Abstract. The conceptual understanding of the preferential water flow is crucial and hence understanding the degree of water percolating rapidly through vertical macropores, or slowly through the low-permeable matrix, is vital in order to assess the risk of contaminants like nitrate and pesticides being transported through a variably-saturated macroporous clay till to drainage. This study compared six different model concepts, using the dual-permeability module of the one-dimensional model DAISY, incorporating three different macropore settings and two different groundwater tables set as lower boundary conditions. The three macropore settings included vertical macropores supplying water directly to *a*) drainage, *b*) drainage and matrix and *c*) drainage and matrix including fractures supplying water to the matrix in the saturated zone. The model study was based on ten years of coherent climate, drainage, and groundwater data from an agricultural clay till field. The estimated drainage obtained with the six model concepts was compared to the measured drainage. No significant discrepancies between the estimated and measured drainage were identified. The model concept with the macropore setting *b*) exposed to groundwater fluctuations measured in the southern part of the field, gave the best description of the drainage. Bromide leaching tests were used to evaluate the mass balance of the model concepts. The estimated water balance of all six concepts revealed that 70% of the precipitation input to drainage was transported via macropores. According to the results of bromide leaching simulation, 54% of the drainage was estimated to be transported via vertical macropores being initiated in the plow layer.

Keywords. Preferential flow, Macropore settings, Field-scale, Automated calibration, Morris screening

1 Introduction

Preferential flow (PF) is a general term for non-uniform, non-equilibrium water flow processes, which can occur in low permeable drained clay tills given the presence of macropores/discontinuities/continuous voids such as earthworm, root channels, sand lenses, and fractures. Today, it is well-recognized that such macropores can provide the main transport pathways for leaching of agrochemicals and nutrients from the soil surface to drainage and groundwater. The occurrence of PF and the associated solute transport have been observed and demonstrated under several field and laboratory conditions (Akay and Fox, 2007; Gjettermann et al., 2004; Larsbo et al., 2009; Nielsen et al., 2010; Petersen et al., 2012; Rosenbom et al., 2009; Stamm et al., 2002; Tofteng et al., 2002). Studies have documented that drainage is affected by the presence of macropores, especially

earthworms (Akay et al., 2008; Frey et al., 2016; Köhne et al., 2006; Larsson and Jarvis, 1999; Petersen et al., 2012; Vogel et al., 2000) providing a direct hydraulic connection between the soil surface and the tile drain. This direct connection may result in rapid transport of nutrients (Cheng et al., 2014; Gärdenäs et al., 2006; Köhne et al., 2006; Larsbo et al., 2009; Larsson and Jarvis, 1999; Mohanty et al., 1998) and other contaminants from the surface into the tile drain system. Bypassing the soil matrix and its retarding capacity (sorption and degradation), the contaminants are transported via tile drains to nearby surface water bodies, such as lakes and rivers, with no or limited possibility of further reduction or retention along this path (Blann et al., 2009; Hansen et al., 2012a; Hinsby et al., 2012; Kronvang et al., 2005). This direct connectivity phenomenon was verified by Akay and Fox (2007), who conducted infiltration experiments in soil columns with an artificial macropore placed directly above or shifted from the subsurface tile drain pipe. The set-up of their experiment allowed the length of the artificial macropores to be varied without disturbing the soil column. The macropores were classified as either surface-connected or buried macropores. They observed that the water arrival time to the tile drain through surface-connected macropores was eight times faster, and about two times faster for buried macropores, than in a soil column with only matrix flow. At field scale, Petersen et al. (2012) showed a direct connection of macropores to the subsurface tile drains by injecting smoke to the tile drain pipes and counting the surface-emitting macropores on sandy loam. They analyzed two 35-m-long tile drain sections for the spatial distribution of emitting macropores while the water table dropped from about 0 cm to 20 to 50 cm below drain depth. From 65 to 96 smoke emitting macropores were identified along the tile drain sections, separately. Geologies incorporating such highways for flow and transport in the shape of macropores connecting the surface/plow layer with the deeper part of the soil can, as described, make them vulnerable in regard to rapid leaching of contaminants to drainage and groundwater. It is, therefore, imperative to be able to account for these highways when assessing the risk of leaching of contaminants through the variably-saturated drained clay till. As demonstrated by Germann (2018) this is not straightforward, since the hydromechanics of the macropores and the interaction with the lower-permeable soil matrix still pose a scientific challenge in terms of avoiding too crude a description thereof. Nevertheless, within the last four decades, different numerical models have been developed, incorporating reality-simplified processes/concepts describing PF and coherent solute transport. With the macropore setting being very complex and varying in space and time, the well-documented models like RZWQM2, MACRO, HYDRUS1D and DAISY (Hansen et al., 2012b; Larsbo and Jarvis, 2003; Ma et al., 2012; Simunek and van Genuchten, 2008) cope with the water flow and solute transport in one dimension using the Richards (1931) equation for capillary flow in the matrix domain and apply different approaches for the macropore domain. Hence, in these models, the soil pore space is divided into two domains: A low-permeable matrix domain with a relatively large storage capacity and a high-permeable macropore domain with a relatively low storage capacity. The Root Zone Water Quality Model, RZWQM2 describes the macropore flow capacity using Poiseuille's Law based on gravity flow in cylindrical pores. The water exchange between the domains is based on the radial or lateral Green-Ampt equation, that accounts for the infiltration front in the matrix surrounding the cylindrical pores or cracks, respectively. Using pore-scale physical laws in RZWQM2 poses a disadvantage, in that it assumes full saturation in macropores and simplifies the geometry of macropores, which is usually tortuous (Simunek et al., 2003). The governing equation for the macropore domain of the dual-permeability model in MACRO (Larsbo and Jarvis, 2003) follows the kinematic wave approach described by Germann (1985), where the macropore flow is controlled by a kinematic exponent, which

reflects the macropore size, distribution, tortuosity and ignores capillary flow. In MACRO, the mass transfer between domains in the absence of gravity is described by the Richards equation, recast as a diffusion equation for a homogeneous medium, where the water content gradient is the driving force. In HYDRUS 1D (Simunek and van Genuchten, 2008) uses the approach of Gerke and van Genuchten (1996) who applied the Richards equation for both matrix and macropore domain. This dual permeability approach requires more, rarely available, specific knowledge about water retention and hydraulic conductivity functions for both matrix and macropore domains and their interface. The mass transfer between the two domains is similar to MACRO, using the first-order mass transfer coefficient and assuming it is proportional to the difference of the pressure head between the two domains. Also, HYDRUS 1D has incorporated different approaches to simulate the flow in the macropore domain, such as the mobile-immobile and dual porosity model, which requires fewer input data. DAISY has been modified by Mollerup (2010) based on the laboratory experiments of Tofteng et al. (2002) and Gjettermann et al. (2004) and the field experiment of Petersen et al. (2012). Tofteng et al. (2002) showed, with an artificial macropore attached to the bottom of a sandbox, that macropores were able to conduct water on pressure potentials as low as -30 cm, which indicates that macropore flow can alter from a typical retention/conductivity function. These findings are essential, since tillage increases the porosity of the plow layer (Petersen et al., 1997), while macropore continuity may be reduced (Roseberg and McCoy, 1992), and a compacted layer – the plow pan, which often occurs at the transition zone between the plow layer and the subsoil – may cause accumulation of water and thus initiate macropore flow (Frey et al., 2012). All of the models mentioned are simplifications of reality and as such, have pros and cons in regard to their description of the hydromechanics of the macropores and the interaction with the surrounding matrix and drainage. Additionally, they need to be able to account for plant cover and fate processes (mineralization-immobilization-turnover, sorption, degradation, effects of soil management, etc.) in an assessment of the leaching risk of agrochemicals. The purpose of this study was to evaluate whether it is possible with the DAISY model to capture the water balance (climate, groundwater fluctuations, water content in the profile and in drainage) of a well-described agricultural clay till field that is tile-drained and prone to preferential transport (Ernstsen et al., 2015), during a 10-year period with/without macropores and, if so, to estimate the degree of macropore flow and the associated transport of bromide to the drains during the period.

2 Materials and Methods

2.1 Field characteristics

In this study, data originated from a tile-drained agricultural clay till field included in the monitoring program PLAP (Pesticide Leaching Assessment Programme of Denmark) (Lindhardt et al., 2001). The field is situated at Silstrup in the North Western part of Denmark (56°55'56"N 8°38'44"E). The field was established in 1999 and has been used for agricultural purposes since 1942 and systematically drained since 1966. The field has been farmed from 1983 without any plot experiments conducted (Lindhardt et al., 2001). The field and the surrounding area are dominated by Weichselian glacial clay till deposits in combination with thin meltwater sand lenses. The underlying geology comprises dislocated slices of clay till and meltwater sand/gravel forming "drains" down to the groundwater. The southern rim of the field contains dislocated clay and silt mixtures in the depth

interval of 4-8 m. This material is underlying half of the field (Fig. S1). According to the geological survey of the field, the top layer of this mixture is the most permeable part of the whole field and seems to dominate the hydraulics of the field-setting (Abiltrup, 1999). In general, the field is heavily fractured and contains a high-density of macropores. In the upper 2 meters of soil, dominated by bioturbation and desiccation cracks, the macropore density was estimated to be 400 pores m^{-2} (Lindhardt et al., 2001) with diameters of 2-5 mm, using the methodology from Klint and Gravesen (1999). The size of the field is 1.69 ha (185 × 91 m). Highest points of the field vary from 41 to 45 m above sea level (m.a.s.l.) (Fig. S2). The groundwater head potentials (in m.a.s.l.), measured in February 2000 from several piezometers and monitoring wells surrounding the field (Fig. S3), indicated that the groundwater tends to flow towards the South West, which is opposite to the topographical slope of the field. This water movement suggests that the significant part of the field is hydraulically connected to the layer with the silty-clay Oligocene deposit, which can be considered as an aquifer, overlaid by a clay till (Freeze and Cherry, 1979) (Fig. S1). The pedological profile investigation was carried out in the North Eastern corner of the field where two profiles were excavated (N-North face, E-East face). The most common horizon subdivision was A_p - B_v - $B_{t(e)}$ and A_p - BC - C_c with an average depth of A_p (plow layer) and B_v / BC of 31 and 140 cm, respectively. The textural analysis showed a plow layer with 18-25% clay and more variable clay content in the underlying soil of up to 43% clay in the eastern profile. This clay content probably decreases towards the southern part of the field since Hansen (1976) found 15% and 24% clay in the topsoil and the underlying soil, respectively. The field was also mapped with a DUALEM21 ground conductivity meter (GCM). The processing and inversion of GCM data were done by Aarhus Workbench using the Aarhus Inv inversion code (Auken et al., 2018) (Fig. S4). The soil hydraulic measurements for soil water retention (SWR) and hydraulic conductivity were conducted on 100- cm^3 and 6280- cm^3 soil cores, respectively. The cores were sampled at three depths corresponding to the A_p -, B -, and C -horizon. The mean retention points showed that the water content gradually decreased with pF (logarithm of the soil water potential [ψ , in $\text{cm H}_2\text{O}$ times -1]) because of the relatively uniform pore size distribution, which is consistent with loamy-clay soil types (Table S1). The SWR, saturated K_s and unsaturated $K(\psi)$ hydraulic conductivity were determined by the methods described in Iversen et al. (2004) and Iversen et al. (2011). The unsaturated hydraulic conductivity showed high variability at -10 $\text{cm H}_2\text{O}$ pressure potential and was significantly lower than the saturated conductivity. The variability in saturated hydraulic conductivity showed differences by two to three orders of magnitude, which indicates the presence of macropores (Fig. S5).

2.2 Field-scale monitoring and field management

The tile drain system of the field consists of five parallel tile drains at approximately 110 cm depth, 18 m apart, established in a south to north direction. They are connected with a transverse tile drain at the northern end of the field. Drainage flow in the drainage outlet well and soil water content were measured hourly and automatically from 2000 to 2010. The drainage flow was calculated from a measured water level above the Thomson weir V-notch (Lindhardt et al., 2001) using a pressure transducer (Druck PDCR 1830, Druck Limited, UK). Hourly weather data has been recorded from 29th April 2000 to 31st December 2010. The weather data includes wind [ms^{-1}], global radiation [Wm^{-2}], air temperature [$^{\circ}\text{C}$] and vapor pressure [Pa] in order to calculate the evaporative demand using the Penman-Monteith Reference Evaporation equation (Allen et al., 1998). The wind speed measurements at 10 m height were scaled to 2 m, assuming logarithmic wind profile and neutral atmosphere (Allen et al.,

1998). Hourly precipitation [mm] was sampled with a tipping bucket gauge (Lambrecht meteo GmbH, Göttingen, Germany) at the upper North Eastern end of the field (Fig. S2).

[Figure 1 is about here]

In Figure 1, the hourly recorded drainage presented in a seasonal accumulation, where a season comprises the period from 1st April until the following 31st March, in order to cover an average crop growing period. The seasonal precipitation ~~sum~~ varied from 691 mm to 1146 mm, with an average of 910 mm for the above-considered time interval. Most of the precipitation records (96%) were obtained from the field, but where the gauge malfunctioned (4% of the records) precipitation was obtained from the nearby meteorological station. The precipitation was obtained in open field conditions, 1.5 m above the soil surface and was corrected to true ground based on factors provided by Allerup and Madsen (1979). This correction was conducted in order to overcome induced errors, mainly due to wind turbulence, which caused the 1.5 m precipitation to be underestimated. To identify the possible solute transport routes, 30 kg ha⁻¹ Potassium Bromide (KBr) was sprayed on 22nd May 2000. Water samples were collected flow-proportionately at the drainage outlet (Ernstsen et al., 2015) for in-lab determinations of bromide (Br⁻) and nitrate (NO₃⁻) concentrations. The accumulated bromide transport is presented for the following two seasons (season - 2000, 2001) after the application in Figure 1a. Soil water content was measured with horizontally installed 30-cm-long TDR (Time Domain Reflectometry) probes at various depths (0.25, 0.6, 0.9, 1.1, 1.9 and 2.1 m with three replicates per depth) in the variably-saturated zone, where the pedological profiling had been conducted (Lindhardt et al., 2001). In this study only the results of replicates at depth -25 cm and -60 cm are presented (Fig. 1b). The measurements were obtained using probes made at Aarhus University and a Campbell CR10X data logger controlling a Tektronix 1502C cable tester (Tektronix Inc., Beaverton, OR, USA). The hourly measured water content (three replicates) were averaged to daily response data, due to the hourly measurements containing a significant amount of missing data due to instrument failure. Further, as the water content measurements were sampled in the northern corner of the field, these measurements may not represent the water flow dynamics and variability of the whole field and especially not the PF (Nimmo, 2012) as the 30 cm long probes integrate by far the size of a macropore, and water flow in bigger pores happens so fast that it may not be captured by hourly measurements. Germann (1985) reported velocities of the wetting shock fronts in the range of 0.3 to 1 mm s⁻¹. However, the hourly measured drainage flow was kept at its hourly time resolution, as it integrates the whole field response to measured hourly rainfall data. The hydraulic response data also included daily groundwater table measurements in piezometers situated at the northern (P4) and southern (P3) end of the field (Fig. 1c, Fig. S2). P4 was placed in clay till in the north, whereas P3 hit dislocated clay-silt layers (Fig. S1 and S2). With the earlier mentioned difference in geology from south to north, a contrast of up to 1.5 meter in the groundwater level was measured during the summer period and, hence, slower drainage with a lower amount may have taken place in the north compared to the south. Unfortunately, this cannot be documented by monitoring data, since only TDR has been deployed at the northern end of the field. In the course of the data period of 2000-2010, five different types of crops were grown: fodder beet (2000, 2008), spring barley (2001, 2005, 2009), pea (2002), maize (2003), winter wheat (2004, 2007) and winter rape (2006). All crops were harvested and analyzed for dry matter yield and nitrogen content, and the phenological development stages of the plants were recorded.

160 2.3 The DAISY model

DAISY is a soil-plant-atmosphere system model incorporating modules describing plant water uptake, plant growth, C-N turnover, and water (drainage transport  percolation to the groundwater), heat, snow-melt and nitrogen dynamics in the soil (Hansen, 2002). Each of these processes is incorporated into modules that are interconnected with each other. In this study, the main focus will be on the soil water module (Hansen et al., 1990; Hansen, 2002; Hansen et al., 2012b; Mollerup, 2010). DAISY uses the Richards equation (Richards, 1931) to solve the one-dimensional water flow in a variably-saturated subsurface porous medium. In DAISY, the Richards equation includes the closed form of the van Genuchten SWR model (Van Genuchten, 1980), which is coupled with the Mualem hydraulic conductivity theory (Mualem, 1976) applied to the matrix domain. In terms of soil solute balance, the model applies the convection-dispersion equation with the ongoing transformation processes and uptake by plants. For the modeling of PF, DAISY assumes two flow regimes: a matrix flow regime where the convection-dispersion equation for solutes is applied, and a macropore regime where only convection is considered. The mass exchange between the two regimes is governed by the water flow through the sink-source strength of the two domains and the model does not consider storage of solutes in the macropores; hence the macropores are only considered as a fast pathway for transport of solutes (Hansen, 2002). The fast flow domain in DAISY is described by a macropore module described by Mollerup (2010) (web address: <https://daisy.ku.dk/publications>) and tested in technical reports, prepared for and published by the Danish Environmental Protection Agency (Hansen et al., 2010a, b, 2012c). Here a macropore is a vertically oriented feature, characterized by physical properties such as length, diameter and density. The macropores are divided into two classes specified by their lower boundary. One class of the macropores ends in the soil matrix, while the other class can be set to end directly in the tile drain. When water is transferred from the matrix to the macroporous domain ending in the matrix, the water is instantaneously moved to the top of the current water level in the macropores. If the pressure difference between the macropore and the matrix exceeds a predefined soil water pressure barrier potential ($\psi_{barrier}$), water will be transferred back to the matrix from the macropore. For the macropores ending in the tile drain, the lower boundary condition has a constant pressure head of zero, meaning that water will be transferred directly into drainage without building up in the macropores. The macropore flow is initiated when the matrix potential exceeds a specific pressure potential called ψ_{init} . Hence, if this pressure potential is exceeded, the macropore domain is activated and water starts to fill up the macropore. When the pressure potential drops below a level called ψ_{term} , inflow to the macropore is terminated. All pressure threshold parameters apply to all macropore classes. The macropore domain concept consists of an equidistant distribution of macropores where the water flow in the domain is quantified by soil water extraction from the matrix, which is based on the water movement in a confined aquifer, towards a well (where the well is represented by a single macropore). The interaction between macropores and surface water follows Poiseuille's Law  (Hillel, 1998) in the same way as in the RZWQM2 model (Ma et al., 2012). The only driver of the water flow is gravity. The macropore model does express viscous flow, as Germann (2018) suggested, since the water flow is lumped to an instantaneous transport within a macropore. Due to the velocities of wetting shock fronts, which is the range of 0.3 to 1 mm s⁻¹, the model could not represent the hydro-mechanical aspects of a turbulent flow, since the basic time step is one hour. When the hydrologic set-up includes a subsurface tile drain at a certain depth, drainage from the soil matrix domain

will only be initiated when the groundwater level rises above this depth. This inflow to the tile drain assumed installed in a flat
195 landscape, is described by the Hooghoudt equation (Hooghoudt, 1940).

2.4 Model concepts

The soil profile in the one-dimensional DAISY model was described based on the pedological survey of the Silstrup field with three different horizons:

- A-horizon – Plow layer to a depth of 31 cm
- 200 – B-horizon – Layer from 31 cm to 140 cm depth
- C-horizon – Layer from 140 cm to 500 cm depth

The discretization of the profile was into 1-cm layers to 50 cm depth, 5 cm to 110 cm depth, and 10-cm intervals to 500 cm depth, including additional steps at the upper and lower boundaries of the horizons. The tile drain was set at a depth of 110 cm and 18 m apart, according to the field characteristics described above. The C-horizon was extended to 500 cm in
205 order to account for the fluctuating groundwater table. To avoid having an unrealistic impermeable layer as a lower boundary condition as the Hooghoudt equation requires, a Dirichlet boundary condition defined by the measured groundwater level was applied to the Hooghoudt equation (Fetter, 2000). The van Genuchten-Mualem (vGM) retention conductivity model was used to describe the water retention and conductivity in all three layers for the matrix domain. The retention parameters (θ_s , θ_r , l , n , and α) of this model and saturated hydraulic conductivity K_s [LT^{-1}] were estimated by fitting the vGM model to the
210 laboratory-measured water retention. The uncertainty boundaries were established by fitting all retention and conductivity data from the corresponding samples of the horizons and combining them to create a retention and conductivity range. (Table 1 and Fig. 4, 5). The unsaturated hydraulic conductivity was fitted to the measured $K(\psi)$ available from different soil cores (Table 1, Fig. 5) for each horizon. The outcome of the fitting gave saturated hydraulic conductivities that were one to two orders of magnitude lower than conductivities measured directly on the undisturbed soil cores (Fig. S5). The initial SWR and hydraulic
215 conductivity parameters were obtained from the best fit of the combined vGM models (Fig. 4, 5). In Table 1, the columns Min. and Max. show the range of the uncertainty boundaries of the parameters assessed from the fitted results. To incorporate PF, a well-connected macropore system needs to be included in the model. To represent the macropore system in the field, three different macropore settings (MSETs) have been included in the model (Fig. 2, Table 2). The division into the different MSETs was based on a field study of Nielsen et al. (2010) conducted on a similar macroporous, sandy-clay loam soil. Because
220 the macropore distribution in a given field is unknown and difficult to describe by soil textural parameters (Lamandé et al., 2011), the following conceptual considerations have been applied. Matrix macropore 1 (MM1) represents all small macropores created by bioturbation or agricultural processes after plowing. This kind of macropore always ends at the bottom of the plow layer. MM2 and MM3 represent the wide (up to 5 mm in diameter) and long macropores created by large earthworms or old root channels. They are present below the depth of the tile drain facilitating, in most periods of the year, a direct connection to
225 the groundwater table. The difference between MM2 and MM3 is the starting depth. MM2 starts at the soil surface, whereas

MM3 starts at the bottom of the plow layer. This difference defines a surface-connected macropore as MM2, and a buried macropore as MM3, consistent with Akay and Fox (2007) and Rosenbom et al. (2009). Matrix macropores are able to increase the fast storage capacity in a clay till which can slow down the breakthrough of the solute transport. The macropores ending in the tile drain (DM1, DM2) are numbered according to the starting depth. The field description (Lindhardt et al., 2001) indicates that the field is heavily fractured, which is the reason for including a long macropore passing through the system to represent a well-connected fracture system of a field in a one-dimensional model (Fig. 2, Table 2).

[Figure 2 is about here]

The concepts represent a clay till profile with: *a*) only drain-connected macropores (DM), *b*) macropores ending up in the drain (DM) and the matrix (MM), and *c*) DM and MM macropores where an MM-type is present through the entire soil column, representing a fracture (FR). With the matrix-macropore-concept applied in DAISY, water cannot percolate out of the bottom of the MM macropore but only through its sides, while water can build up inside the macropore if the surrounding matrix has sufficiently low permeability. Given this model constraint, a thin, permeable sand layer (even though not present) needed to be added at the bottom of the model profile to facilitate constant drainage of the FR macropore. The soil texture properties of this sand layer “D-horizon” (Fig. 2) was taken from the soil database at the Department of Agroecology “Jordprofildatabasen” (Madsen et al., 1992), and the vGM parameters were generated by HYPRES (Wösten et al., 1999). The initial macropore parameters (Table 2) were extracted from the field study of Nielsen et al. (2010), where they counted the stained macropores along a drain trench, after a tracer experiment. MM1 density ρ_{MM1} was set to 100 m^{-2} to represent the large amount of bioturbation. The remaining macropore properties were set arbitrarily since they were considered to have been applied in the model calibration process. The initial fracture diameter and distribution (d_{FR} and ρ_{MM1}) were taken from Rosenbom et al. (2009) and Lindhardt et al. (2001), respectively. To apply realistic boundary conditions for the model, hourly precipitation, evapotranspiration and crop developments were used as the upper boundary condition, and the depth to groundwater table was used as a lower boundary condition. The latter was monitored on a daily basis. Given the large difference in groundwater table level monitored in piezometer P4 in the northern part of the field and P3 in the southern part (Fig. S1) during the summer, the flow through the profile exposed to both conditions was evaluated for all three MSETs; *a*), *b*), and *c*):

250 – MSET *a*) + P3

– MSET *a*) + P4

– MSET *b*) + P3

– MSET *b*) + P4

– MSET *c*) + P3

255 – MSET *c*) + P4

In such a clay till it is imperative to account for the fluctuating groundwater table and coherent drainage to be able to account for the water balance in the system over time addressing the field, including the degree of macropore flow. This study should be seen as a “learning” study, which can help to delineate the degree of preferential flow and transport through fields in which one can only have knowledge about the fluctuations of the groundwater table and knowledge about the presence of tile drains.

260 2.5 Model performance and objective function

In order to calibrate the six model concepts towards the desired performance by fitting monitoring data automatic calibration procedure was set up. Efficiency criteria were defined as mathematical measures to evaluate model performance, e.g., how well a given model fits the available observations (Krause et al., 2005). Several studies have discussed which efficiency criteria to use in a hydrological modeling context (Krause et al., 2005; Muleta, 2011; Singh et al., 2016; Willems, 2009). According to Krause et al. (2005), most of the efficiency measures that use the squared deviation tend to be sensitive to peak flows, which is an inherent characteristic in tile-drained soils. In this study, the Normalized Mean Absolute Error (nMAE) was used to avoid giving extra weight to peak drainage. This performance measure was chosen with reference to Muleta (2011), who tested efficiency measures based on the minimization of the squared, absolute, and log of the error terms. For proper automated calibration, several different objectives might need to be considered in order to avoid pushing errors into an unexamined domain of the model (Madsen, 2000). The objective function for the calibration procedure in the present study synthesizes four different sub-objectives. Primarily the hourly drainage and cumulative drainage observations were taken into account in order to take control of the dynamical behavior of the model and the water quantity leaving the clay till profile. To further constrain the model and to have a better representation of the soil water dynamics, the daily soil water content represented by TDR measurements at 25 cm (SWC25) and 60 cm depth (SWC60) were added to the objective function as two sub-objectives. Since the model was constrained to different objectives with different units, the four MAEs represented in Eq. (1) were normalized by means of the corresponding observations, in order to aggregate them into one objective function, to be used for automated calibration.

$$nMAE_{year}^{obj} = \frac{\frac{1}{N} \sum_{i=1}^N |sim_{year,i}^{obj} - obs_{year,i}^{obj}|}{\overline{obs_{year}^{obj}}} \quad (1)$$

,where N is the number of observations of a given objective within a year and

$$\overline{obs_{year}^{obj}} = \frac{1}{N} \sum_{i=1}^N obs_{year,i}^{obj} \quad (2)$$

$$\overline{nMAE}^{obj} = \frac{1}{K} \sum_{k=1}^K nMAE_{year,i}^{obj} \quad (3)$$

,where K is the number of calibration years Given the substantial differences between years, the nMAE was calculated for each objective on a yearly basis. The mean of the yearly nMAEs was used as a measure of the performance of the model during the years included in the calibration period. Thus, the final multi-objective function was expressed as:

$$nMAE^{Final} = nMAE^{Drainage} + nMAE^{Cum.Drainage} + nMAE^{SWC25} + nMAE^{SWC60} \quad (4)$$

285 For the evaluation of the models, nMAE (range [0, +∞]) was used primarily, as it is the inverse version of Volumetric Efficiency (VE) proposed by Criss and Winston (2008). Besides nMAE, standard evaluation measures, nRMSE (Normalized Root Mean Squared Error) with the normalization of the maximum deviation of the inspected period (range [0, +∞]) and KGE (Kling – Gupta Efficiency) (range [-∞,1]) (Gupta et al., 2009) are also presented. According to Singh et al. (2005) and Hansson and Hokfelt (1975), nRMSE and nMAE values, less than half the standard deviation of the measured data may be considered low, and that either is appropriate for model evaluation. In terms of KGE, a model result higher than 0.5 is considered satisfactory. These values further called threshold (TH).

2.6 Sensitivity analysis and calibration procedure

A calibration year was defined for the period from 1st April until the following 31st March as it was introduced earlier in section 2.2. The number of years in the complete calibration period were from 1st April 2003 to 31st March 2008. This period was chosen to cover a broad range of yearly precipitation characteristics, with marked differences in total amount and seasonal distribution (Fig 1a). The Morris sensitivity screening method (Campolongo et al., 2007; Morris, 1991) was applied to the model parameters that were considered to have an impact on the multi-objective function. The sensitivity screening was done based on the different sub-objectives. Each parameter was screened against each sub-objective separately and selected as sensitive based on either one, two, three, or all four sub-objectives. The non-sensitive parameters were set to their nominal values. The sensitive parameters were calibrated by the DEoptim algorithm. The Differential Evolution Optimization (DEoptim) (Storn and Price, 1997) was used to calibrate the model. DEoptim is a global optimization genetic algorithm, which uses biology-inspired operations of crossover, mutation, and selection on a population, in order to minimize an objective function over the course of successive generations. For the search of the global optimum, the multi-objective function was used. The sensitivity analysis and the calibration were carried out with the R statistical programming language (Team, 2017). The RDAISY toolbox (Jabloun et al., 2014), with the combination of the “*sensitivity*” package (Pujol et al., 2017) and “*DEoptim*” R packages (Mullen et al., 2011) was used to perform the sensitivity screening and the model calibration.

3 Results and discussion

3.1 Simple calibration of the DAISY crop parameters

The dynamics of soil water content and the matrix-macropore interface depend not only directly on soil physics, but also on evaporation and plant water use. The actual evapotranspiration was determined by the reference evaporation, the crop coefficient for the corresponding vegetation and the water transport capability of the given crop root system. Therefore, the crop module of DAISY was calibrated to the measured phenological development stages and harvested dry matter yield (Fig. S9). According to Plauborg et al. (2010), by matching the simulated dry matter yields with the measured ones, the simulated

evapotranspiration may be at the right level for Danish conditions, as the standard crop parameters included in the DAISY
315 crop database are assessed from experiments in a temperate climate and based on the strong relation between accumulated
transpiration and biomass production (Hsiao et al., 2007; Steduto et al., 2009, 2007). However, a check of the most essential
parameters for transpiration such as crop development, was carried out, as these parameters may show differences between
genotypes within species. Further details on crop calibration can be found in Hansen et al. (1990), Hansen (2002) and Hansen
et al. (2012b).

320 3.2 Impact of direct drainage macropores on model performance

The performance of the model applying the groundwater table measurements from P3, before (single permeability model) and
after the introduction of macropores (the dual-permeability model, MSET *b*) without calibration of parameters, was tested.
The two model set-ups yielded 1.09 and 1.37 nMAE, respectively, for the drainage sub-objective, when tested for the drainage
325 year 2006-2007. Even though the single permeability model “mathematically” performed better than the dual-permeability
model, it was not capable of capturing the rapid drainage dynamics (Fig. 3). This is in agreement with the findings of Akay
et al. (2008).

[Figure 3 is about here]

The non-calibrated dual-permeability model MSET *b*) + P3 was parameterized with the initial parameter values described in
Tables 1 and 2. The model was able to depict the drainage dynamics, but the proportion of water leaving the clay till profile via
330 drainage was almost twice that of the measured (Fig. 3).

3.3 Sensitivity analysis of the six models

For the model set-up of MSET *a*), *b*) and *c*), 26, 32, and 35 parameters, respectively, were identified as probable sensitive
parameters (Table 1 and 2). The difference in the number of parameters was due to the macropore parameters specified for
each macropore setting. Besides the macropore parameters of the MSETs, all parameters related to the SWR and hydraulic
335 conductivity were kept for horizons A, B and C as well as the thickness of the A- and B-horizons. The latter two were included,
based on the variation in horizon thickness from the pedological profile description. In addition, Table 1 presents the uncertainty
boundaries (columns Min. and Max.), which were used in the sensitivity analysis. For the A-horizon, the uncertainty range was
extended for the vGM parameters, after the inspection of the SWR range from PLAP (Iversen et al., 2004; Lindhardt et al.,
2001). By inspecting the resistivity map of the field, the corner where the sample was taken has the highest clay content in
340 the whole field (Fig. S4). The macropore parameter ranges were based on the macropore studies of (Nielsen et al., 2010;
Rosenbom et al., 2009). According to the Morris sampling strategy, 270 to 360 parameter sets were obtained depending on
the MSET. As previously mentioned, in order to identify the important parameters, the sub-objectives (Drainage, Cumulative
Drainage, SWC25, and SWC60) were separately screened. The results of the sensitivity screening were turned into the Morris
distance(ϵ) (Ciric et al., 2012; Jabloun, 2015), which represents the Euclidean distance of the parameter from (0,0) on the
345 $\mu^* - \sigma$ coordinate system (Campolongo et al., 2007). Thus, all the sensitive parameters that have an impact on either one or

more sub-objectives were considered for the calibration procedure. The sensitivity criteria for Drainage, Cumulative Drainage, SWC25, and SWC60 were set to $\epsilon \leq 0.2, 0.2, 0.1,$ and $0.1,$ respectively. The criteria were set arbitrarily by observing the sensitivity screening outputs (Table 1 and 2, Fig. S6-S8). The sensitivity screening gave values of 14/16, 13/15, and 19/19 for model with MSET *a*), *b*) and *c*) with lower boundary P3/P4, respectively. All non-sensitive parameters were set to their nominal values and excluded from the calibration.

[Table 1 is about here]

The sensitivity screening showed that for the models, the A- and B-horizon water retention and hydraulic conductivity parameters dominated (Table 1, Fig. S6-S8). This was anticipated, due to their strong influence on the sub-objectives (SWC25 and SWC60). In the macropore domains, the pressure parameters were also found to be sensitive in all models, with the exception of $\psi_{barrier}$ in model MSET *b*) - P3 (Table 2). The most interesting result of the sensitivity screening of all the models was that the MM dead-end macropores had almost zero influence on the flow through the profile. This is probably because the MM macropore is filled up with water quickly without being able to release water through the low permeable surrounding matrix at the bottom of the macropore. The MM macropores contribute very little thereafter to the rest of the hydraulic environment. Neither did the diameter of the macropores show any effect on any of the objectives, which is consistent with the study of Ahuja et al. (1993), who stated that to determine the maximum flow rate, one only needs to adopt a relevant pore size, instead of identifying the distribution of the macropore sizes in a given field.

[Table 2 is about here]

3.4 Calibration of the water balance of the six models

In over 30000 model runs, the multi-objective function (nMAE) was minimized to 0.75-0.85 for all six models using data from the period 1st April 2003 to 31st March 2008. The calibrated sub-objectives are shown in Table 3. The outcomes of the calibration of MSETs *a*), *a*), and *c*) did not differ significantly from each other, although, according to KGE settings, *a*) performed significantly better than the other MSETs (Table 3). The more complex MSET *c*) (incorporating a fracture together with the D horizon) underperformed (nMAE=0.81-0.85) compared to MSET *a*) (nMAE=0.79/0.81) and *a*) (nMAE=0.75/0.79). This may be because the fracture concept cannot be incorporated in DAISY; not being in direct contact with the tile drain has no significant impact on the drainage. The different lower boundary condition (P3 and P4) had little influence on the calibration outcome, but the performance measures disagreed on which of them had the greatest impact on the modeled field. If nMAE is taken into account, P3 outperforms P4 in all model concepts; for KGE and nRMSE, the exact opposite is true. According to the TH, the multi-objective resulted in satisfactory results in all models according to nMAE and KGE, but non-satisfactory by nRMSE.

[Table 3 is about here]

3.4.1 Soil water retention and hydraulic conductivity

The calibrated hydraulic parameters for the A- horizon differed in all models compared with the initial SWR range from PLAP (Fig. 4). The calibrated models showed a more realistic representation of sandy clay loam, while the SWR range from PLAP showed a very high air entry pressure, which is more characteristic for clay soil. The constant water content at the wet end
380 was reduced to higher water pressure from -50 to around -4 cm, reflecting conceptually that air entry pressures in all models were increased, thereby increasing the potential for infiltration and redistribution within the plow layer. The SWR of the B- and C-horizons remained within the observed ranges. In order to validate the calibrated SWRs of the A-horizon, the observed SWR ranges from previous studies conducted on this field (Katuwal et al., 2015; Naveed et al., 2016; Norgaard et al., 2015), where 65 soil samples were taken from the whole field in a 60 x 165 m grid, are superimposed in Figure 4 (orange band) over
385 the data from PLAP and the calibration. As Figure 4 shows, all calibrated SWRs mimic the shape of the SWR range of the studies.

[Figure 4 is about here]

The calibrated hydraulic conductivities were all within the observed ranges (Fig. 5), although the C-horizon conductivity was at the higher end of the observed range. For the applied two different lower boundary conditions (P3, P4), the MSETs showed
390 similarity between the calibrated models in SWRs and the measured, unsaturated hydraulic conductivity.

3.4.2 Soil water content at 25 and 60 cm

The SWC measurements at 25 cm depth were well described by the six models (Fig. S10 and S11, upper graph). The models captured the groundwater fluctuations and plant water uptake in the growing season, which is causing drying in the A-horizon, and the models reacted to the sudden saturation from the surface due to precipitation. There are discrepancies compared to
395 the measured values due to the expected heterogeneity of the drained field not being taken into account by the TDR point measurements. The ability to describe the SWC measurements at 60 cm depth was not as good as for the upper depth, due to the measured soil water content at 60 cm depth not responding to plant water uptake and the groundwater changes in the same way as at 25 cm depth, in the growing season 2003 and 2005, and there was a delayed reaction from the TDR in the growing season of 2007 according to the model results. Hence, the simulated soil water content at 60 cm depth did not capture the
400 relatively stable and close to saturation content observed during 2003 and 2005, whereas it did capture the dynamic and level of the water content in 2004 and dynamic in 2006 (Fig. S10 and S11, middle graph). The discrepancy between measured and simulated soil water content in 2003 and 2005 could be explained by the low rooting depth at this locality in the field where TDR was permanently installed, given that all the models predicted the soil water content well at 25 cm depth from 2003 until 2008 and at 60 cm depth during 2004 and 2006.

405

[Figure 5 is about here]

3.4.3 Calibrated drainage dynamics of the six models

In the drainage year 2006-2007 (part of the calibration period), the dynamics of the drainage were captured completely when applying the three MSETs (Fig. 6), although they did not capture timing and some of the amplitude of the measured drainage in March 2007. In this period, the temperature was around or below zero degrees, which could indicate that the precipitation
410 fell as snow, which is not well captured by the rain gauge at 1.5 m above the soil surface. Some measurements in this period were taken from the nearby experimental station (Geonor, rain gauge, weighing principle) and hence not fully representative of the field. The measured peak in drainage could be caused by snowmelt due to an increase in air temperature. The discrepancy between the estimated and measured could thus be explained by the numerical interpretation of the precipitation by the sub-model for snow accumulation and melt incorporated in DAISY. In this sub-model, low temperatures determine the amount of
415 snow-rain mixture and the possible snowmelt is determined by global radiation, air temperature and heat flux on the ground surface (Hansen et al., 1990). The timing of the fast increase in estimated drainage (due to snowmelt) was, therefore, delayed around a week in the simulated results, which ~~may be explained partly by too low a precipitation input to the model.~~

[Figure 6 is about here]

The other significant disagreement between the model results and the measurements was in mid-December 2006, most likely
420 caused by measurement errors, where measurements indicate zero flux in the drainage, while in this month the model predicted one of the highest fluxes (Fig. 6). In general, however, all six models performed well. The best calibration result was achieved with model with MSET *b*) + P3, where nMAE was 0.53 for the calibration period for drainage. The comparison of the outcome of applying the two different groundwater tables revealed that all models with P3 outperformed those using P4 as the lower boundary condition in terms of nMAE. It was also clear that P3 set-ups performed much better during the single, sudden flow
425 events such as in October 2006 where the groundwater seems to supply less drainage from the field than with P4 setups. The dynamics of the drainage, including zero fluxes, were perfectly captured applying P3, whereas with P4 the simulated fluxes tended to be high during the period with measured zero flux, probably because the groundwater kept supplying water to the drains. It is also worth pointing out that P4 set-ups performed better for nRMSE and KGE than for nMAE, even though there are visible discrepancies between the observed and modeled flow. This is a clear example of what Muleta (2011) concluded,
430 that using squared deviations tends to overestimate the goodness of fit because peak flows will be given excessive weight.

3.5 Evaluation of model performance

3.5.1 Drainage and soil water content dynamics

In order to provide an unbiased evaluation of a model fit on the calibration dataset (2003 - 2008), the evaluation periods chosen were 1st May 2000 to 31st March 2001 and 1st April 2008 to 31st March 2009. The latter period was chosen because the
435 drainage events were more frequent in this year, with drainage occurring on 224 days, whereas in the following year there were only 115 days of drainage. Both selected periods included continuous drainage over the winter period with distinct peak flows, but also included sudden cloudburst-induced drainage in the dry periods. Like the calibration, all models performed well in

terms of predicting the dynamics of the drainage (Fig. 7). The results show that the model with MSET *b*) performed better than MSET (*a*) and *c*). In the evaluation period of 2008 the *b*) setting seemed to perform the best with nMAE₂₀₀₀ values for the P3 and P4 lower boundary conditions of 0.48 and 0.52, respectively. In the evaluation period of 2000, setting *a*) performed the best for P3, with nMAE₂₀₀₀ = 0.39, and setting *b*) performed the best for P4, with nMAE₂₀₀₀ = 0.39. In the 2000-2001 period, setting *b*) performed marginally worse than the other settings for P3, although the amplitude of the measured drainage matched the *b*) setting better in the winter season. When comparing the lower boundaries, P4 captured the winter period better with setting *b*) the year 2000 than P3, although the individual sudden drainage events were under predicted in contrast to MSET *b*) + P3. Additionally, the same identified groundwater- induced drainage surplus appeared here as well with P4, at times when the measurements showed zero flux. Overall, applying the P3 groundwater condition tended to give a better description of the dynamics of the drainage. The reason could be that P3 is installed in a dislocated clay and silt layer that is hydraulically more well-connected to the groundwater aquifer than P4, which is placed in a clay till.

[Figure 7 is about here]

For situations with fast drainage response to heavy rain, a distinct heavy rain event was screened for model response in SWC at 25 cm depth and drain flow on 8th June 2003 (Fig. 8). All MSETs and lower boundary setups were able to depict the sudden increase in water content, as well as the immediate water transport to the drain. For the lower boundary, models with P3 were able to simulate the dynamics better. This drainage response is more dependent on the accumulated water above the B-horizon rather than direct transport from the surface. These findings are consistent with the observation of Rosenbom et al. (2008) and Nimmo (2012) that water/solutes can be preferentially transported even though the matrix is only partially saturated below the plow layer during the summer season. Therefore it can be concluded that the DAISY model with Richards' equation, combined with Mollerup's approach (Mollerup, 2010) to PF, is capable of describing PF in unsaturated conditions. Although the model does not account for viscous flow, as a Darcy-based model, it still may indeed represent preferential flow to the drainage over the assessed 10 year period (Germann, 2018).

[Figure 8 is about here]

3.5.2 Transport pathways

The water balance and distribution of different flows and transport pathways to the drain system as a result of the conceptual descriptions of the field were evaluated for the drainage year 2008 – 2009. As a percentage of the annual precipitation, the models did not differ significantly from each other (Table 4), although the transport to the drainage with P3 showed higher matrix and macropore water transport to the drain.

[Table 4 is about here]

The optimal fit to the field measurements was achieved by the model with MSET *b*) + P3 (Fig. 9) estimating a high macropore contribution to drainage (113 mm, 70% of total drainage). In contrast to *a*) + P3, the matrix contribution to drainage was somewhat higher, although the macropore input remained of the same magnitude (Table 4). Since macropore setting *a*) does

470 not consider MM macropores, only leaching through the matrix can bypass the tile drain and enter the groundwater. The amount of percolation to the groundwater was similar for all macropores (34-36% of the annual precipitation). This indicates that even though settings *b*) and *c*) include the MM and FR macropores as extra transport pathways, no more water percolation to the groundwater (sum of matrix and macropore percolation) appeared. Hence, the simulated degree of contribution from the macropores and matrix to drainage appeared to be a good indication of reality. For setting *c*) the distribution followed *a*) and
475 *b*) when applying P3 and it had a relatively similar outcome to setting *b*). The implemented fracture gave no extra input to macropore percolation. The simulated results with MSET *c*) + P4 did not follow the other results.

[Figure 9 is about here]

3.5.3 Bromide transport

Another essential point of the model evaluation was to compare BR^- transport of the application 22nd May 2000 (Fig. 10).
480 After the application of $30 \text{ kg KBr ha}^{-1}$, which is the equivalent of $20.14 \text{ kg Br}^- \text{ ha}^{-1}$, Fodder beet and Spring Barley were sown in 2000 and 2001, respectively. This showed even though BR^- is considered a conservative tracer by hydrologists, with limited interactions with the soil microbiome and crop, BR^- has been proven to be taken up by crops to a substantial degree (Shtangeeva, 2017). In this modeling case, with P3 as the lower boundary condition, 61%, 57% and 52% of the applied amount
485 was 59%, 60%, and 54%. This amount of BR^- uptake was not unprecedented in beet crops, as Kohler et al. (2005) found 50% of initially applied BR^- in harvested sugar beet. However, it must be mentioned that in the present study no crop calibration has been done towards BR^- uptake.

[Figure 10 is about here]

Two heavy rain events occurred around the day of the application of Br^- , the first event causing little drain flow, but the
490 second almost instantly initiating drain flow. The instantaneous occurrence of Br^- in the drainage at a 5.1 mg l^{-1} concentration reflects the presence of macropore flow. Figure 10 shows that the Br^- was retained throughout the summer period, but started to leach out during the drainage season and the breakthrough ended mid-November. However, due to some retardation in the matrix and in crop residues, later appearances of Br^- can be observed. As shown in Figure 10, MSETs with the P3 boundary condition ($n\text{MAE}_{\text{BR}} = 0.85\text{-}0.93$, $n\text{MAE}_{\text{BRC}} = 0.14\text{-}0.21$) performed significantly better than any other with P4 ($n\text{MAE}_{\text{BR}} = 1.07\text{-}1.19$, $n\text{MAE}_{\text{BRC}} = 0.45\text{-}0.64$), even though P4 set-ups performed marginally better for this specific year in terms of
495 drainage dynamics and cumulative drainage. For model with MSET *a*) + P4, considerable transport of Br^- resulted, where $K_{s,B}$ ($1.46 \text{ cm}^{-\text{h}}$) was 2.25 times larger than the average K_s ($0.65 \text{ cm}^{-\text{h}}$) for all set-ups, and therefore more Br^- leached to the drain through the matrix. For this model, $K_{s,C}$ ($0.19 \text{ cm}^{-\text{h}}$) was also one magnitude lower than $K_{s,B}$, which allowed the water to build up above the C-horizon, which is the reason for the high proportion of matrix water in the drainage (Table 1).
500 Also, if matrix leaching is included, the different MSETs with P4 resulted in percolation levels that were 1.5-2 times higher than in P3. This supports the hypothesis that the observed lower boundary at P4 had no, or limited, hydrological connection to the field (Table S2).

For all models, the macropore transport of Br^- from the field to the drain substantially outweighed the matrix transport. As suspected, the DM1 macropore class transported the majority of the solute, indicating that the solute did not move further
505 down in the matrix and was being held in the plow layer (A-horizon) to some degree. As Animation S1 shows, after the spraying of the Br^- the plume starts to diffuse into the plow layer after the first few hourly rain events, and when the pressure potential exceeds the threshold, all macropores related to the plow layer (DM1, MM1, MM2) are activated and facilitate the transport of Br^- to the drainage, or below the drain level. On 25th October 2000, 156 days after the application, the rainy season initiated the Br^- movement in the plow layer again and allowed Br^- to slowly diffuse towards the B-horizon (Animation S2).
510 The animation shows that although the plume had already reached the middle of the B-horizon, the majority of the Br^- transport to the drain or below was caused by the remaining concentration in the plow layer. The summarized solute inflow(+) and solute outflow(-) show (Fig. 11) that the transport mechanism was mainly driven by the Br^- build-up above the plow layer, causing large amounts of PF leaching in the soil column.

[Figure 11 is about here]

515 3.6 Perspective

The present study and results call for further studies to understand the transport of agro-chemicals, such as the optimization of the model with MSET *b*) + P3 with respect to transport of Br^- , nitrate, and applying pesticides. Such future studies could reveal how nitrogen leaching will be affected in the plow layer by mineralization and denitrification processes and further transported to the drainage systems through DM macropores. In the present study, all models proved that the majority of drainage was
520 caused by the DM1 macropores, which collected the water mainly from the plow layer. This reveals that there is a high risk of applied soluble agrochemicals and nutrients, which are incorporated to the plow layer (such as injected slurry), being leached to the tile drain system (Larsson and Jarvis, 1999).

4 Conclusions

In this study, a one-dimensional model code including different MSETs and a representation of artificial drainpipes in an
525 agricultural clay till field was tested in order to describe the measured water and mass balance, with a focus on drainage. The modeling exercise showed that Darcy flow-based models with coupled dual permeability capabilities could model with high precision for a long-term period while accounting for PF. Two groundwater table measurements, P3 and P4, were collected at the southern and northern borders of the field, respectively, and the results showed that the groundwater table measured at P4 did not truly reflect the water balance of the field, which indicates the importance of a correct lower boundary. The model with
530 MSET *b*) exposed to groundwater fluctuations measured in the southern part (P3) of the field gave the best description of the drainage of the field. Further, the results of this model study revealed that 70% percent of the overall drainage was supplied via macropores and of the applied tracer, 54% leached directly from the plow layer. Based on the different conceptual settings, the majority of drainage seemed to be primarily the result of rapid precipitation infiltration from the surface to the plow layer, and from there via preferential pulse flow to the drain or below, through macropores. The applied Br^- tracer test and modeling

535 revealed that in this heterogeneous soil with yearly soil tillage (harrowing and plowing) and, therefore, most likely a temporary increase of the soil porosity in the plow layer, the buried macropores could have a more significant impact on transport than surface-connected macropores.

Video supplement. Animation S1. Simulated bromide transport in the macropore and the matrix media from 22nd May 2000 to 31st May 2000 of concepts *a*), *b*) and *c*) with lower boundary conditions P3 and P4. The animation can be downloaded from the following LINK

540 *Video supplement. Animation S2.* Simulated bromide transport in the macropore and the matrix media from 15th October 2000 to 31st December 2000 of concepts *a*), *b*) and *c*) with lower boundary conditions P3 and P4. The animation can be downloaded from the following LINK

Author contributions. David Nagy(DN) carried out the development of the conceptualization and methodology under the co-supervision of Annette E. Rosenbom(AER) and Bo Vangsø Iversen(BVI) and main supervision of Finn Plauborg(FP). DN developed the model calibration code with the help of Mohamed Jabloun, performed the simulations and prepared the manuscript with contributions from all co-authors. AER and BVI provided the PLAP experiment data of Silstrup, whereas FP provided the corresponding climate data. AER and FP are responsible for the data curation of the experiment.

List of Figures

| | | | |
|-----|---|--|----|
| 760 | 1 | a) Measured monthly precipitation [mm] with seasonally accumulated drainage [mm] and bromide transport [g ha^{-1}], b) Measured soil water content [$\text{cm}^3 \text{cm}^{-3}$] at depth -25 cm and -60 cm b.g.s., c) Measured groundwater depth at location P3 and P4 [cm]. | 27 |
| 765 | 2 | The three macropore settings (MSETs) applied in the clay till profile. The depth [cm] is given as depth below soil surface: a) Only macropores ending in the tile drain (DM), b) The same as a) but including macropores ending in the matrix (MM), and c) The same as b) but including macropores representing a fracture (FR) penetrating the entire soil profile (horizons A-C) and a highly permeable matrix horizon D. | 28 |
| 770 | 3 | Performance of the single (S) and dual (D) permeability model set-ups in describing measured drainage during the period 1 st September 2006 to 31 st March 2007. Values in brackets are for the entire calibration period 1 st April 2003 to 31 st March 2008. | 29 |
| 775 | 4 | Laboratory measurement ranges of SWR (black error bar) of A-, B- and C-horizons from the east and north pedological faces (Fig. S5, Table S1-S2) from PLAP; the SWR uncertainty boundary based on the fitted laboratory data (gray ribbon); calibrated models' SWR for all horizons; assessed SWR measurement ranges (brown error bar) and uncertainty boundary (orange ribbon) (Literature) only for the A-horizon from Katuwal et al. (2015), Naveed et al. (2016) and Norgaard et al. (2015). | 30 |
| 780 | 5 | Laboratory measurement ranges of $K(\psi)$ (black point) of A-, B- and C-horizons from the east and north pedological faces (Fig. S5, Tables S1, S2,) from PLAP; $K(\psi)$ uncertainty boundary based on the fitted laboratory data (gray ribbon); calibrated models' $K(\psi)$ for all horizons; assessed $K(\psi)$ measurements (brown points) and uncertainty boundary (orange ribbon) (Literature) for only the A-horizon from Katuwal et al. (2015), Naveed et al. (2016) and Norgaard et al. (2015). | 31 |
| 785 | 6 | Performance of the six models (including three MSETs a), b) and c) using the groundwater table from P3 and P4) to describe measured drainage during the period 1 st September 2006 to 31 st March 2007. nMAE, nRMSE and KGE of the six models are given for the presented period and in brackets for the whole calibration period of drainage from 1 st April 2003 to 31 st March 2008. | 32 |
| 790 | 7 | Performance of the six models (MSETs a), b) and c) applying the groundwater table from P3 and P4) to describe measured drainage during the evaluation period 2000-2001 and 2008-2009. The nMAE, nRMSE and KGE of the six models are given for the presented period, and in brackets the nMAE for the whole calibration period of drainage from 1 st April 2003 to 31 st March 2008. | 33 |
| | 8 | Measured and simulated drainage and SWC dynamic response to the heavy rain event on 8 th June 2003. | 34 |
| | 9 | Simulated accumulated drainage input from the matrix and macropore domains, accumulated matrix and macropore percolation, and measured drainage with the corresponding nMAE, nRMSE and KGE for 2008-2009 drainage at 1.1 m drain level for all six models. | 35 |

| | | | |
|-----|----|--|----|
| 795 | 10 | Simulated accumulated BR^- transport to drainage from matrix and macropore domain and measured BR^- transport in the drain flow, with the corresponding nMAE ($\text{TH}_{\text{BR}} = 2.14$, $\text{TH}_{\text{BRC}} = 0.27$), nRMSE ($\text{TH}_{\text{BR}} = 1.9$, $\text{TH}_{\text{BRC}} = 15.3$) and KGE ($\text{TH} = 0.5$) for 2000-2001 for all the six model setups (BR = BR^- dynamics, BRC = Cumulative BR^- transport). | 36 |
| | 11 | The summarized Br^- solute inflow (+) and solute outflow (-) by depth below the surface, for all six models. . . | 37 |

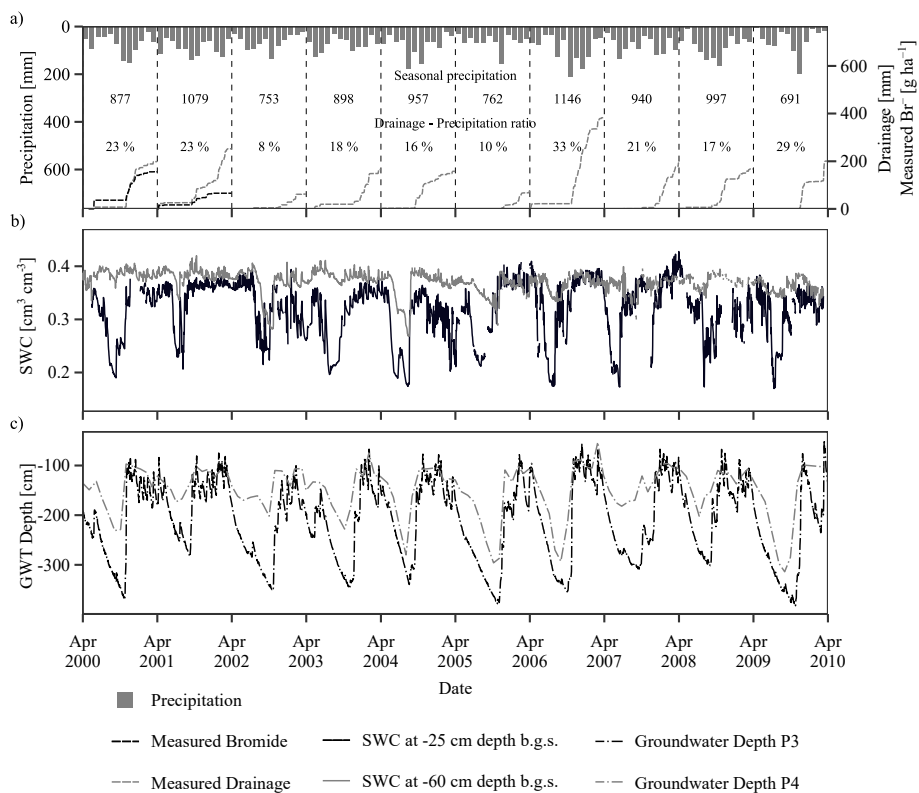

Figure 1. a) Measured monthly precipitation [mm] with seasonally accumulated drainage [mm] and bromide transport [g ha^{-1}], b) Measured soil water content [$\text{cm}^3 \text{cm}^{-3}$] at depth -25 cm and -60 cm b.g.s., c) Measured groundwater depth at location P3 and P4 [cm].

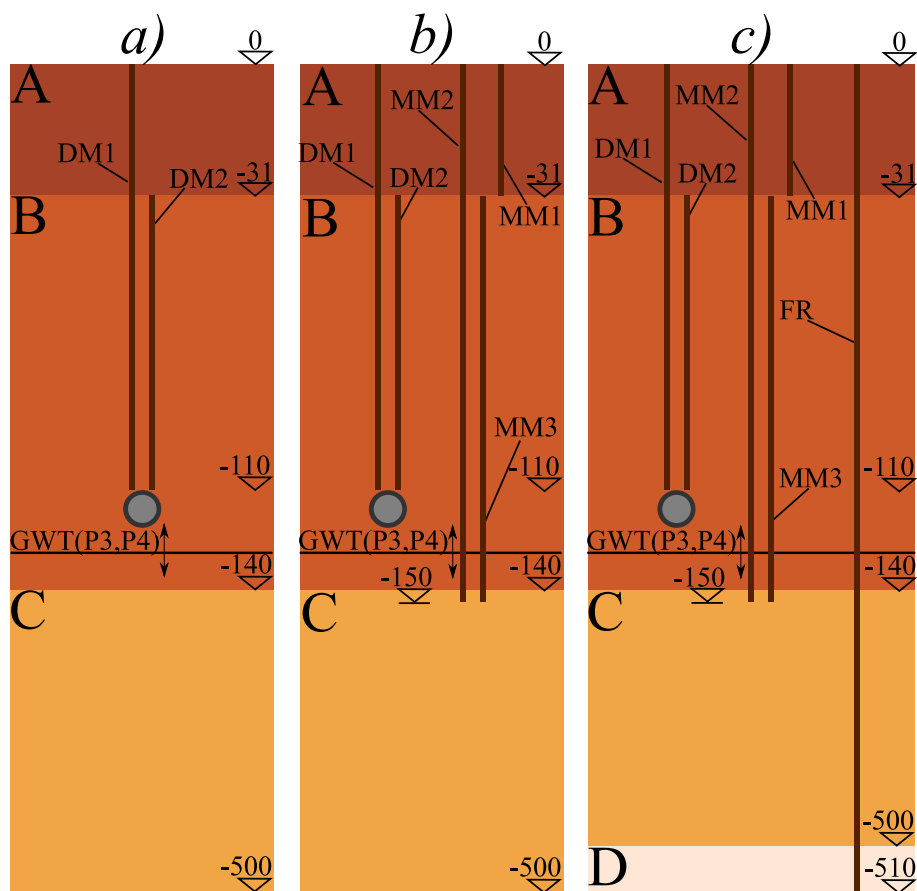

Figure 2. The three macropore settings (MSETs) applied in the clay till profile. The depth [cm] is given as depth below soil surface: *a*) Only macropores ending in the tile drain (DM), *b*) The same as *a*) but including macropores ending in the matrix (MM), and *c*) The same as *b*) but including macropores representing a fracture (FR) penetrating the entire soil profile (horizons A-C) and a highly permeable matrix horizon D.

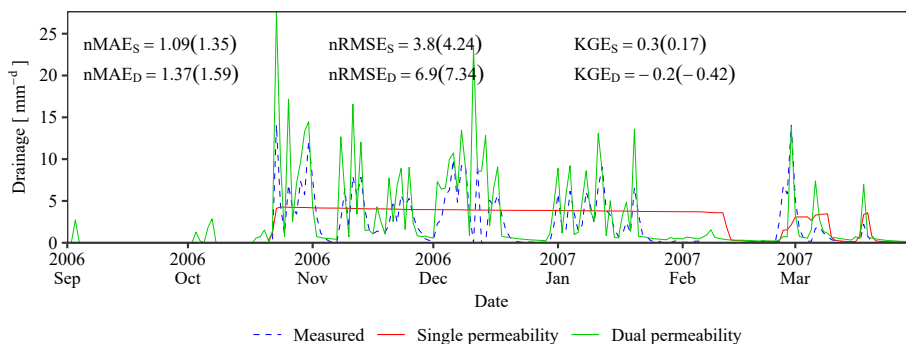

Figure 3. Performance of the single (S) and dual (D) permeability model set-ups in describing measured drainage during the period 1st September 2006 to 31st March 2007. Values in brackets are for the entire calibration period 1st April 2003 to 31st March 2008.

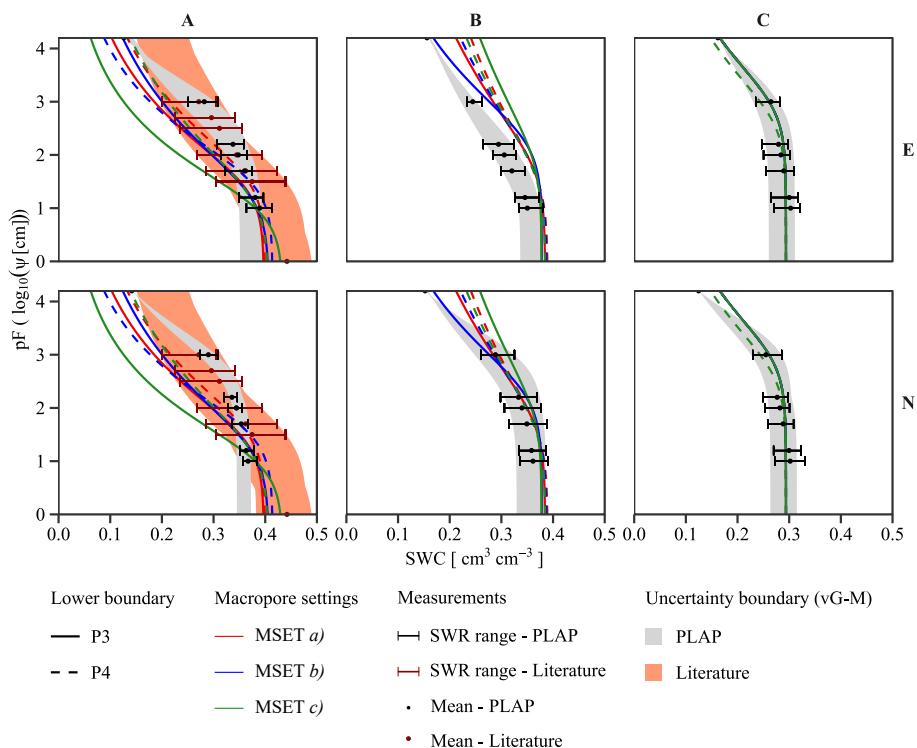

Figure 4. Laboratory measurement ranges of SWR (black error bar) of A-, B- and C-horizons from the east and north pedological faces (Fig. S5, Table S1-S2) from PLAP; the SWR uncertainty boundary based on the fitted laboratory data (gray ribbon); calibrated models' SWR for all horizons; assessed SWR measurement ranges (brown error bar) and uncertainty boundary (orange ribbon) (Literature) only for the A-horizon from Katuwal et al. (2015), Naveed et al. (2016) and Norgaard et al. (2015).

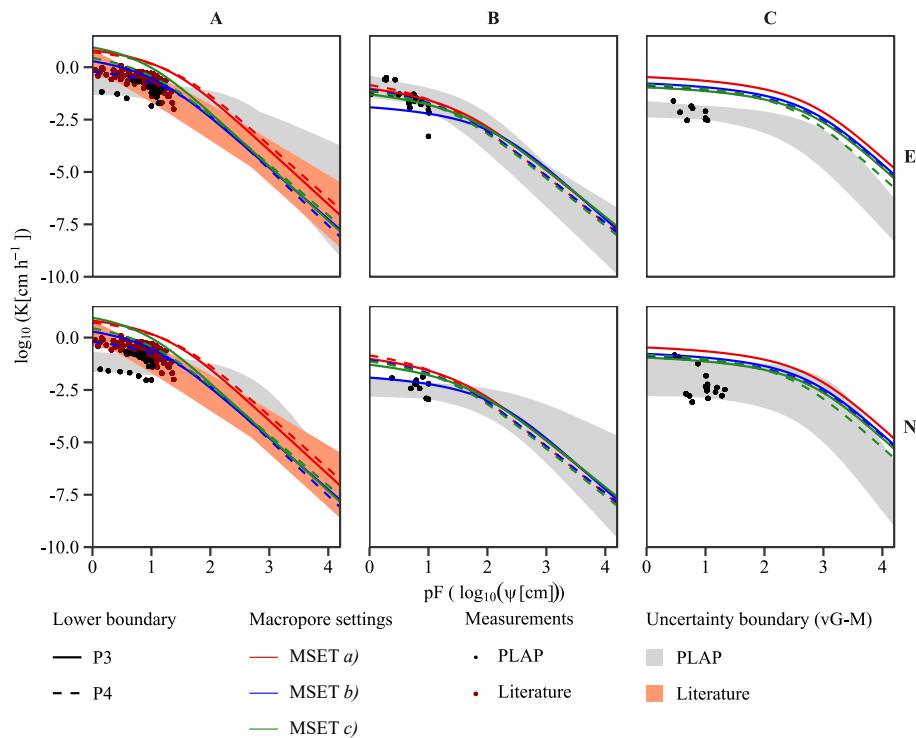

Figure 5. Laboratory measurement ranges of $K(\psi)$ (black point) of A-, B- and C-horizons from the east and north pedological faces (Fig. S5, Tables S1, S2,) from PLAP; $K(\psi)$ uncertainty boundary based on the fitted laboratory data (gray ribbon); calibrated models' $K(\psi)$ for all horizons; assessed $K(\psi)$ measurements (brown points) and uncertainty boundary (orange ribbon) (Literature) for only the A-horizon from Katuwal et al. (2015), Naveed et al. (2016) and Norgaard et al. (2015).

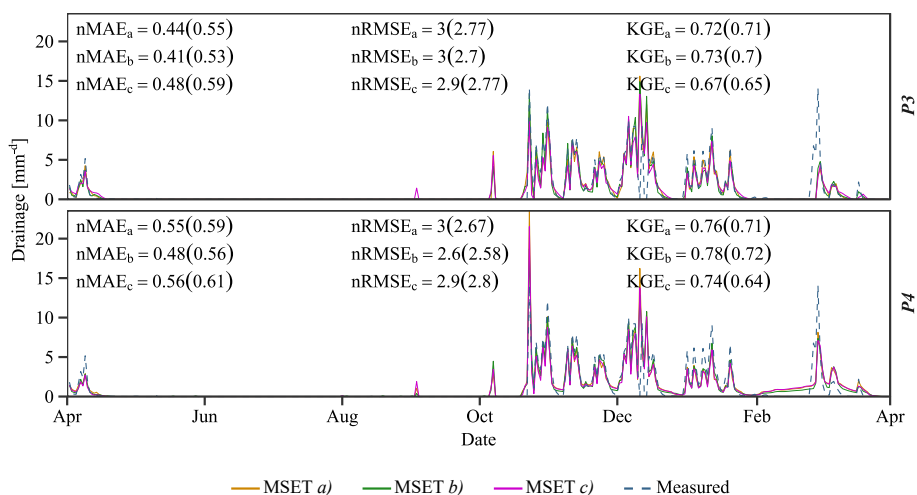

Figure 6. Performance of the six models (including three MSETs *a*, *b* and *c*) using the groundwater table from P3 and P4) to describe measured drainage during the period 1st September 2006 to 31st March 2007. nMAE, nRMSE and KGE of the six models are given for the presented period and in brackets for the whole calibration period of drainage from 1st April 2003 to 31st March 2008.

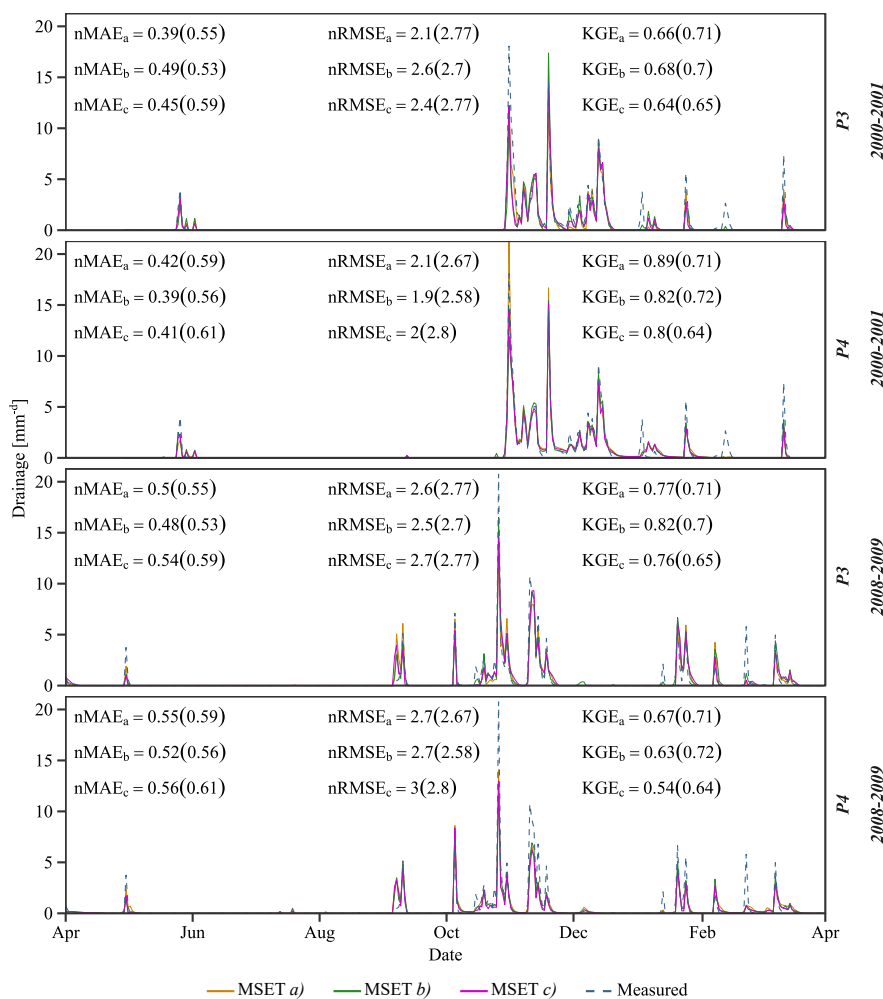

Figure 7. Performance of the six models (MSETs *a*, *b*) and *c*) applying the groundwater table from P3 and P4 to describe measured drainage during the evaluation period 2000-2001 and 2008-2009. The nMAE, nRMSE and KGE of the six models are given for the presented period, and in brackets the nMAE for the whole calibration period of drainage from 1st April 2003 to 31st March 2008.

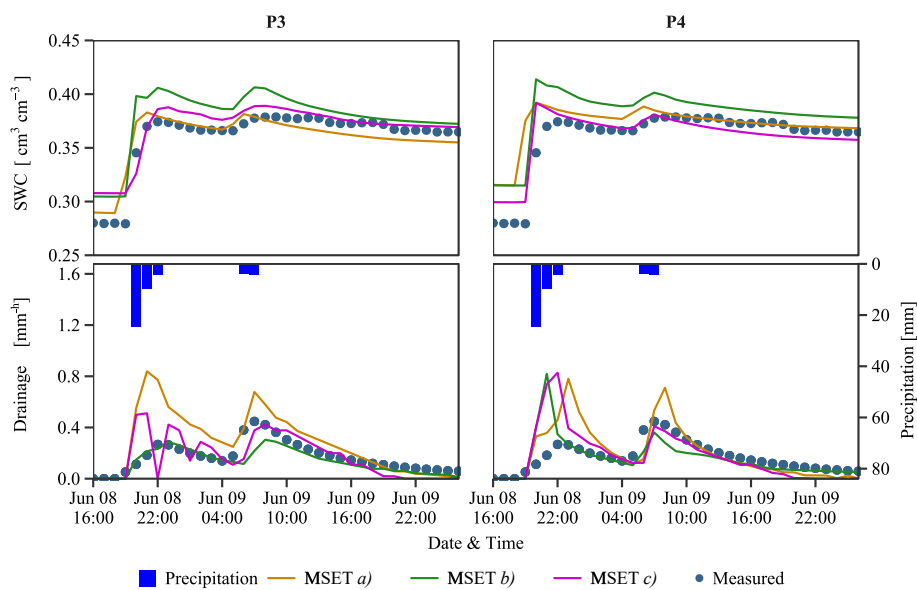

Figure 8. Measured and simulated drainage and SWC dynamic response to the heavy rain event on 8th June 2003.

Figure 9. Simulated accumulated drainage input from the matrix and macropore domains, accumulated matrix and macropore percolation, and measured drainage with the corresponding nMAE, nRMSE and KGE for 2008-2009 drainage at 1.1 m drain level for all six models.

Figure 10. Simulated accumulated BR^- transport to drainage from matrix and macropore domain and measured BR^- transport in the drain flow, with the corresponding $n\text{MAE}$ ($\text{TH}_{\text{BR}} = 2.14$, $\text{TH}_{\text{BRC}} = 0.27$), $n\text{RMSE}$ ($\text{TH}_{\text{BR}} = 1.9$, $\text{TH}_{\text{BRC}} = 15.3$) and KGE ($\text{TH} = 0.5$) for 2000–2001 for all the six model setups ($\text{BR} = \text{BR}^-$ dynamics, $\text{BRC} = \text{Cumulative } \text{BR}^-$ transport).

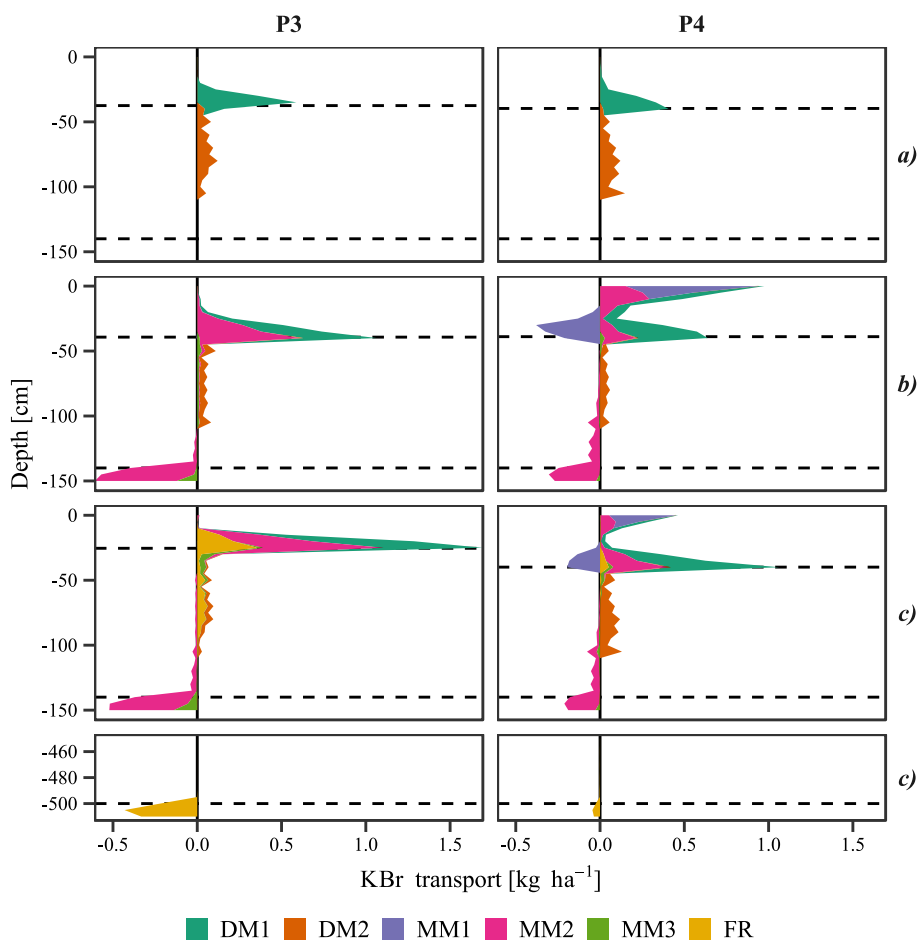

Figure 11. The summarized Br^- solute inflow (+) and solute outflow (-) by depth below the surface, for all six models.

List of Tables

| | | | |
|---|-----|---|----|
| 1 | 800 | Optimization of hydraulic parameters (vGM) of the matrix for macropore settings (MSETs) <i>a</i> , <i>b</i>) and <i>c</i>). Initial values and selected minimum and maximum uncertainty boundaries are based on laboratory measurements (Table S1). Best calibration for MSET <i>b</i>) shows the result from the best calibration being restricted by the two different fluctuating groundwater tables monitored in wells P3 or P4. The MSET column shows which of the given matrix parameter is active at the given MSET. Sensitivity lists of the MSETs for which a given parameter is sensitive with given the lower boundaries (P3 and P4). Gray rows are the non-sensitive parameters. | 39 |
| 2 | 805 | Optimization of hydraulic parameters of the macropores for macropore settings (MSETs) <i>a</i> , <i>b</i>) and <i>c</i>). Initial values and selected minimum and maximum uncertainty boundaries are mostly based on Nielsen et al. (2010) (Table S2). Best calibration for MSET <i>b</i>) shows the result from the best calibration being restricted by the two different fluctuating groundwater tables monitored in wells P3 or P4. The MSET column shows which of the given macropore parameters is active at the given MSET. Sensitivity lists of the MSETs for which a given parameter is sensitive with the lower boundaries (P3 and P4) given. Gray rows are the non-sensitive parameters. | 40 |
| 3 | 810 | The calibrated performance measures nMAE, nRMSE and KGE of the sub-objectives (Drainage, Cumulative Drainage (Cum. Drainage), SWC25, and SWC60) for the three different macropore settings (MSETs) <i>a</i> , <i>b</i> , and <i>c</i>) in combination with the two lower boundary conditions (P3 and P4) for the calibration period 1st April 2003 to 31st March 2008. Bold values indicating objectives which are better than the threshold value (nMAE, nRMSE - $SD_{obs/2}$, KGE - 0.5). | 41 |
| 4 | 815 | Accumulated water contribution to drainage from matrix and macropores (DM1, DM2 and the sum of the two) and percolation through the matrix and macropore at 1.1 m depth (depth of drain) in mm, and as a percentage of the annual precipitation (997 mm) for the period 2008-2009 for all six models (MSET <i>a</i> , <i>b</i>) and <i>c</i>) applying groundwater tables from P3 and P4). | 42 |

Table 1. Optimization of hydraulic parameters (vGM) of the matrix for macropore settings (MSETs) *a*), *b*) and *c*). Initial values and selected minimum and maximum uncertainty boundaries are based on laboratory measurements (Table S1). Best calibration for MSET *b*) shows the result from the best calibration being restricted by the two different fluctuating groundwater tables monitored in wells P3 or P4. The MSET column shows which of the given matrix parameter is active at the given MSET. Sensitivity lists of the MSETs for which a given parameter is sensitive with given the lower boundaries (P3 and P4). Gray rows are the non-sensitive parameters.

| Matrix parameters | Initial | Uncertainty boundaries | | Best calibration <i>MSET b</i>) | | MSET | Sensitivity | |
