

ANSWERS TO REFEREE 1

General comments

Martin et al. promise a study regarding the multi-constellation GNSS interferometry for soil moisture retrievals. The study does not live up to its title, since in fact, multiple single constellations are analyzed, yet there is no integration of data from the different constellations. Because of this, the current study merely seems a replication of a well-known methodology with little novelty. As expected, the authors do indeed show reasonable agreement between soil moisture estimated from GNSS interferometry and in situ measurements. I found the paper poorly structured, the statistical analysis incomplete, and the discussion lacking depth. The findings of this study are at best incremental.

Answer:

The proposed solution is based on the individual study of each satellite constellation, obtaining equivalent results for the three constellations, so the reviewer is right in saying that there is no integration of constellations. A new figure (which can be seen below), Figure 14 in the revised text, will be introduced in the final version of the manuscript with the combined solution of the three constellations as the average of the sum of the respective solutions, this new figure can be considered as a combined multi-constellation solution.

Figure 14. GNSS (GPS+GLONASS+GALILEO combination) comparison of daily soil moisture. The results of the geodetic and mass-market antennas are compared with the reference gravimetric data set.

A restructuring of the document will be carried out and the statistical study and discussion will be completed (see below as an answer to other suggestions).

The most important novelties of the research are technological, but we think they are important for the actual implementation of the technique in the agricultural sector: The introduction of GALILEO and GLONASS constellations produce a much larger sample set of observations around the antenna, and, specially, the introduction of mass-market GNSS sensors will greatly reduce the costs making the technique viable.

Specific comments

- From figure 2, can you please explain where exactly the reference soil moisture measurements were taken in reference to the ellipses around the antenna? How did you account for spatial offsets in the order of meters between the reference and GNSS soil moisture measurements?

Answer:

The results presented reflect the average value of soil moisture around the GNSS antenna per day obtained from all tracks of all satellites per constellation or using the three constellations as an average, so, there is no offset to consider, the average values obtained from GNSS technology have been compared with the in situ samples obtained in the soil (one per day except weekends). No bias in the results can be expected since the ground around the antenna is very homogeneous. Nonetheless, the location of the samples will be included in the Figure 2 as is suggested by the referee:

Figure 2. GNSS Fresnel ellipses around the geodetic antenna during one of the observation days. GPS constellations satellites are shown in black, GLONASS satellites are shown in red, and GALILEO satellites are shown in blue. Green circle is the location where soil samples have been taken.

- P1L21: Correlation coefficients are not expressed as percentages

Answer:

It has been changed in the revised version of the manuscript (new line 19).

- P1L27-28: The native resolution of the SMAP passive sensor is approximately 36 km. With no active sensor, the 9 km product is created by integrating non-SMAP data sources. Therefore, 36 km is the more correct resolution to mention in comparison with SMOS. Sentinel-1 sensors have a revisit time of 12 days. 2 Sentinel-1 sensors are in orbit, which decreases the revisit time. The spatial resolution is in the order of 10s of m. Please modify.

Answer:

It has been changed in the revised version of the manuscript (new lines 25-28).

- P3L82-84: Please elaborate on what L1, E1, L2, E5 and L2C are for non-specialist readers.

Answer:

The radio-signal structure of GPS, GLONASS and GALILEO systems are similar. Different carrier signals in the L-band are broadcast, L1 and L2 corresponds with the two main frequencies of the signal emitted from the GPS satellites and E1 and E5 with the two main frequencies of the signal emitted from the GALILEO satellites. In contrast to GPS and GALILEO, GLONASS satellites transmit carrier signals at different frequencies from a basic L frequency (explained in the section 3.1 of the manuscript).

L2C corresponds to the Civil L2 signal of the block satellites IIR-M and IIF of the GPS constellation, available only since 2005 when the first block IIR-M was launched. This signal is designed specifically to meet commercial needs, which increases robustness of the signal, improve resistance to interference, and improve accuracy (Leick et al., 2015).

This explanation is included in the revised version of the manuscript (lines 102-116).

- P6L166-167. Figures 7-10 portray very little additional information in reference to Figures 5-6, and the differences with Figures 5-6 are not well described in the text.

Answer:

Our first idea was to include a complete example for each constellation for a better understanding of the results. This is the only difference between the graphs, so, in comparison, they should be very similar since they show a good complete trace of a satellite. However, as is explained in the discussion section, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 db-Hz between the

geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a). This effect has an impact in the range of the reflected signal. This explanation is included in the results section as a justification for the inclusion of the figures (lines 229-232).

- Can you please elaborate on the comparison between the GNSS-derived soil moisture and reference datasets? And on the difference between the results from the geodetic and mass-marked antennas. A statistical analysis could include simple linear regression, from which deviation from the 1:1 line and goodness-of-fit values could be discussed, among others. The statistical analysis is poor and incomplete.

Answer:

Table 1 is completed with the information of the GNSS results (that is, including the three satellite constellations combination), and, also, including new statistical scores.

The following explanations are included in the revised manuscript (Results and discussion sections)

MAE is the mean absolute error, RMSE is the root mean square error, mean and Std. are the mean and the standard deviation of the differences.

The Pearson correlation coefficient can be used to summarize the strength of the linear relationship between two data samples. Spearman correlation can be used to summarize if two variables are related by a nonlinear relationship, such that the relationship is stronger or weaker across the distribution of the variables.

Pearson and Spearman correlation are equivalent between Geodesic and Mass-market antenna for every constellation and comparing the constellations. These means that a lineal relationship can be considered between the soil moisture results obtained from all GNSS antennas and the sample observations.

If we consider the results obtained for every constellation independently, equivalent results between geodetic and mass-market antenna is obtained for RMSE, MAE, Mean and Std., showing the good performance of the mass-market antenna.

The worst results in terms of RMSE, MAE and Std. were obtained for GALILEO constellation, probably because there aren't as many satellites in the constellation as the GPS and GLONASS constellations have. GLONASS constellation offers slight improvement in terms of RMSE, MAE and Std. results in comparison with GPS, whose range of values appears more compressed for both the geodetic and mass-market antennas, probably because GPS constellation, in the moment of the observations, had three different satellite blocks (blocks IIR, IIF and IIF) with different capabilities, and GLONASS only two (blocks M and K).

However, the ranges of RMSE, MAE and Std. considering GPS, GLONASS and GALILEO constellations (both geodetic and mass-market antennas) are less than 0.01 m³/m³ and less than 0.15 for Pearson or Spearman correlation, so we can consider that the

three constellations produce similar V_{GNSS} values, regardless of the type of antenna used.

This last conclusion opens the possibility of using the three constellations in combination as the average value obtained from the value of each of the constellations. The last two columns of Table 1 show the statistical summary of this combination for both the geodetic and the mass-market antenna, where it can be seen that the values obtained are equivalent to those of the previous columns.

Table 1. Statistical summary of the soil moisture estimates from the GPS, GALILEO and GLONASS constellations with the reference (in situ) values. GNSS is the combination of the three constellations. RMSE is the root mean square error, MAE is the mean absolute error and Std. is the standard deviation of the differences.

	GPS vs. in situ		GALILEO vs. in situ		GLONASS vs. in situ		GNSS vs. in situ	
	Geodetic	Mass-market	Geodetic	Mass-market	Geodetic	Mass-market	Geodetic	Mass-market
RMSE (m^3/m^3)	0.025	0.026	0.028	0.024	0.020	0.020	0.022	0.022
Pearson correlation	0.77	0.72	0.75	0.76	0.83	0.84	0.80	0.81
Spearman correlation	0.78	0.75	0.80	0.80	0.82	0.85	0.78	0.81
MAE (m^3/m^3)	0.020	0.021	0.023	0.020	0.016	0.016	0.017	0.018
Mean (m^3/m^3)	0.002	-0.003	-0.001	0.005	0.000	0.002	0.001	0.001
Std (m^3/m^3)	0.025	0.026	0.028	0.023	0.020	0.020	0.022	0.022

- P6L175-176. The discussion starts with a table of results. Please move this to the Results section. Can you in the Discussion section elaborate a bit more on your findings, for example why did the GLONASS retrieval outperform the other retrievals?

Answer:

All sections will be restructured in the revised version. The answer to the GLONASS constellation can be read in the previous comment.

- The paper is poorly structured: parts of the Introduction (including figures) would fit better in the Methods section, the Results has preprocessing and processing headers but not really results, some results are given in the Discussion section.

Answer:

Thank you very much for the comment. All sections will be restructured in the revised version.

- It is unclear to me why the authors wrote an opening paragraph covering spaceborne soil moisture retrievals when the paper covers another topic.

Answer:

If the GNSS-IR technique is considered as another remote sensing technique for estimating soil moisture, this paragraph makes sense in the state-of-the-art section as a reference to locate the differences of the GNSS-IR technique in terms of resolution and temporal latency with respect to the images obtained by Earth observation satellites. In the revised version of the manuscript the idea that the GNSS-IR technique should be considered within the remote sensing techniques will be written (lines 41-43 of the revised manuscript).

- It is unclear to me why the authors did not integrate the BEIDOU constellation.

Answer:

Because the receivers used in the experiment could not decode the information of the BEIDU satellites. This will be added in the revised version of the manuscript (lines 59-60).

Comments in the manuscript

General answer:

All spelling, syntactic and grammatical errors are corrected in the revised version.

-Section 2.1. What is meant with 'our' sector? In addition, most of this paragraph is not relevant to the study.

Answer:

Sorry, 'our' sector means agricultural sector. The paragraph describes the activities of the center, since, on its website (<https://www.fundacioncajamarvalencia.es/es/comun/>), they cannot be read in English.

- Please explain what NMEA GSV is for non-specialist readers.

Answer:

NMEA is an acronym for the National Marine Electronics Association. Today in the world of GNSS, NMEA is a standard data format supported by all manufacturers to output measurement data from a sensor in a pre-defined format in ASCII. In the case of GNSS, it output position, velocity, time and satellite related data (for the constellations that the antenna can decode). There are quite a few NMEA messages or sentences, not

just one. Specifically, GSV sentences provide integer numbers for elevation, azimuth and signal-to-noise ratio.

This explanation will be added in the revised manuscript (lines 133-137).

-What is meant with 'uncut'?

Answer:

No signal interruptions, it will be changed in the revised version of the manuscript (lines 189, 190, and 206).

-GPS 23

Answer:

Changed by GPS satellite number 23, following this criteria after the specific number of a satellite de word number is included in all the revised manuscript.

ANSWERS TO REFEREE 2

General comments

- I found this study to be succinct, and it did not try to overreach its goals. However, there were some problems with the methodology that should be cleared up before it is published. Particularly, the authors used the relationship between SNR phase and soil moisture from the work presented in Chew et al. (2014) to convert SNR observations to soil moisture for their own sensors. But, the relationship that we developed in that work is ONLY applicable to the Trimble NetRS receiver and choke ring antenna. Different antennas and receivers could have vastly different relationships between SNR phase and soil moisture. For example, the Zephyr antenna actually has a negative relationship between phase and soil moisture, not a positive one. So, using this conversion factor with the particular hardware used in this study is not appropriate. Instead, the authors should just present the correlations between phase and gravimetric soil moisture for the different antennas/receivers and constellations used, and they should derive their own relationships (and put these in a table). The mistake in methodology erases their conclusions about the relative performances in terms of RMSE of the different constellations and geodetic-quality versus mass market receivers. The conclusions should be re-thought after the methodology is revised.

Answer:

Thank you very much for the comment. We followed the methodology explained in Zhang et al. (2017) considering the satellites with a correlation higher than 80% with the reference soil moisture observations. The linear relationship (in degrees) we found is summarized in the following table:

	<i>Geodetic antenna</i>	<i>Mass-market antenna</i>
<i>GPS constellation</i>	<i>157.97</i>	<i>330.50</i>
<i>GALILEO constellation</i>	<i>60.97</i>	<i>144.93</i>
<i>GLONASS constellation</i>	<i>22.18</i>	<i>33.33</i>

However, as in the case of the paper by Zhang et al. (2017), we obtained good results (those presented in the manuscript) by applying the linear relationship of 65.1 degrees in all cases, so we thought that generalizing to this value can simplify the methodology since no reference values are needed (that is what we expressed at the end of the discussion section of the manuscript).

We think that the idea is still valid since the only problem would be the change of sign in the value of the linear relationship, so we would like to continue with the generalization of the method, although the last sentence of the discussion section should be changed accordingly to what the reviewer suggests, recommending that the linear relationship should be calculated based on soil moisture reference values in order to know the sign of the linear relationship and, in case of positive sign, 65.1 can be used as a mean valid value to obtain accurate results.

The table above is included in the revised manuscript as Table 1, and this justification is also included (third paragraph of section results).

- If you do not have residual soil moisture values, you can usually estimate them based off of the soil type (as was done for the PBOH2O GNSS-IR network). Though, that requires having a long enough time series to make the assumption that, at some point during the time series, soil moisture was low enough to hit the residual value.

Answer:

This comment is added in the revised version (lines 353-355) and the reference included: (<https://www.unavco.org/data/gps-gnss/derived-products/pbo-h2o/documentation/documentation.html#soil>)

- It is too bad that during the entire experiment, there was only one dry down. It would be a much stronger paper if the experiment could be redone during a more interesting time of year (in terms of soil moisture variability), though perhaps this is not possible.

Answer:

We agree with the reviewer at this point, we had to remove all the equipment since the Cajamar center scientists needed to start with a planting cycle.

- The figures showing the time series of soil moisture retrievals are very difficult to see. The black versus grey dots, and how clustered they are together, make it difficult to distinguish any relative differences.

Answer:

Color figures will be included in the final version of the manuscript:

Figure 11. GPS comparison of daily soil moisture. The results of the geodetic and mass-market antennas are compared with the reference gravimetric data set.

Figure 12. GLONASS comparison of daily soil moisture. The results of the geodetic and mass-market antennas are compared with the reference gravimetric data set.

Figure 13. GALILEO comparison of daily soil moisture. The results of the geodetic and mass-market antennas are compared with the reference gravimetric data set.

- The spatial resolution of SMAP is actually 40 km (gridded to 36 km) since the radiometer is the only instrument onboard that works.

Answer:

Thank you very much for the comment, the introduction section is changed accordingly (lines 26-27).

ANSWERS TO THE EDITOR

Editor comments

-In the revised version you should be clear about the novelty of this manuscript.

Answer:

The novelty is clearly emphasized in the introduction section of the revised manuscript (lines 58-66).

-In your response to reviewer 2, you have defended the methods used. I will send the revised version back to the reviewer with the specific question to judge your arguments on this. I therefore suggest to also copy (as shorter version of) this defense to the revised version.

Answer:

Included in the revised version: new Table 1, lines 181-186, third paragraph of section results and lines 353-356 in the discussion section.

-Another important point, raised by reviewer 1, is that the structure of the manuscript can be significantly improved. You have acknowledged this in your response, and I'm looking forward to the improvements in the revised version.

Answer:

The structure of the revised manuscript has been improved.

- A minor point from my side is that within the field of hydrology, precipitation is generally expressed as L/T, so in Fig. 11-13, I suggest to report the precipitation in mm/d.

Answer:

It is changed in the figures of the revised version of the manuscript.

Multi-constellation GNSS interferometric reflectometry with mass-market sensors as a solution for soil moisture monitoring

Abstract. Per capita arable land is decreasing due to rapidly increasing population, and fresh water is becoming scarce and more expensive. Therefore, farmers should continue to use technology and innovative solutions to improve efficiency, save input costs, and optimise environmental resources (such as water). In the case study presented in this manuscript, the GNSS-IR technique was used to monitor soil moisture during 66 days, from December 3, 2018, to February 6, 2019, in the installations of the Cajamar Centre of Experiences, Paiporta, Valencia, Spain. Two main objectives were pursued. The first was the extension of the technique to a multi-constellation solution using GPS, GLONASS, and GALILEO satellites, and the second was to test whether mass-market sensors could be used for this technique. Both objectives were achieved. At the same time the GNSS observations were made, soil samples taken at 5 cm depth were used for soil moisture determination to establish a reference dataset. Based on a comparison with that reference data set, all GNSS solutions, including the three constellations and the two sensors (geodetic and mass-market), were highly correlated, with a correlation coefficient between 0.7 and 0.85.

1 Introduction

Soil moisture is a fundamental component of the hydrological cycle, and a key observable variable for optimising agricultural irrigation management. Additionally, soil moisture monitoring has been one of the main goals of the remote sensing satellite missions Soil Moisture and Ocean Salinity (SMOS), (Kerr et al., 2001), Soil Moisture Active Passive (SMAP), (Chan et al. 2016), and Sentinel-1, (Mattia et al., 2018). SMOS is used to derive global maps of soil moisture every three days at a spatial resolution of about 50 km, SMAP every two-three days with a spatial resolution of about 40 km (gridded to 36 km since the radiometer is the only instrument on board that works), and one Sentinel-1 satellite 12 days (two Sentinel-1 satellites are in orbit which decreases the revisit time) with a spatial resolution of about 1 km.

To obtain information about soil moisture at a very local scale and continuously, Global Navigation Satellite System (GNSS) reflectometry began to be tested as a possible solution (Masters et al., 2002; Zavorotny et al., 2003; Katzberg et al., 2005).

This was possible because GNSS satellites transmit in the L-band (microwave frequency), so the GNSS signal reflected by

nearby surfaces and recorded by the antenna contains information about the environment surrounding the antenna (scale of about 1000 m²). In particular, the ground-reflected global positioning system signal measured by a geodetic-quality GNSS system can be used to infer temporal changes in near-surface soil moisture. This technique, known as GNSS-interferometric reflectometry (GNSS-IR), analyses changes in the interference pattern of the direct and reflected signals, (Fig. 1), which are recorded in signal-to-noise ratio (SNR) data, as interferograms. Thus, GNSS-IR can be considered as another remote sensing technique for monitoring soil moisture in a local scale and continuously, independent from climatological conditions (the technique is valid in raining and foggy conditions) and illumination (day or night). Temporal fluctuations in the phase of the interferogram are indicative of changes in near-surface (depth of about 5-7 cm) volumetric soil moisture content, (Larson et al., 2008a, 2008b).

Commercially available geodetic-quality GNSS receivers and antennas can be used for GNSS-IR. The method has been tested with the Global Positioning System (GPS) satellite constellation, and it has been shown to provide consistent measurements of upper surface soil moisture content, (Larson et al., 2008a, 2008b, 2010; Larson and Nievinski, 2013; Chew et al., 2014, 2015, 2016; Small et al., 2015; Vey et al., 2015; Wan et al., 2015; Chen et al., 2016; Zhang et al., 2017).

With the use of the GPS constellation, the GPS-IR reflection footprint is far from homogeneous, Fig. 2, and some tracks cannot be included in the process and analysis (Vey et al., 2015; Chew et al., 2016). Therefore, GPS-IR needs to evolve to Global Navigation Satellite System reflectometry, GNSS-IR, where multi-constellation observation provides the solution. The integration of new navigation satellite constellations will produce a more homogeneous footprint around the antenna (Fig. 2). Roussel et al. (2016) introduced the GLONASS Russian constellation to retrieve soil moisture over bare soil, but there are no references in the literature for the European GALILEO or Chinese BEIDU constellations. Roesler and Larson (2018) provided a software tool for generating map GNSS-IR reflection zones that support GPS, GLONASS, GALILEO, and BEIDU constellations.

Therefore, the first novelty of this research was to extend, compare and combine the GPS-IR methodology to a multi-constellation scenario (GPS, GLONASS, and GALILEO; BEIDU is not introduced in this research because the antennas used in the experiment are not able to decode BEIDU signals), which will produce a much larger sample set of observations around the antenna than is obtained with only the GPS constellation, as shown in Fig. 2.

Additionally, geodetic-quality GNSS receivers and antennas are an expensive solution. If we keep in mind that the final market will be the agricultural market, a technique developed using those devices will never be introduced into the sector. Thus, the (main) second novelty of this research was the introduction of mass-market GNSS sensors as the basis for the technique. If the use of these mass-market devices can be confirmed, it will be possible to use them (one or several) at the same time to add redundancies, at a very low cost.

Bajado hacia abajo[1]: The GNSS-IR footprint for a single rising or setting satellite is an elongated ellipse in the direction of the satellite track (Fresnel ellipse or zones; Larson et al., 2010; Wan et al., 2015; Vey et al., 2015; Roesler and Larson, 2018). As the satellite rises and the elevation angle increases, the Fresnel zone becomes smaller and closer to the GNSS antenna. Data with elevation angles higher than 30 degrees should be discarded from the SNR series because they contain no significant oscillations and cannot be retrieved reliably. Data with elevation angles lower than 5 degrees should also be discarded in order to avoid strong multipath effects from trees, artificial surfaces, and structures surrounding the antenna. A GNSS satellite takes about one hour to rise from an elevation angle of 5 degrees to an angle of 30 degrees.¶

2 Materials and methods

2.1 Location of the experiment

The experiment was conducted in the installations of the Cajamar Centre of Experiences, located in Paiporta, Valencia, Spain (39°25'3'' N, 0°25'4'' W), which is an agricultural research technology centre (https://www.fundacioncajamarvalencia.es/es/comun/actividades/ in Spanish).

The centre began its activities in 1994. Some of the research topics carried out by the centre are the valorisation of agricultural by-products and the use of microorganisms in food, pharmaceuticals, and aesthetics using the latest biotechnology resources; the design of new containers and bio-functional formats for the marketing of healthy foods with high added value; improvement in irrigation automation, biological control management, and agronomic management in organic production; and the introduction of alternative value crops and new varieties that guarantee the sustainability of agricultural sector.

2.2 Instrumental and observations

A geodetic GNSS receiver (Trimble R10 GNSS receiver, from the Department of Cartographic Engineering Geodesy and Photogrammetry of the Universitat Politècnica de València) and a mass-market receiver (Navilock GNSS receiver based on a u-blox 8 UBX-M8030-KT chipset with a built-in antenna) connected to a Raspberry Pi 3 as a control device and for storing the observations, were used to obtain multi-constellation SNR observables (GPS, GLONASS and GALILEO). Five seconds sample rate observations were obtained simultaneously for both sensors (Fig. 3).

The radio-signal structure of GPS, GLONASS and GALILEO systems are similar. Different carrier signals in the L-band are broadcast, L1 and L2 corresponds with the two main frequencies of the signal emitted from the GPS satellites and E1 and E5 with the two main frequencies of the signal emitted from the GALILEO satellites. In contrast to GPS and GALILEO, GLONASS satellites transmit carrier signals at different frequencies from a basic L frequency, GLONASS L1 frequencies are:

$$f_{L1} = f_0 + k * \Delta f_{L1} \quad k = 1, 2, \dots, 24, \quad (1)$$

where $f_0 = 1602.0 \text{ MHz}$, and $\Delta f_{L1} = 0.5625 \text{ MHz}$, and k is the carrier number assigned to the specific GLONASS satellite (Hoffmann et al., 2008). Thus, the frequency for each satellite should be computed and included in the GLONASS file.

The frequencies used in the experiment were L1, for the GPS and GLONASS satellite constellations and E1 for the GALILEO constellation. This choice was forced because the mass-market device could not track the L2 or E5 satellite signals. However, Vey et al. (2011) showed that the soil moisture root mean square difference between L2C and L1 was only $0.03 \text{ m}^3/\text{m}^3$. L2C corresponds to the Civil L2 signal of the block satellites IIR-M and IIF of the GPS constellation, available only since 2005 when the first block IIR-M was launched. This signal is designed specifically to meet commercial needs, which increases robustness of the signal, improve resistance to interference, and improve accuracy (Leick et al., 2015).

125 The GNSS-IR footprint for a single rising or setting satellite is an elongated ellipse in the direction of the satellite track (Fresnel ellipse or zones; Larson et al., 2010; Wan et al., 2015; Vey et al., 2015; Roesler and Larson, 2018). As the satellite rises and the elevation angle increases, the Fresnel zone becomes smaller and closer to the GNSS antenna. Data with elevation angles higher than 30 degrees should be discarded from the SNR series because they contain no significant oscillations and cannot be retrieved reliably. Data with elevation angles lower than 5 degrees should also be discarded in order to avoid strong multipath effects from trees, artificial surfaces, and structures surrounding the antenna. A GNSS satellite takes about one hour to rise from an elevation angle of 5 degrees to an angle of 30 degrees.

130 The geodetic GNSS receiver ~~store~~ the observations (including SNR data) in the commonly used RINEX files, so the elevation and azimuth of a satellite for an epoch should be computed from the observation RINEX file and the navigation RINEX file, (Hofmann-Wellenhof et al., 2008).

135 The mass-market receiver uses NMEA GSV sentences to provide integer numbers for elevation, azimuth and signal-to-noise ratio (SNR) directly. NMEA is an acronym for the National Marine Electronics Association. GNSS NMEA is a standard data format supported by all manufacturers to output measurement data from a sensor in a pre-defined format in ASCII. In the case of GNSS, it output position, velocity, time and satellite related data (for the constellations that the antenna can decode). There are quite a few NMEA messages or sentences, specifically, GSV sentences provide integer numbers for elevation, azimuth and signal-to-noise ratio.

140 The results were compared with soil moisture measurements based on soil samples taken at a depth of 5 cm and weighed before and after being dried (gravimetric method) in a laboratory (Fig. 4). These measurements were considered the reference dataset. The soil samples were taken one per day except weekends and the location, in comparison with the antenna position, can be seen in Fig. 2.

In total, 66 days of measurements, from December 3, 2018, to February 6, 2019, were observed, processed, and analysed. The height of the antennas from the ground was 1.80 m for the geodetic GNSS device and 1.84 m for the mass-market device.

145 Precipitation data were added in the final plot results. These data were obtained from a meteorological station located in the Cajamar Experiences Centre (100 meters from the GNSS antennas).

2.3 Theoretical background

The theoretical background is based on the procedure developed by Larson et al., (2010) and detailed in Chew et al., (2014), vey et al., (2015), and Zhang et al., (2017). Each valid track of a satellite ~~should be~~ separated into ascending path and descending path.

150 The processing of each satellite track can be summarised as follows:

- 1) SNR data are converted from dB units to linear scale in volts using the conversion equation (S stands for SNR in the next equation and for the rest of equations in the manuscript) $S_{linear} = 10^{S/20}$ (vey et al., 2016).
- 2) A low-order polynomial (second degree) is fit to the S_{linear} in order to eliminate the direct satellite signal, so that the reflected signal is isolated: $S_{linear}^{reflected}$, (Wan et al., 2015; Chew et al., 2016).

- 3) A Lomb-Scargle periodogram (Lomb, 1976; Press et al., 1992; Roesler and Larson, 2018), is then computed from $S_{lineal}^{reflected}$, and the track goes to the next step only if there is a clear signal that reflects a primary wave. Tracks with multiple peaks or low maximum average power (less than four times the background noise) are not included in the next step. If the Lomb-Scargle periodogram is computed using the sine elevation angle as the input X axis, the result converts the frequency into antenna height in the output X axis. Only tracks with computed antenna height consistent with the measured antenna height (less than 0.1 meters difference), go to the next step.
- 4) The selected tracks are modelled using the expression below:

$$S_{lineal}^{reflected} = A \cos\left(\frac{4\pi h}{\lambda} \sin e + \phi\right) \quad (2)$$

The equation means that $S_{lineal}^{reflected}$ can be modelled in terms of the amplitude A and phase offset ϕ of a primary wave. λ is the GNSS wavelength (L1 for GPS and GLONASS and E1 for GALILEO), e is the satellite elevation, and h is the antenna height, which is assumed to be a constant due to the low signal penetration on the ground (Chew et al., 2014; Roussel et al., 2016; Zhang et al., 2017). The least squares algorithm (Strang and Borre, 1997; Leick et al., 2015) is used to estimate A and ϕ .

5) Chew et al., (2013) derived a linear relationship between the previously computed phase offset and soil moisture with a slope of 65.1° in order to obtain the GNSS-derived volumetric water content, VW_{GNSS} (m^3/m^3). V stands for VW_{GNSS} in the next equation and for the rest of the manuscript:

$$V_{GNSS} = \frac{\Delta\phi_t}{65.1} + V_{Residual} \quad (3)$$

However, this value should be computed using the reference values in order to convert the satellite tracks phase values into GNSS-derived volumetric water content, because this linear relationship can be positive or negative. Zhang et al. (2017) showed the importance of this adjustment with the test data in order to obtain better results (their results showed a decrease of the final standard deviation from 0.036 m^3m^{-3} -using the linear relationship of 65.1°- to 0.008 m^3m^{-3} -using the adjusted linear relationship-).

$V_{Residual}$ in Equation 3, is the minimum soil moisture observation from the reference data set (obtained from the soil samples). This minimum value should be taken from the reference observations as long as the GNSS observation is continuous and without interruptions. In the case that there is any interruption in the GNSS observation data, this value must be chosen again among the reference values after the interruption. $\Delta\phi_t = \phi - \phi_o$ is calculated with respect to a reference phase ϕ_o computed in this work as proposed by Chew et al. (2016): the mean of the lowest 15%

Eliminado: Chew et al., (2013) derived a linear relationship between the previously computed phase offset and soil moisture with a slope of 65.1°. We used this value to convert the phase values of each track into GNSS-derived volumetric water content, VW_{GNSS} (m^3/m^3), V stands for VW_{GNSS} in the next equation and for the rest of equations in the manuscript.

$$V_{GNSS} = \frac{\Delta\phi_t}{65.1} + V_{Residual} \quad (2)$$

where $V_{Residual}$

205 of the computed phases for each satellite tracks during the retrieval period. \emptyset_o should be computed again in the case of interruption of the GNSS signal. Ascending and descending paths for the same satellite are treated separately.

6) Finally, the mean V value of all satellite tracks of the same constellation that pass at different times during the day is computed, so the final GNSS soil moisture represents a temporal average for all observations analyzed during one day. To address the objectives of this research, we have three different results, one for each GNSS constellation.

210 3 Results

3.1 Processing

RINEX observation and navigation files from the geodetic GNSS antenna were used to generate the input file for the processing process. This file contained year, month, day, hour, satellite identification, SNR, elevation, and azimuth for every observed epoch. We computed three different files (GPS, GALILEO and GLONASS). The frequency for each GLONASS satellite

215 should be also computed and included in the GLONASS file.

The file containing the NMEA observations from the mass-market antenna was used to generate three different input files for the processing process, one for each satellite constellation. However, due to the integer nature of the SNR, elevation, and azimuth observation numbers, an extra processing step was included for the mass-market observation files. This step used the navigation files from the International GNSS Service (IGS) repository (<http://www.igs.org>) to compute float numbers for

220 elevation and azimuth values of the observed satellites.

The rest of the processing followed the steps defined in the previous section. Only full GNSS tracks data covering more than 30 minutes and cover more than 10 degrees of elevation in its trajectory were considered in our study.

3.2 Results

The geodetic antenna SNR data in volts for satellite GPS number 23 are shown in Fig. 5a, the SNR data with the direct signal removed are shown in Fig. 5b, the Lomb-Scargle periodogram for the SNR reflected signal is shown in Fig. 5c, and the SNR reflected signal with the adjusted wave (Step 4 in the previous section) is shown in Fig. 5d. Fig. 6 portrays the same concepts for the same satellite but using the mass-market antenna observations. Fig. 7 and 8 portray the same concepts for the GLONASS satellite number 5, and Fig. 9 and 10 display these for the GALILEO satellite number 21.

225

The SNR values from the geodetic antenna and the mass-market antenna for the GPS constellation are similar, as suggested in Li and Geng (2019), because the u-blox chipset uses an active, right-handed, circularly polarized antenna with uniform antenna gain. However, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 db-Hz between the geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a).

230

A linear relationship between reference data and every GNSS constellation and antenna was computed using the methodology proposed by Zhang et al. (2017), the results can be seen in Table 1. Based on the positive values for all lineal relationships and

Eliminado: cut

Eliminado: However, Zhang et al. (2017) showed that it is important to adjust the linear relationship with the test data in order to obtain better results (their results showed a decrease of the final standard deviation from 0.036 m³m⁻³ -using the linear relationship of 65.1°- to 0.008 m³m⁻³).

270 the conclusions on Zhang et al. (2017), a slope of 65.1° between the all GNSS computed phase offset and the soil moisture
was used to homogenize the results among different constellations and the two different antennas.
275 However, two different values for $V_{Residual}$ and ϕ_0 were used due to an outage of the electrical power during three days (from
day 40 to day 42 of the experiment), where no observations were recorded.
The results presented the average value of soil moisture around the geodetic and mass-market antennas per day, obtained from
all valid GNSS tracks of all satellites per constellation or using the three constellations.
Fig. 11, 12, and 13 show a comparison of the daily soil moisture from GPS, GLONASS, and GALILEO, respectively, where
the results of the geodetic and mass-market antennas can be compared with the reference gravimetric data set. Daily
precipitation amounts are also included in the figures.
Finally, Fig. 14 show the combined solution of the three constellations as an average of the results of the individual solutions,
280 which can be considered as a combined multi-constellation solution.
The numerical values for Fig. 11, 12, 13 and 14 are listed in Table 2, where MAE is the mean absolute error, RMSE is the root
mean square error, mean and Std. are the mean and the standard deviation respectively between the GNSS antennas and the
reference values. The Pearson correlation coefficient can be used to summarize the strength of the linear relationship between
two data samples. Spearman correlation can be used to summarize if two variables are related by a nonlinear relationship, such
285 that the relationship is stronger or weaker across the distribution of the variables.

4 Discussion

Based in the results summarized in Table 2, equivalent results between geodetic and mass-market antenna is obtained for
RMSE, MAE, Mean and Std., showing the good performance of the mass-market antenna. Pearson and Spearman correlation
are equivalent between Geodesic and Mass-market antenna for every constellation and comparing the constellations. These
290 confirms that a lineal relationship can be considered between the soil moisture results obtained from all GNSS antennas and
the sample observations.
The worst results in terms of RMSE, MAE and Std. were obtained for GALILEO constellation, probably because there aren't
as many satellites in the constellation as the GPS and GLONASS constellations have. GLONASS constellation offers slight
improvement in terms of RMSE, MAE and Std. results in comparison with GPS. GLONASS range of values appears more
295 compressed for both the geodetic and mass-market antennas, probably because GPS constellation, in the moment of the
observations, had three different satellite blocks (blocks IIR, IIF and IIF) with different capabilities, and GLONASS only two
(blocks M and K). However, the ranges of RMSE, MAE and Std. considering GPS, GLONASS and GALILEO constellations
(both geodetic and mass-market antennas) are less than 0.01 m3/m3 and less than 0.15 for Pearson or Spearman correlation,
so we can consider that the three constellations produce similar V_{GNSS} values, regardless of the type of antenna used, opening
300 the possibility of using the three constellations in combination as a multi-constellation solution. The last two columns of Table

2 show the statistical summary of the constellations combination for both the geodetic and the mass-market antenna, where it can be seen that the values obtained are equivalent to those of the previous columns.

Our RMS results using the a priori slope values of 65.1° are comparable with those obtained by Zhang et al. (2017), who processed six months of continuous observations and obtained a mean standard deviation value of $0.036 \text{ m}^3/\text{m}^3$, and those of Vey et al. (2015), who processed 6 years of observations and obtained a standard deviation value of $0.06 \text{ m}^3/\text{m}^3$.

The SNR bias between the geodetic and mass-market antenna for GLONASS and GALILEO constellations (Fig. 7b and 8b and Fig. 9b and 10b) has no effects in the final phase offset variations for the adjusted wave.

According to Step 3 of Section 2.3, the 70% of the GPS tracks recorded by the geodetic antenna were considered valid for processing, as were 73% for GALILEO, and 74% for GLONASS. This percentage is reduced to around a 10% if we consider the tracks recorded by the mass-market antenna. Nonetheless, one of the main important problems in this research is related with the selection of the correct tracks to be processed and adjusted using Step 4 of Section 2.3. Based on the mentioned criteria (tracks with multiple peaks or low maximum average power and computed reflector height consistent with the measured antenna height), some tracks that should not be processed are finally processed (around 8% of all tracks irrespective the constellation). These wrongly processed tracks introduce outliers in the computed V_{GNSS} , which are eliminated in the daily final mean V_{GNSS} computation because they produce a high RMS in the daily computations using all satellites. One way to accomplish this task could be to use good figures, such as those from Fig. 5c Fig. 5d, to produce a valid set of training images and use machine learning tools (image recognition) to decide automatically whether a new track can be considered as a good track (so it can be processed) or not. This idea is currently under development.

In situ observations are needed to solve Eq. 3 ($V_{Residual}$ parameter). However, if there are no reference values, this constant cannot be included, and the results will present an offset in comparison with the real values. However, the results can be used in a relative way, that is, can be used to infer VWC variations from one day to another. This relative comparison can be performed only if the observations are continuous. If there is an interruption in the raw data (because the antenna is turned off) of more than two or three hours, the previous reference is lost and the relative comparisons should start again (from the moment the antenna is turned on again). In situ observations are also needed if we want to adjust the linear relationship between the computed phase offset and the soil moisture, as is developed in Zhang et al. (2017); however, if there are no reference values, they can be estimated based on the soil type (URL 1). Though, that requires having a long enough time series to make the assumption that, at some point during the time series, soil moisture was low enough to hit the residual value. However, in case the linear relationship is positive, a value of 65.1° can also be used to obtain acceptable results.

5 Conclusions

The case study presented in this research is focused on the GNSS SNR data acquisition and processing using the GNSS-IR technique to monitor soil moisture. The main objectives of this research were the use, comparison and combination of GPS,

Eliminado: The best results were obtained for the GLONASS constellation, whose range of values appears more compressed for both the geodetic and mass-market antennas in comparison with the GPS and GALILEO results. The worst results were obtained for GALILEO constellation. However, the ranges between these results are less than $0.01 \text{ m}^3/\text{m}^3$ for RMS and 0.15 for correlation, so we can consider that the three constellations produce similar V_{GNSS} values, as do the geodetic and mass-market antennas.

Movido hacia arriba[4]: The SNR values from the geodetic antenna and the mass-market antenna for the GPS constellation are similar, as suggested in Li and Geng (2019), because the u-blox chipset uses an active, right-handed, circularly polarised antenna with uniform antenna gain. However, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 dB-Hz between the geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a).

Eliminado: The SNR values from the geodetic antenna and the mass-market antenna for the GPS constellation are similar, as suggested in Li and Geng (2019), because the u-blox chipset uses an active, right-handed, circularly polarised antenna with uniform antenna gain. However, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 dB-Hz between the geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a). This effect has an impact in the range of the reflected signal (Fig. 7b and 8b and Fig. 9b and 10b), but it has no effects in the final phase offset variations for the adjusted wave.

375 GLONASS, and GALILEO constellations solutions and the use and comparison of a geodetic and mass-market antenna solutions.

Independent GPS, GLONASS, and GALILEO solutions were generated to demonstrate that the technique can be extended to a multi-constellation solution. This is necessary because a single constellation solution presents a reflection footprint that is far from homogeneous around the antenna and because 30-35% of the observed satellite tracks of the geodetic antenna are not valid for processing (40-45% if the mass-market antenna is considered).

380 The use of a mass-market GNSS antenna was confirmed to be a viable tool for GNSS-IR, with the caution of using the IGS navigation files to transform the observed integer numbers obtained in the NMEA messages for the elevation and azimuth of the satellites into floating numbers. With the use of mass-market sensors, it will become possible to design scenarios with several GNSS stations generating redundant observations. Therefore, maps of soil moisture variations by specific and selective areas of soil, cultivation, and/or management can be generated, instead of obtaining only an average value for the entire observation area.

385 GNSS-IR is still a technique with numerous technological challenges in order to becoming a competitive solution with respect to current observation techniques, but it has great potential with regard to continuity of observation (can be implemented in a real or quasi-real time scenario), precision, and measurement acquisition cost if mass-market antennas are used.

Abstract. Per capita arable land is decreasing due to rapidly increasing population, and fresh water is becoming scarce and more expensive. Therefore, farmers should continue to use technology and innovative solutions to improve efficiency, save input costs, and optimise environmental resources (such as water). In the case study presented in this manuscript, the GNSS-IR technique was used to monitor soil moisture during 66 days, from December 3, 2018, to February 6, 2019, in the installations of the Cajamar Centre of Experiences, Paiporta, Valencia, Spain. Two main objectives were pursued. The first was the extension of the technique to a multi-constellation solution using GPS, GLONASS, and GALILEO satellites, and the second was to test whether mass-market sensors could be used for this technique. Both objectives were achieved. At the same time the GNSS observations were made, soil samples taken at 5 cm depth were used for soil moisture determination to establish a reference dataset. Based on a comparison with that reference data set, all GNSS solutions, including the three constellations and the two sensors (geodetic and mass-market), were highly correlated, with a correlation coefficient between 0.7 and 0.85.

1 Introduction

Soil moisture is a fundamental component of the hydrological cycle, and a key observable variable for optimising agricultural irrigation management. Additionally, soil moisture monitoring has been one of the main goals of the remote sensing satellite missions Soil Moisture and Ocean Salinity (SMOS), (Kerr et al., 2001), Soil Moisture Active Passive (SMAP), (Chan et al. 2016), and Sentinel-1, (Mattia et al., 2018). SMOS is used to derive global maps of soil moisture every three days at a spatial resolution of about 50 km, SMAP every two-three days with a spatial resolution of about 40 km (gridded to 36 km since the radiometer is the only instrument on board that works), and one Sentinel-1 satellite 12 days (two Sentinel-1 satellites are in orbit which decreases the revisit time) with a spatial resolution of about 1 km.

To obtain information about soil moisture at a very local scale and continuously, Global Navigation Satellite System (GNSS) reflectometry began to be tested as a possible solution (Masters et al., 2002; Zavorotny et al., 2003; Katzberg et al., 2005).

This was possible because GNSS satellites transmit in the L-band (microwave frequency), so the GNSS signal reflected by

nearby surfaces and recorded by the antenna contains information about the environment surrounding the antenna (scale of about 1000 m²). In particular, the ground-reflected global positioning system signal measured by a geodetic-quality GNSS system can be used to infer temporal changes in near-surface soil moisture. This technique, known as GNSS-interferometric reflectometry (GNSS-IR), analyses changes in the interference pattern of the direct and reflected signals, (Fig. 1), which are recorded in signal-to-noise ratio (SNR) data, as interferograms. Thus, GNSS-IR can be considered as another remote sensing technique for monitoring soil moisture in a local scale and continuously, independent from climatological conditions (the technique is valid in raining and foggy conditions) and illumination (day or night). Temporal fluctuations in the phase of the interferogram are indicative of changes in near-surface (depth of about 5-7 cm) volumetric soil moisture content, (Larson et al., 2008a, 2008b).

Commercially available geodetic-quality GNSS receivers and antennas can be used for GNSS-IR. The method has been tested with the Global Positioning System (GPS) satellite constellation, and it has been shown to provide consistent measurements of upper surface soil moisture content, (Larson et al., 2008a, 2008b, 2010; Larson and Nievinski, 2013; Chew et al., 2014, 2015, 2016; Small et al., 2015; Vey et al., 2015; Wan et al., 2015; Chen et al., 2016; Zhang et al., 2017).

With the use of the GPS constellation, the GPS-IR reflection footprint is far from homogeneous, Fig. 2, and some tracks cannot be included in the process and analysis (Vey et al., 2015; Chew et al., 2016). Therefore, GPS-IR needs to evolve to Global Navigation Satellite System reflectometry, GNSS-IR, where multi-constellation observation provides the solution. The integration of new navigation satellite constellations will produce a more homogeneous footprint around the antenna (Fig. 2). Roussel et al. (2016) introduced the GLONASS Russian constellation to retrieve soil moisture over bare soil, but there are no references in the literature for the European GALILEO or Chinese BEIDU constellations. Roesler and Larson (2018) provided a software tool for generating map GNSS-IR reflection zones that support GPS, GLONASS, GALILEO, and BEIDU constellations.

Therefore, the first novelty of this research was to extend, compare and combine the GPS-IR methodology to a multi-constellation scenario (GPS, GLONASS, and GALILEO; BEIDU is not introduced in this research because the antennas used in the experiment are not able to decode BEIDU signals), which will produce a much larger sample set of observations around the antenna than is obtained with only the GPS constellation, as shown in Fig. 2.

Additionally, geodetic-quality GNSS receivers and antennas are an expensive solution. If we keep in mind that the final market will be the agricultural market, a technique developed using those devices will never be introduced into the sector. Thus, the (main) second novelty of this research was the introduction of mass-market GNSS sensors as the basis for the technique. If the use of these mass-market devices can be confirmed, it will be possible to use them (one or several) at the same time to add redundancies, at a very low cost.

Bajado hacia abajo[1]: The GNSS-IR footprint for a single rising or setting satellite is an elongated ellipse in the direction of the satellite track (Fresnel ellipse or zones; Larson et al., 2010; Wan et al., 2015; Vey et al., 2015; Roesler and Larson, 2018). As the satellite rises and the elevation angle increases, the Fresnel zone becomes smaller and closer to the GNSS antenna. Data with elevation angles higher than 30 degrees should be discarded from the SNR series because they contain no significant oscillations and cannot be retrieved reliably. Data with elevation angles lower than 5 degrees should also be discarded in order to avoid strong multipath effects from trees, artificial surfaces, and structures surrounding the antenna. A GNSS satellite takes about one hour to rise from an elevation angle of 5 degrees to an angle of 30 degrees.¶

2 Materials and methods

2.1 Location of the experiment

The experiment was conducted in the installations of the Cajamar Centre of Experiences, located in Paiporta, Valencia, Spain (39°25'3'' N, 0°25'4'' W), which is an agricultural research technology centre (https://www.fundacioncajamarvalencia.es/es/comun/actividades/ in Spanish).

The centre began its activities in 1994. Some of the research topics carried out by the centre are the valorisation of agricultural by-products and the use of microorganisms in food, pharmaceuticals, and aesthetics using the latest biotechnology resources; the design of new containers and bio-functional formats for the marketing of healthy foods with high added value; improvement in irrigation automation, biological control management, and agronomic management in organic production; and the introduction of alternative value crops and new varieties that guarantee the sustainability of agricultural sector.

2.2 Instrumental and observations

A geodetic GNSS receiver (Trimble R10 GNSS receiver, from the Department of Cartographic Engineering Geodesy and Photogrammetry of the Universitat Politècnica de València) and a mass-market receiver (Navilock GNSS receiver based on a u-blox 8 UBX-M8030-KT chipset with a built-in antenna) connected to a Raspberry Pi 3 as a control device and for storing the observations, were used to obtain multi-constellation SNR observables (GPS, GLONASS and GALILEO). Five seconds sample rate observations were obtained simultaneously for both sensors (Fig. 3).

The radio-signal structure of GPS, GLONASS and GALILEO systems are similar. Different carrier signals in the L-band are broadcast, L1 and L2 corresponds with the two main frequencies of the signal emitted from the GPS satellites and E1 and E5 with the two main frequencies of the signal emitted from the GALILEO satellites. In contrast to GPS and GALILEO, GLONASS satellites transmit carrier signals at different frequencies from a basic L frequency, GLONASS L1 frequencies are:

$$f_{L1} = f_0 + k * \Delta f_{L1} \quad k = 1, 2, \dots, 24, \quad (1)$$

where $f_0 = 1602.0 \text{ MHz}$, and $\Delta f_{L1} = 0.5625 \text{ MHz}$, and k is the carrier number assigned to the specific GLONASS satellite (Hoffmann et al., 2008). Thus, the frequency for each satellite should be computed and included in the GLONASS file.

The frequencies used in the experiment were L1, for the GPS and GLONASS satellite constellations and E1 for the GALILEO constellation. This choice was forced because the mass-market device could not track the L2 or E5 satellite signals. However, Vey et al. (2011) showed that the soil moisture root mean square difference between L2C and L1 was only $0.03 \text{ m}^3/\text{m}^3$. L2C corresponds to the Civil L2 signal of the block satellites IIR-M and IIF of the GPS constellation, available only since 2005 when the first block IIR-M was launched. This signal is designed specifically to meet commercial needs, which increases robustness of the signal, improve resistance to interference, and improve accuracy (Leick et al., 2015).

125 The GNSS-IR footprint for a single rising or setting satellite is an elongated ellipse in the direction of the satellite track (Fresnel ellipse or zones; Larson et al., 2010; Wan et al., 2015; Vey et al., 2015; Roesler and Larson, 2018). As the satellite rises and the elevation angle increases, the Fresnel zone becomes smaller and closer to the GNSS antenna. Data with elevation angles higher than 30 degrees should be discarded from the SNR series because they contain no significant oscillations and cannot be retrieved reliably. Data with elevation angles lower than 5 degrees should also be discarded in order to avoid strong multipath effects from trees, artificial surfaces, and structures surrounding the antenna. A GNSS satellite takes about one hour to rise from an elevation angle of 5 degrees to an angle of 30 degrees.

130 The geodetic GNSS receiver ~~store~~ the observations (including SNR data) in the commonly used RINEX files, so the elevation and azimuth of a satellite for an epoch should be computed from the observation RINEX file and the navigation RINEX file, (Hofmann-Wellenhof et al., 2008).

135 The mass-market receiver uses NMEA GSV sentences to provide integer numbers for elevation, azimuth and signal-to-noise ratio (SNR) directly. NMEA is an acronym for the National Marine Electronics Association. GNSS NMEA is a standard data format supported by all manufacturers to output measurement data from a sensor in a pre-defined format in ASCII. In the case of GNSS, it output position, velocity, time and satellite related data (for the constellations that the antenna can decode). There are quite a few NMEA messages or sentences, specifically, GSV sentences provide integer numbers for elevation, azimuth and signal-to-noise ratio.

140 The results were compared with soil moisture measurements based on soil samples taken at a depth of 5 cm and weighed before and after being dried (gravimetric method) in a laboratory (Fig. 4). These measurements were considered the reference dataset. The soil samples were taken one per day except weekends and the location, in comparison with the antenna position, can be seen in Fig. 2.

145 In total, 66 days of measurements, from December 3, 2018, to February 6, 2019, were observed, processed, and analysed. The height of the antennas from the ground was 1.80 m for the geodetic GNSS device and 1.84 m for the mass-market device. Precipitation data were added in the final plot results. These data were obtained from a meteorological station located in the Cajamar Experiences Centre (100 meters from the GNSS antennas).

2.3 Theoretical background

The theoretical background is based on the procedure developed by Larson et al., (2010) and detailed in Chew et al., (2014), vey et al., (2015), and Zhang et al., (2017). Each valid track of a satellite ~~should be~~ separated into ascending path and descending path.

150 The processing of each satellite track can be summarised as follows:

- 1) SNR data are converted from dB units to linear scale in volts using the conversion equation (S stands for SNR in the next equation and for the rest of equations in the manuscript) $S_{linear} = 10^{S/20}$ (vey et al., 2016).
- 2) A low-order polynomial (second degree) is fit to the S_{linear} in order to eliminate the direct satellite signal, so that the reflected signal is isolated: $S_{linear}^{reflected}$, (Wan et al., 2015; Chew et al., 2016).

Movido (inserción)[1]

Eliminado: ¶

Eliminado: aves

Eliminado: Only full-tracks data covering more than 30 minutes and cover more than 10 degrees of elevation in its trajectory were considered in our study.

Eliminado: was

- 3) A Lomb-Scargle periodogram (Lomb, 1976; Press et al., 1992; Roesler and Larson, 2018), is then computed from $S_{lineal}^{reflected}$, and the track goes to the next step only if there is a clear signal that reflects a primary wave. Tracks with multiple peaks or low maximum average power (less than four times the background noise) are not included in the next step. If the Lomb-Scargle periodogram is computed using the sine elevation angle as the input X axis, the result converts the frequency into antenna height in the output X axis. Only tracks with computed antenna height consistent with the measured antenna height (less than 0.1 meters difference), go to the next step.
- 4) The selected tracks are modelled using the expression below:

$$S_{lineal}^{reflected} = A \cos\left(\frac{4\pi h}{\lambda} \sin e + \phi\right) \quad (2)$$

The equation means that $S_{lineal}^{reflected}$ can be modelled in terms of the amplitude A and phase offset ϕ of a primary wave. λ is the GNSS wavelength (L1 for GPS and GLONASS and E1 for GALILEO), e is the satellite elevation, and h is the antenna height, which is assumed to be a constant due to the low signal penetration on the ground (Chew et al., 2014; Roussel et al., 2016; Zhang et al., 2017). The least squares algorithm (Strang and Borre, 1997; Leick et al., 2015) is used to estimate A and ϕ .

5) Chew et al., (2013) derived a linear relationship between the previously computed phase offset and soil moisture with a slope of 65.1° in order to obtain the GNSS-derived volumetric water content, VW_{GNSS} (m^3/m^3). V stands for VW_{GNSS} in the next equation and for the rest of the manuscript:

$$V_{GNSS} = \frac{\Delta\phi_t}{65.1} + V_{Residual} \quad (3)$$

However, this value should be computed using the reference values in order to convert the satellite tracks phase values into GNSS-derived volumetric water content, because this linear relationship can be positive or negative. Zhang et al. (2017) showed the importance of this adjustment with the test data in order to obtain better results (their results showed a decrease of the final standard deviation from 0.036 m^3m^{-3} -using the linear relationship of 65.1°- to 0.008 m^3m^{-3} -using the adjusted linear relationship-).

$V_{Residual}$ in Equation 3, is the minimum soil moisture observation from the reference data set (obtained from the soil samples). This minimum value should be taken from the reference observations as long as the GNSS observation is continuous and without interruptions. In the case that there is any interruption in the GNSS observation data, this value must be chosen again among the reference values after the interruption. $\Delta\phi_t = \phi - \phi_o$ is calculated with respect to a reference phase ϕ_o computed in this work as proposed by Chew et al. (2016): the mean of the lowest 15%

Eliminado: Chew et al., (2013) derived a linear relationship between the previously computed phase offset and soil moisture with a slope of 65.1°. We used this value to convert the phase values of each track into GNSS-derived volumetric water content, VW_{GNSS} (m^3/m^3), V stands for VW_{GNSS} in the next equation and for the rest of equations in the manuscript.

$$V_{GNSS} = \frac{\Delta\phi_t}{65.1} + V_{Residual} \quad (2)$$

where $V_{Residual}$

Eliminado: uncut

Eliminado: cut

Eliminado: cut

205 of the computed phases for each satellite tracks during the retrieval period. \emptyset_o should be computed again in the case of interruption of the GNSS signal. Ascending and descending paths for the same satellite are treated separately.

6) Finally, the mean V value of all satellite tracks of the same constellation that pass at different times during the day is computed, so the final GNSS soil moisture represents a temporal average for all observations analyzed during one day. To address the objectives of this research, we have three different results, one for each GNSS constellation.

210 **3 Results**

3.1 Processing

RINEX observation and navigation files from the geodetic GNSS antenna were used to generate the input file for the processing process. This file contained year, month, day, hour, satellite identification, SNR, elevation, and azimuth for every observed epoch. We computed three different files (GPS, GALILEO and GLONASS). The frequency for each GLONASS satellite

215 should be also computed and included in the GLONASS file.

The file containing the NMEA observations from the mass-market antenna was used to generate three different input files for the processing process, one for each satellite constellation. However, due to the integer nature of the SNR, elevation, and azimuth observation numbers, an extra processing step was included for the mass-market observation files. This step used the navigation files from the International GNSS Service (IGS) repository (<http://www.igs.org>) to compute float numbers for

220 elevation and azimuth values of the observed satellites.

The rest of the processing followed the steps defined in the previous section. Only full GNSS tracks data covering more than 30 minutes and cover more than 10 degrees of elevation in its trajectory were considered in our study.

3.2 Results

The geodetic antenna SNR data in volts for satellite GPS number 23 are shown in Fig. 5a, the SNR data with the direct signal

225 removed are shown in Fig. 5b, the Lomb-Scargle periodogram for the SNR reflected signal is shown in Fig. 5c, and the SNR reflected signal with the adjusted wave (Step 4 in the previous section) is shown in Fig. 5d. Fig. 6 portrays the same concepts for the same satellite but using the mass-market antenna observations. Fig. 7 and 8 portray the same concepts for the GLONASS satellite number 5, and Fig. 9 and 10 display these for the GALILEO satellite number 21.

The SNR values from the geodetic antenna and the mass-market antenna for the GPS constellation are similar, as suggested in

230 Li and Geng (2019), because the u-blox chipset uses an active, right-handed, circularly polarized antenna with uniform antenna gain. However, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 db-Hz between the geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a).

A linear relationship between reference data and every GNSS constellation and antenna was computed using the methodology proposed by Zhang et al. (2017), the results can be seen in Table 1. Based on the positive values for all lineal relationships and

Eliminado: cut

Eliminado: However, Zhang et al. (2017) showed that it is important to adjust the linear relationship with the test data in order to obtain better results (their results showed a decrease of the final standard deviation from 0.036 m³m⁻³ -using the linear relationship of 65.1°- to 0.008 m³m⁻³).[¶]

270 the conclusions on Zhang et al. (2017), a slope of 65.1° between the all GNSS computed phase offset and the soil moisture
was used to homogenize the results among different constellations and the two different antennas.
However, two different values for $V_{Residual}$ and ϕ_0 were used due to an outage of the electrical power during three days (from
day 40 to day 42 of the experiment), where no observations were recorded.
275 The results presented the average value of soil moisture around the geodetic and mass-market antennas per day, obtained from
all valid GNSS tracks of all satellites per constellation or using the three constellations.
Fig. 11, 12, and 13 show a comparison of the daily soil moisture from GPS, GLONASS, and GALILEO, respectively, where
the results of the geodetic and mass-market antennas can be compared with the reference gravimetric data set. Daily
precipitation amounts are also included in the figures.
280 Finally, Fig. 14 show the combined solution of the three constellations as an average of the results of the individual solutions,
which can be considered as a combined multi-constellation solution.
The numerical values for Fig. 11, 12, 13 and 14 are listed in Table 2, where MAE is the mean absolute error, RMSE is the root
mean square error, mean and Std. are the mean and the standard deviation respectively between the GNSS antennas and the
reference values. The Pearson correlation coefficient can be used to summarize the strength of the linear relationship between
two data samples. Spearman correlation can be used to summarize if two variables are related by a nonlinear relationship, such
285 that the relationship is stronger or weaker across the distribution of the variables.

4 Discussion

Based in the results summarized in Table 2, equivalent results between geodetic and mass-market antenna is obtained for
RMSE, MAE, Mean and Std., showing the good performance of the mass-market antenna. Pearson and Spearman correlation
are equivalent between Geodesic and Mass-market antenna for every constellation and comparing the constellations. These
290 confirms that a lineal relationship can be considered between the soil moisture results obtained from all GNSS antennas and
the sample observations.
The worst results in terms of RMSE, MAE and Std. were obtained for GALILEO constellation, probably because there aren't
as many satellites in the constellation as the GPS and GLONASS constellations have. GLONASS constellation offers slight
improvement in terms of RMSE, MAE and Std. results in comparison with GPS. GLONASS range of values appears more
295 compressed for both the geodetic and mass-market antennas, probably because GPS constellation, in the moment of the
observations, had three different satellite blocks (blocks IIR, IIF and IIF) with different capabilities, and GLONASS only two
(blocks M and K). However, the ranges of RMSE, MAE and Std. considering GPS, GLONASS and GALILEO constellations
(both geodetic and mass-market antennas) are less than 0.01 m3/m3 and less than 0.15 for Pearson or Spearman correlation,
so we can consider that the three constellations produce similar V_{GNSS} values, regardless of the type of antenna used, opening
300 the possibility of using the three constellations in combination as a multi-constellation solution. The last two columns of Table

2 show the statistical summary of the constellations combination for both the geodetic and the mass-market antenna, where it can be seen that the values obtained are equivalent to those of the previous columns.

Our RMS results using the a priori slope values of 65.1° are comparable with those obtained by Zhang et al. (2017), who processed six months of continuous observations and obtained a mean standard deviation value of $0.036 \text{ m}^3/\text{m}^3$, and those of Vey et al. (2015), who processed 6 years of observations and obtained a standard deviation value of $0.06 \text{ m}^3/\text{m}^3$.

The SNR bias between the geodetic and mass-market antenna for GLONASS and GALILEO constellations (Fig. 7b and 8b and Fig. 9b and 10b) has no effects in the final phase offset variations for the adjusted wave.

According to Step 3 of Section 2.3, the 70% of the GPS tracks recorded by the geodetic antenna were considered valid for processing, as were 73% for GALILEO, and 74% for GLONASS. This percentage is reduced to around a 10% if we consider the tracks recorded by the mass-market antenna. Nonetheless, one of the main important problems in this research is related with the selection of the correct tracks to be processed and adjusted using Step 4 of Section 2.3. Based on the mentioned criteria (tracks with multiple peaks or low maximum average power and computed reflector height consistent with the measured antenna height), some tracks that should not be processed are finally processed (around 8% of all tracks irrespective the constellation). These wrongly processed tracks introduce outliers in the computed V_{GNSS} , which are eliminated in the daily final mean V_{GNSS} computation because they produce a high RMS in the daily computations using all satellites. One way to accomplish this task could be to use good figures, such as those from Fig. 5c Fig. 5d, to produce a valid set of training images and use machine learning tools (image recognition) to decide automatically whether a new track can be considered as a good track (so it can be processed) or not. This idea is currently under development.

In situ observations are needed to solve Eq. 3 ($V_{Residual}$ parameter). However, if there are no reference values, this constant cannot be included, and the results will present an offset in comparison with the real values. However, the results can be used in a relative way, that is, can be used to infer VWC variations from one day to another. This relative comparison can be performed only if the observations are continuous. If there is an interruption in the raw data (because the antenna is turned off) of more than two or three hours, the previous reference is lost and the relative comparisons should start again (from the moment the antenna is turned on again). In situ observations are also needed if we want to adjust the linear relationship between the computed phase offset and the soil moisture, as is developed in Zhang et al. (2017); however, if there are no reference values, they can be estimated based on the soil type (URL 1). Though, that requires having a long enough time series to make the assumption that, at some point during the time series, soil moisture was low enough to hit the residual value. However, in case the linear relationship is positive, a value of 65.1° can also be used to obtain acceptable results.

5 Conclusions

The case study presented in this research is focused on the GNSS SNR data acquisition and processing using the GNSS-IR technique to monitor soil moisture. The main objectives of this research were the use, comparison and combination of GPS,

Eliminado: The best results were obtained for the GLONASS constellation, whose range of values appears more compressed for both the geodetic and mass-market antennas in comparison with the GPS and GALILEO results. The worst results were obtained for GALILEO constellation. However, the ranges between these results are less than $0.01 \text{ m}^3/\text{m}^3$ for RMS and 0.15 for correlation, so we can consider that the three constellations produce similar V_{GNSS} values, as do the geodetic and mass-market antennas.

Movido hacia arriba[4]: The SNR values from the geodetic antenna and the mass-market antenna for the GPS constellation are similar, as suggested in Li and Geng (2019), because the u-blox chipset uses an active, right-handed, circularly polarised antenna with uniform antenna gain. However, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 db-Hz between the geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a).

Eliminado: The SNR values from the geodetic antenna and the mass-market antenna for the GPS constellation are similar, as suggested in Li and Geng (2019), because the u-blox chipset uses an active, right-handed, circularly polarised antenna with uniform antenna gain. However, the SNR values for GLONASS and GALILEO present a systematic bias of about 3-5 db-Hz between the geodetic and mass-market antennas (Fig. 7a and 8a and Fig. 9a and 10a). This effect has an impact in the range of the reflected signal (Fig. 7b and 8b and Fig. 9b and 10b), but it has no effects in the final phase offset variations for the adjusted wave.

375 GLONASS, and GALILEO constellations solutions and the use and comparison of a geodetic and mass-market antenna solutions.

Independent GPS, GLONASS, and GALILEO solutions were generated to demonstrate that the technique can be extended to a multi-constellation solution. This is necessary because a single constellation solution presents a reflection footprint that is far from homogeneous around the antenna and because 30-35% of the observed satellite tracks of the geodetic antenna are not valid for processing (40-45% if the mass-market antenna is considered).

380 The use of a mass-market GNSS antenna was confirmed to be a viable tool for GNSS-IR, with the caution of using the IGS navigation files to transform the observed integer numbers obtained in the NMEA messages for the elevation and azimuth of the satellites into floating numbers. With the use of mass-market sensors, it will become possible to design scenarios with several GNSS stations generating redundant observations. Therefore, maps of soil moisture variations by specific and selective areas of soil, cultivation, and/or management can be generated, instead of obtaining only an average value for the entire observation area.

385 GNSS-IR is still a technique with numerous technological challenges in order to becoming a competitive solution with respect to current observation techniques, but it has great potential with regard to continuity of observation (can be implemented in a real or quasi-real time scenario), precision, and measurement acquisition cost if mass-market antennas are used.
