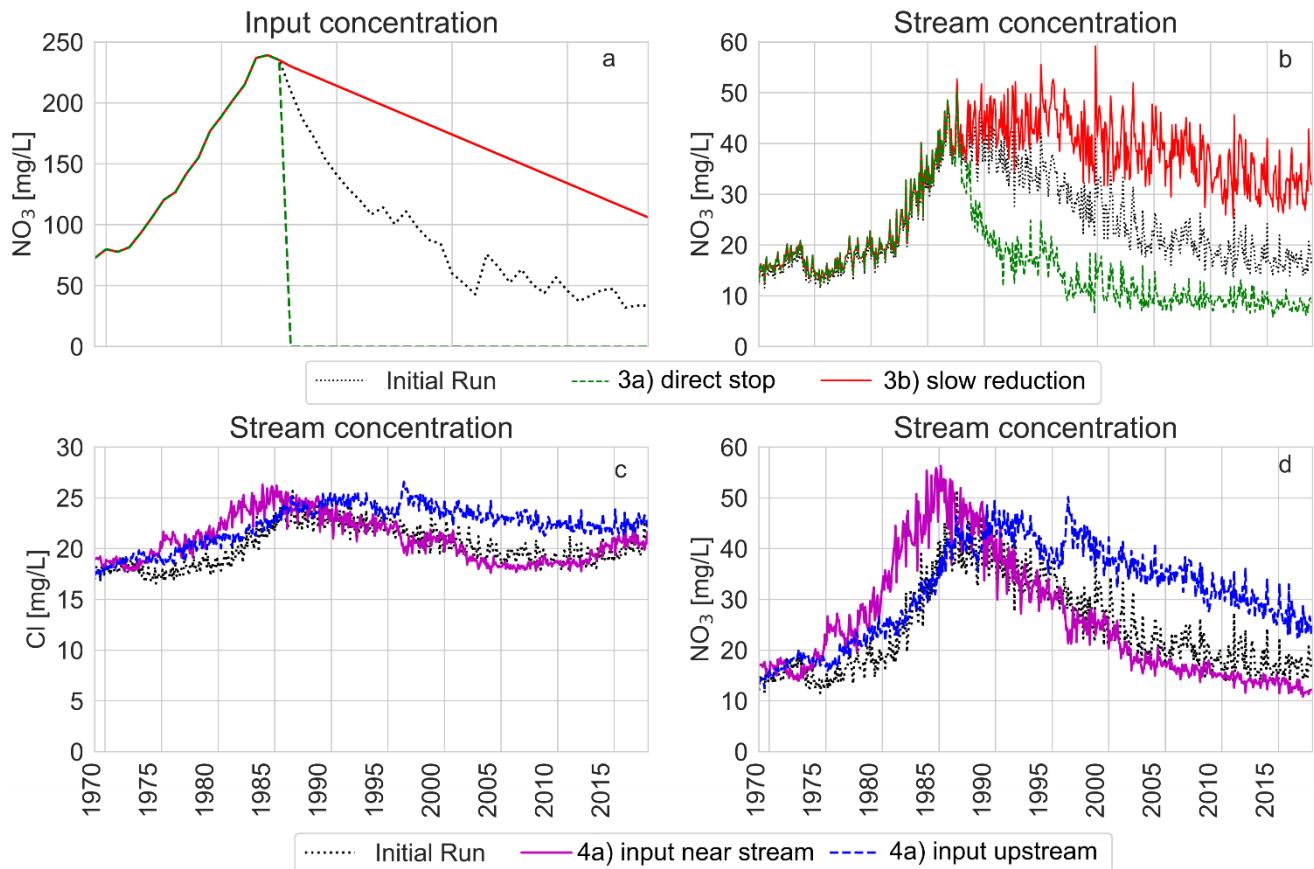

Figure 6. Panel a and b show the effect of two scenarios with changes in the nitrate input curve for the upstream of the catchment. Note the difference in scale of the yx-axis between the left and right panels. Panels c and d show the effect of spatial changes in land-use on both chloride (c) and nitrate (d): only agriculture inside of a 200 m strip around the stream (4aBuffer scenario 1), and only agriculture outside of the same buffer strip (4bBuffer scenario 2). In both scenarios agricultural parts have 50% agriculture and 50% nature, so that the total amount fraction of fields is approximately equal to that in the real catchment.

1085

1090

Figure 7. Effect of denitrification for the upstream part of the catchment using different conceptualizations: zero order denitrification (5a) and denitrification in deep layers (5b).

1095 **Figure 8. Output concentrations for a hypothetical catchment with an exponential TTD with and a MTT of 5 or 10, following three input scenarios: a direct stop of the input, a slow decrease in the input (decrease 1% of maximum per timestep) and a fast decrease of the input (decrease 5% of max per timestep).**

1100

Figure 9. Graphical representation of Table 4 showing the time lag in output concentration (time to peak) on changes in the input for an exponential TTD. The time lag is based on both the MTT and the speed of decrease of the input, a direct stop in the input always results in a direct response in the output. Figure 8 shows some of the scenarios used to construct this Figure.

1105

Figure 10. Contributing areas fluctuate with wetness conditions due to changing flow paths. GCA is the Groundwater Contributing Area which is where discharge was infiltrated and RCA is the Runoff Contributing Area which is where discharge is generated. Areas between the two different contributing areas are 'inactive' and do not actively influence stream discharge.

1110

1115 **Figure 9.** Contributing area in the model for a dry (top; summer 2006) and a wet (bottom; winter 2006/2007) period. Colors represent the travel time towards the stream with blue TT >25 year and red TT < 1 year (similar to Figure 3). Notice the large increase in the runoff contributing area in the downstream part of the catchment during wet periods which results from the extensive agricultural drainage system. Background map ESRI_StreetMap_World_2D, Sources: Esri, DeLorme, NAVTEQ, USGS, NRCAN, METI, iPC, TomTom, http://services.arcgisonline.com/ArcGIS/rest/services/ESRI_StreetMap_World_2D/MapServer.

1120 **Figure 10.** Contributing areas fluctuate with wetness conditions due to changing flow paths. GCA is the Groundwater Contributing Area which is where discharge was infiltrated and RCA is the Runoff Contributing Area which is where discharge is generated. Areas between the two different contributing areas are 'inactive' and do not actively influence stream discharge.

1125 **Table 1.** Overview of the collected chloride and nitrate measurements.

Location	Parameters	Period	Source	Total amount of samples
Upstream	Cl, NO ₃	1969 - 1981	Higler et al., 1981	15
Upstream	Cl, NO ₃	1992	Hoek, 1992	1
Upstream	NO ₃	1980 - 1990	Dam et al., 1993	2
Upstream	Cl, NO ₃	1998	Van der Aa et al., 1999	1
Upstream	Cl, NO ₃	2004 - 2005	Verdonschot en Loeb, 2008	2

Upstream	Cl, NO ₃	1985 - 2018	Waterboard Vechtstromen	245
Downstream	Cl, NO ₃	1992	Hoek, 1992	1
Downstream	Cl, NO ₃	1985 - 2018	Waterboard Vechtstromen	282

Table 2. Exploration of the model behaviour under different scenarios.

Set	Parameter
-	Base case. Variable input, no denitrification
1a	Unsaturated zone hydrological delay Travel Time
1b	Unsaturated zone N species delay Travel Time only part of N
2	Increased saturated zone travel times Mean Travel Time
3	Different temporal input of solutes Input
4	Spatial differences in solute input Input
5	Denitrification in the saturated zone Travel Time, depth

1130 **Table 3. Summarized results of the exploration of the model behaviour.**

Set		Peak concentration change [mg/L]		Time to peak change [years]		Conc. in 2016 change [TU]
		Cl	NO ₃	Cl	NO ₃	Tritium
1a	Unsaturated zone, delay 5 years	0	0	+5	+5	-0.29
1b	Unsaturated zone, delay 10 years on 50% of N	0	-11	0	+10	0
2	Increased sat. zone travel times, factor 5	-5	-20	+10	+10	-0.63
<u>3a</u>	Different temporal input 1: direct stop N	0	0	0	0	0
<u>3b</u>	Different temporal input 2: slower reduction N	0	+2	0	+10	0
<u>4a</u>	Spatial differences in solute input 1	+1	+5	-1	-1	0
<u>4b</u>	Spatial differences in solute input 2	0	-1	+7	+4	0
<u>5a</u>	Denitrification saturated zone zero order	0	-15	0	0	0
<u>5b</u>	Denitrification saturated zone deep layers	0	-15	0	0	0

Table 4. Time to peak [years] of the output concentrations following a change in the input for different rates of changes and MTTs.

Slope of decrease [fraction of max / step]		Mean Travel Time (MTT)					
		<i>Young</i>	5	10	20	50	<i>Old</i>
		±	5	10	20	50	100
<i>Slower decrease</i>	0.2	0	12	29	40	55	90
	0.5	0	8	20	38	51	76
-	±	0	6	15	27	44	58

-	2	0	4	10	18	29	37
-	5	0	1	5	9	14	16
-	10	0	1	3	5	7	8
-	20	0	0	1	2	3	4
-	30	0	0	1	1	2	2
	Faster	40	0	0	0	1	2
	decrease	50	0	0	0	1	1
